General Chair Preface

Welcome everyone!

It is my pleasure to welcome you all to Atlanta, Georgia, for the 2013 NAACL Human Language Technologies conference. This is a great opportunity to reconnect with old friends and make new acquaintances, learn the latest in your own field and become curious about new areas, and also to experience Atlanta's warm southern hospitality. That hospitality starts with Priscilla Rasmussen! Priscilla thinks about everything that we all take for granted: the registration that just took place, the rooms in which we sit, the refreshments that keep us energized, and the social events that make this conference so fun, and many other details that you would miss if they weren't there. Please introduce yourself and say hi. Priscilla is the backbone of the NAACL organization. Thank you!

This conference started a year ago, when Hal Daumé III and Katrin Kirchhoff graciously agreed to be program co-chairs. It is no exaggeration to say how much their dedication has shaped this conference and how grateful I am for their initiative and hard work. Thank you Hal and Katrin, especially for all the fun discussion that made the work light and the year go by fast! This conference could not have happened with you.

Thanks go to the entire organizing committee. As I am writing this to be included in the proceedings, I am grateful for the fantastic detailed and proactive work by Colin Cherry and Matt Post, the publications chairs. The tutorials chairs, Katrin Erk and Jimmy Lin, selected, and solicited, 6 tutorials to present in depth material on some of the diverse topics represented in our community. Chris Dyer and Derrick Higgins considered which projects shine best when shown as a demonstration. The workshops chairs for NAACL, Sujith Ravi and Luke Zettlemoyer, worked jointly with ACL and EMNLP to select the workshops to be held at NAACL. They also worked with ICML 2013 to co-host workshops that bridge the two communities, in addition to the Joint NAACL/ICML symposium.

Posters from the student research workshop are part of the poster and demonstrations session on Monday night. This is a great opportunity for the students to be recognized in the community and to benefit from lively discussion of their presentations (attendees take note!) Annie Louis and Richard Socher are the student research workshop chairs, and Julia Hockenmaier and Eric Ringger generously share their wisdom as the faculty advisors. The student research workshop itself will be held on the first day of workshops. There are so many people who contribute their time to the behind-the-scenes organization of the conference, without which the conference cannot take place. Asking for money is probably not a natural fit for anyone, but Chris Brew worked on local sponsorship, and Dan Bikel and Patrick Pantel worked to obtain sponsorship across the ACL conferences this year - thank you! Jacob Eisenstein had the more fun role of distributing money as the student volunteer coordinator, and we thank all of the student volunteers who will be helping to run a smooth conference. Kristy Boyer kept the communication "short and tweet" using a variety of social media (and old-fashioned media too). An important part of the behind-the-scenes efforts that enable a conference like NAACL to come together are the sponsors. We thank all of the sponsors for the contributions to the conference , both for the general funding made available as well as the specific programs that are funded through sponsorship. You can read more about these sponsors in our conference handbook.

This year there are several initiatives, and if successful, we hope they'll be part of NAACL conferences

in the future. One is to make the proceedings available prior to the conference; we hope you will benefit from the extra time to read the papers beforehand. Another is for tutorials and all oral presentations to be recorded on video and made available post-conference. We are also delighted to host presentations, in both oral and poster formats, from the new Transactions of the ACL journal, to enhance the impact these will already have as journal publications. Finally, Matt Post is creating a new digital form of conference handbook to go with our digital age; thanks also go to Alex Clemmer who has prepared the paper copy that you may be reading right now. We hope you use the #NAACL2013 tag when you are tweeting about the conference or papers at the conference; together, we'll be creating a new social media corpus to explore.

Once again, we are pleased to be co-located with *SEM conference, and the SemEval workshop. We are lucky to have ICML 2013 organized so close in time and place. Several researchers who span the two communities have reconvened the Joint NAACL/ICML symposium on June 15, 2013. In addition, two workshops that address areas of interest to both NAACL and ICML members have been organized on June 16th, as part of the ICML conference.

NAACL 2013 has given me a great appreciation for the volunteering that is part of our culture. Besides the organizing committee itself, we are guided by the NAACL executive board, who think about questions with a multi-year perspective. I also want to recognize the members who first initiated and now maintain the ACL Anthology, where all of our published work will be available to all in perpetuity, a fabulous contribution and one that distinguishes our academic community.

Have a fun conference!

Lucy Vanderwende, Microsoft Research
NAACL HLT 2013 General Chair

Program Chair Preface

Welcome to NAACL HLT 2013 in Atlanta, Georgia. We have an exciting program consisting of six tutorials, 24 sessions of talks (both for long and short papers), an insane poster madness session that includes posters from the newly revamped student research workshop, ten workshops and two additional cross-pollination workshops held jointly with ICML (occurring immediately after NAACL HLT, just one block away). There are a few innovations in the conference this year, the most noticeable of which is the twitter channel [#naacl2013](#) and the fact that we are the first conference to host papers published in the Transactions of the ACL journal – there are six such papers in our program, marked as [TACL]. We are very excited about our two invited talks, one on Monday morning and one Wednesday morning. The first is by Gina Kuperberg, who will talk about “Predicting Meaning: What the Brain tells us about the Architecture of Language Comprehension.” The second presenter is our own Kathleen Kckeown, who will talk about “Natural Language Applications from Fact to Fiction.”

The morning session on Tuesday includes the presentation of best paper awards to two worthy recipients. The award for Best Short Paper goes to Marta Recasens, Marie-Catherine de Marneffe and Christopher Potts for their paper “The Life and Death of Discourse Entities: Identifying Singleton Mentions” The award for Best Student Paper goes to the long paper “Automatic Generation of English Respellings” by Bradley Hauer and Greg Kondrak. We gratefully acknowledge IBM’s support for the Student Best Paper Award. Finally, many thanks to the Best Paper Committee for selecting these excellent papers!

The complete program includes 95 long papers (of which six represent presentations from the journal Transactions of the ACL, a first for any ACL conference!) and 51 short papers. We are excited that the conference is able to present such a dynamic array of papers, and would like to thank the authors for their great work. We worked hard to keep the conference to three parallel sessions at any one time to hopefully maximize a participant’s ability to see everything she wants! This represents an acceptance rate of 30% for long papers and 37% for short papers. More details about the distribution across areas and other statistics will be made available in the NAACL HLT Program Chair report on the ACL wiki: <http://aclweb.org/adminwiki/index.php?title=Reports>

The review process for the conference was double-blind, and included an author response period for clarifying reviewers’ questions. We were very pleased to have the assistance of 350 reviewers, each of whom reviewed an average of 3.7 papers, in deciding the program. We are especially thankful for the reviewers who spent time reading the author responses and engaging other reviewers in the discussion board. Assigning reviewers would not have been possible without the hard work of Mark Dredze and his miracle assignment scripts. Furthermore, constructing the program would not have been possible without 22 excellent area chairs forming the Senior Program Committee: Eugene Agichtein, Srinivas Bangalore, David Bean, Phil Blunsom, Jordan Boyd-Graber, Marine Carpuat, Joyce Chai, Vera Demberg, Bill Dolan, Doug Downey, Mark Dredze, Markus Dreyer, Sandra Harabagiu, James Henderson, Guy Lapalme, Alon Lavie, Percy Liang, Johanna Moore, Ani Nenkova, Joakim Nivre, Bo Pang, Zak Shafran, David Traum, Peter Turney, and Theresa Wilson. Area chairs were responsible for managing paper assignments, collating reviewer responses, handling papers for other area chairs or program chairs who had conflicts of interest, making recommendations for paper acceptance or rejection, and nominating best papers from their areas. We are very grateful for the time and energy

that they have put into the program.

There are a number of other people that we interacted with who deserve a hearty thanks for the success of the program. Rich Gerber and the START team at Softconf have been invaluable for helping us with the mechanics of the reviewing process. Matt Post and Colin Cherry, as publications co-chairs, have been very helpful in assembling the final program and coordinating the publications of the workshop proceedings. There are several crucial parts of the overall program that were the responsibility of various contributors, including Annie Louis, Richard Socher, Julia Hockenmaier and Eric Ringger (Student Research Workshop chairs, who did an amazing job revamping the SRW); Jimmy Lin and Katrin Erk (Tutorial Chairs); Luke Zettlemoyer and Sujith Ravi (Workshop Chairs); Chris Dyer and Derrick Higgins (Demo Chairs); Jacob Eisenstein (Student Volunteer Coordinator); Chris Brew (Local Sponsorship Chair); Patrick Pantel and Dan Bikell (Sponsorship Chairs); and the new-founded Publicity chair who handled #naacl2013 tweeting among other things, Kristy Boyer.

We would also like to thank Chris Callison-Burch and the NAACL Executive Board for guidance during the process. Michael Collins was amazingly helpful in getting the inaugural TACL papers into the NAACL HLT conference. Priscilla Rasmussen deserves, as always, special mention and warmest thanks as the local arrangements chair and general business manager. Priscilla is amazing and everyone who sees her at the conference should thank her.

Finally, we would like to thank our General Chair, Lucy Vanderwende, for both her trust and guidance during this process. She helped turn the less-than-wonderful parts of this job to roses, and her ability to organize an incredibly complex event is awe inspiring. None of this would have happened without her.

We hope that you enjoy the conference!

<i>A Cross-language Study on Automatic Speech Disfluency Detection</i>	703
Wen Wang, Andreas Stolcke, Jiahong Yuan and Mark Liberman.....	703
<i>Distributional semantic models for the evaluation of disordered language</i>	709
Masoud Rouhizadeh, Emily Prud'hommeaux, Brian Roark and Jan van Santen	709
<i>Atypical Prosodic Structure as an Indicator of Reading Level and Text Difficulty</i>	715
Julie Medero and Mari Ostendorf	715
<i>Using Document Summarization Techniques for Speech Data Subset Selection</i>	721
Kai Wei, Yuzong Liu, Katrin Kirchhoff and Jeff Bilmes	721
<i>Semi-Supervised Discriminative Language Modeling with Out-of-Domain Text Data</i>	727
Arda Çelebi and Murat Saraçlar	727
<i>More than meets the eye: Study of Human Cognition in Sense Annotation</i>	733
Salil Joshi, Diptesh Kanodia and Pushpak Bhattacharyya.....	733
<i>Improving Lexical Semantics for Sentential Semantics: Modeling Selectional Preference and Similar Words in a Latent Variable Model</i>	739
Weiwei Guo and Mona Diab	739
<i>Linguistic Regularities in Continuous Space Word Representations</i>	746
Tomas Mikolov, Wen-tau Yih and Geoffrey Zweig	746
<i>TruthTeller: Annotating Predicate Truth</i>	752
Amnon Lotan, Asher Stern and Ido Dagan	752
<i>PPDB: The Paraphrase Database</i>	758
Juri Ganitkevitch, Benjamin Van Durme and Chris Callison-Burch	758
<i>Exploiting the Scope of Negations and Heterogeneous Features for Relation Extraction: A Case Study for Drug-Drug Interaction Extraction</i>	765
Md. Faisal Mahbub Chowdhury and Alberto Lavelli	765
<i>Graph-Based Seed Set Expansion for Relation Extraction Using Random Walk Hitting Times</i>	772
Joel Lang and James Henderson	772

<i>Distant Supervision for Relation Extraction with an Incomplete Knowledge Base</i>	777
Bonan Min, Ralph Grishman, Li Wan, Chang Wang and David Gondek	777
<i>Measuring the Structural Importance through Rhetorical Structure Index</i>	783
Narine Kokhlikyan, Alex Waibel, Yuqi Zhang and Joy Ying Zhang	783
<i>Separating Fact from Fear: Tracking Flu Infections on Twitter</i>	789
Alex Lamb, Michael J. Paul and Mark Dredze	789
<i>Differences in User Responses to a Wizard-of-Oz versus Automated System</i>	796
Jesse Thomason and Diane Litman	796
<i>Improving the Quality of Minority Class Identification in Dialog Act Tagging</i>	802
Adinoyi Omuya, Vinodkumar Prabhakaran and Owen Rambow	802
<i>Discourse Connectors for Latent Subjectivity in Sentiment Analysis</i>	808
Rakshit Trivedi and Jacob Eisenstein	808
<i>Coherence Modeling for the Automated Assessment of Spontaneous Spoken Responses</i>	814
Xinhao Wang, Keelan Evanini and Klaus Zechner	814
<i>Disfluency Detection Using Multi-step Stacked Learning</i>	820
Xian Qian and Yang Liu	820
<i>Using Semantic Unification to Generate Regular Expressions from Natural Language</i>	826
Nate Kushman and Regina Barzilay	826
<i>Probabilistic Frame Induction</i>	837
Jackie Chi Kit Cheung, Hoifung Poon and Lucy Vanderwende	837
<i>A Quantum-Theoretic Approach to Distributional Semantics</i>	847
William Blacoe, Elham Kashefi and Mirella Lapata	847
<i>Answer Extraction as Sequence Tagging with Tree Edit Distance</i>	858
Xuchen Yao, Benjamin Van Durme, Chris Callison-Burch and Peter Clark	858
<i>Open Information Extraction with Tree Kernels</i>	868
Ying Xu, Mi-Young Kim, Kevin Quinn, Randy Goebel and Denilson Barbosa	868
<i>Finding What Matters in Questions</i>	878
Xiaoqiang Luo, Hema Raghavan, Vittorio Castelli, Sameer Maskey and Radu Florian	878
<i>A Just-In-Time Keyword Extraction from Meeting Transcripts</i>	888
Hyun-Je Song, Junho Go, Seong-Bae Park and Se-Young Park	888
<i>Same Referent, Different Words: Unsupervised Mining of Opaque Coreferent Mentions</i>	897
Marta Recasens, Matthew Can and Daniel Jurafsky	897
<i>Global Inference for Bridging Anaphora Resolution</i>	907
Yufang Hou, Katja Markert and Michael Strube	907

<i>Classifying Temporal Relations with Rich Linguistic Knowledge</i>	918
Jennifer D'Souza and Vincent Ng	
<i>Improved Information Structure Analysis of Scientific Documents Through Discourse and Lexical Constraints</i>	928
Yufan Guo, Roi Reichart and Anna Korhonen	
<i>Adaptation of Reordering Models for Statistical Machine Translation</i>	938
Boxing Chen, George Foster and Roland Kuhn	
<i>Multi-Metric Optimization Using Ensemble Tuning</i>	947
Baskaran Sankaran, Anoop Sarkar and Kevin Duh	
<i>Grouping Language Model Boundary Words to Speed K-Best Extraction from Hypergraphs</i>	958
Kenneth Heafield, Philipp Koehn and Alon Lavie	
<i>A Systematic Bayesian Treatment of the IBM Alignment Models</i>	969
Yarin Gal and Phil Blunsom	
<i>Unsupervised Metaphor Identification Using Hierarchical Graph Factorization Clustering</i>	978
Ekaterina Shutova and Lin Sun	
<i>Three Knowledge-Free Methods for Automatic Lexical Chain Extraction</i>	989
Steffen Remus and Chris Biemann	
<i>Combining Heterogeneous Models for Measuring Relational Similarity</i>	1000
Alisa Zhila, Wen-tau Yih, Christopher Meek, Geoffrey Zweig and Tomas Mikolov	
<i>Broadly Improving User Classification via Communication-Based Name and Location Clustering on Twitter</i>	1010
Shane Bergsma, Mark Dredze, Benjamin Van Durme, Theresa Wilson and David Yarowsky	
<i>To Link or Not to Link? A Study on End-to-End Tweet Entity Linking</i>	1020
Stephen Guo, Ming-Wei Chang and Emre Kiciman	
<i>A Latent Variable Model for Viewpoint Discovery from Threaded Forum Posts</i>	1031
Minghui Qiu and Jing Jiang	
<i>Identifying Intention Posts in Discussion Forums</i>	1041
Zhiyuan Chen, Bing Liu, Meichun Hsu, Malu Castellanos and Riddhiman Ghosh	
<i>Dependency-based empty category detection via phrase structure trees</i>	1051
Nianwen Xue and Yaqin Yang	
<i>Target Language Adaptation of Discriminative Transfer Parsers</i>	1061
Oscar Täckström, Ryan McDonald and Joakim Nivre	
<i>Emergence of Gricean Maxims from Multi-Agent Decision Theory</i>	1072
Adam Vogel, Max Bodoia, Christopher Potts and Daniel Jurafsky	

<i>Open Dialogue Management for Relational Databases</i>	1082
Ben Hixon and Rebecca J. Passonneau	
<i>A method for the approximation of incremental understanding of explicit utterance meaning using predictive models in finite domains</i>	1092
David DeVault and David Traum.....	
<i>Paving the Way to a Large-scale Pseudosense-annotated Dataset</i>	1100
Mohammad Taher Pilehvar and Roberto Navigli.....	
<i>Labeling the Languages of Words in Mixed-Language Documents using Weakly Supervised Methods</i>	1110
Ben King and Steven Abney	
<i>Learning Whom to Trust with MACE</i>	1120
Dirk Hovy, Taylor Berg-Kirkpatrick, Ashish Vaswani and Eduard Hovy.....	
<i>Supervised All-Words Lexical Substitution using Delexicalized Features</i>	1131
György Szarvas, Chris Biemann and Iryna Gurevych.....	
<i>A Tensor-based Factorization Model of Semantic Compositionalty</i>	1142
Tim Van de Cruys, Thierry Poibeau and Anna Korhonen	
<i>A Participant-based Approach for Event Summarization Using Twitter Streams</i>	1152
Chao Shen, Fei Liu, Fuliang Weng and Tao Li.....	
<i>Towards Coherent Multi-Document Summarization</i>	1163
Janara Christensen, Mausam, Stephen Soderland and Oren Etzioni	
<i>Generating Expressions that Refer to Visible Objects</i>	1174
Margaret Mitchell, Kees van Deemter and Ehud Reiter	
<i>Supervised Learning of Complete Morphological Paradigms</i>	1185
Greg Durrett and John DeNero	
<i>Optimal Data Set Selection: An Application to Grapheme-to-Phoneme Conversion</i>	1196
Young-Bum Kim and Benjamin Snyder.....	
<i>Knowledge-Rich Morphological Priors for Bayesian Language Models</i>	1206
Victor Chahuneau, Noah A. Smith and Chris Dyer.....	

Conference Program

Monday, June 10, 2013

- 8:45–9:00 Welcome to NAACL 2013!
- 9:00–10:10 Invited talk by Gina Kuperberg – Predicting Meaning: What the Brain tells us about the Architecture of Language Comprehension
- 10:10–10:40 Break

M1a: Machine Translation

- 10:40-11:05 *Model With Minimal Translation Units, But Decode With Phrases*
Nadir Durrani, Alexander Fraser and Helmut Schmid
- 11:05-11:30 *Beyond Left-to-Right: Multiple Decomposition Structures for SMT*
Hui Zhang, Kristina Toutanova, Chris Quirk and Jianfeng Gao
- 11:30-11:55 *Improved Reordering for Phrase-Based Translation using Sparse Features*
Colin Cherry
- 11:55-12:20 *Simultaneous Word-Morpheme Alignment for Statistical Machine Translation*
Elif Eyigöz, Daniel Gildea and Kemal Oflazer

M1b: Information Extraction

- 10:40-11:05 *Multi-faceted Event Recognition with Bootstrapped Dictionaries*
Ruihong Huang and Ellen Riloff
- 11:05-11:30 *Named Entity Recognition with Bilingual Constraints*
Wanxiang Che, Mengqiu Wang, Christopher D. Manning and Ting Liu
- 11:30-11:55 *Minimally Supervised Method for Multilingual Paraphrase Extraction from Definition Sentences on the Web*
Yulan Yan, Chikara Hashimoto, Kentaro Torisawa, Takao Kawai, Jun'ichi Kazama and Stijn De Saeger
- 11:55-12:20 *Relation Extraction with Matrix Factorization and Universal Schemas*
Sebastian Riedel, Limin Yao, Andrew McCallum and Benjamin M. Marlin

Monday, June 10, 2013 (continued)

M1c: Cognitive and Psycholinguistics

- 10:40-11:05 *Extracting the Native Language Signal for Second Language Acquisition*
Ben Swanson and Eugene Charniak
- 11:05-11:30 *An Analysis of Frequency- and Memory-Based Processing Costs*
Marten van Schijndel and William Schuler
- 11:30-11:55 *Cross-Lingual Semantic Similarity of Words as the Similarity of Their Semantic Word Responses*
Ivan Vulić and Marie-Francine Moens
- 11:55-12:20 *Combining multiple information types in Bayesian word segmentation*
Gabriel Doyle and Roger Levy
- 12:20–2:00 Lunch

M2a: Parsing and Syntax

- 2:00-2:25 *Training Parsers on Incompatible Treebanks*
Richard Johansson
- 2:25-2:50 *Learning a Part-of-Speech Tagger from Two Hours of Annotation*
Dan Garrette and Jason Baldridge
- 2:50-3:15 *Experiments with Spectral Learning of Latent-Variable PCFGs*
Shay B. Cohen, Karl Stratos, Michael Collins, Dean P. Foster and Lyle Ungar

Monday, June 10, 2013 (continued)

M2b: Topic Modeling and Text Mining

- 2:00-2:25 *Representing Topics Using Images*
Nikolaos Aletras and Mark Stevenson
- 2:25-2:50 *Drug Extraction from the Web: Summarizing Drug Experiences with Multi-Dimensional Topic Models*
Michael J. Paul and Mark Dredze
- 2:50-3:15 *Towards Topic Labeling with Phrase Entailment and Aggregation*
Yashar Mehdad, Giuseppe Carenini, Raymond T. Ng and Shafiq Joty
- 3:15-3:40 *Topic Segmentation with a Structured Topic Model*
Lan Du, Wray Buntine and Mark Johnson

M2c: Spoken Language Processing

- 2:00-2:25 *Text Alignment for Real-Time Crowd Captioning*
Iftekhar Naim, Daniel Gildea, Walter Lasecki and Jeffrey P. Bigham
- 2:25-2:50 *Discriminative Joint Modeling of Lexical Variation and Acoustic Confusion for Automated Narrative Retelling Assessment*
Maider Lehr, Izhak Shafran, Emily Prud'hommeaux and Brian Roark
- 2:50-3:15 *Using Out-of-Domain Data for Lexical Addressee Detection in Human-Human-Computer Dialog*
Heeyoung Lee, Andreas Stolcke and Elizabeth Shriberg
- 3:15-3:40 *Segmentation Strategies for Streaming Speech Translation*
Vivek Kumar Rangarajan Sridhar, John Chen, Srinivas Bangalore, Andrej Ljolje and Rathinavelu Chengalvarayan

3:40–4:10 Break

4:10–6:00 Poster madness!

- Enforcing Subcategorization Constraints in a Parser Using Sub-parses Recombining*
Seyed Abolghasem Mirroshandel, Alexis Nasr and Benoît Sagot

- Large-Scale Discriminative Training for Statistical Machine Translation Using Held-Out Line Search*
Jeffrey Flanigan, Chris Dyer and Jaime Carbonell

Monday, June 10, 2013 (continued)

Measuring Term Informativeness in Context
Zhaohui Wu and C. Lee Giles

Unsupervised Learning Summarization Templates from Concise Summaries
Horacio Saggion

Classification of South African languages using text and acoustic based methods: A case of six selected languages
Peleira Nicholas Zulu

Improving Syntax-Augmented Machine Translation by Coarsening the Label Set
Greg Hanneman and Alon Lavie

Keyphrase Extraction for N-best Reranking in Multi-Sentence Compression
Florian Boudin and Emmanuel Morin

Development of a Persian Syntactic Dependency Treebank
Mohammad Sadegh Rasooli, Manouchehr Kouhestani and Amirsaeid Moloodi

Improving reordering performance using higher order and structural features
Mitesh M. Khapra, Ananthakrishnan Ramanathan and Karthik Visweswarah

Massively Parallel Suffix Array Queries and On-Demand Phrase Extraction for Statistical Machine Translation Using GPUs
Hua He, Jimmy Lin and Adam Lopez

Discriminative Training of 150 Million Translation Parameters and Its Application to Pruning
Hendra Setiawan and Bowen Zhou

Applying Pairwise Ranked Optimisation to Improve the Interpolation of Translation Models
Barry Haddow

Dialectal Arabic to English Machine Translation: Pivoting through Modern Standard Arabic
Wael Salloum and Nizar Habash

What to do about bad language on the internet
Jacob Eisenstein

Monday, June 10, 2013 (continued)

Minibatch and Parallelization for Online Large Margin Structured Learning
Kai Zhao and Liang Huang

Improved Part-of-Speech Tagging for Online Conversational Text with Word Clusters
Olutobi Owoputi, Brendan O'Connor, Chris Dyer, Kevin Gimpel, Nathan Schneider and Noah A. Smith

Parser lexicalisation through self-learning
Marek Rei and Ted Briscoe

Mining User Relations from Online Discussions using Sentiment Analysis and Probabilistic Matrix Factorization
Minghui Qiu, Liu Yang and Jing Jiang

Focused training sets to reduce noise in NER feature models
Amber McKenzie

Learning to Relate Literal and Sentimental Descriptions of Visual Properties
Mark Yatskar, Svitlana Volkova, Asli Celikyilmaz, Bill Dolan and Luke Zettlemoyer

Morphological Analysis and Disambiguation for Dialectal Arabic
Nizar Habash, Ryan Roth, Owen Rambow, Ramy Eskander and Nadi Tomeh

Using a Supertagged Dependency Language Model to Select a Good Translation in System Combination
Wei-Yun Ma and Kathleen McKeown

Dudley North visits North London: Learning When to Transliterate to Arabic
Mahmoud Azab, Houda Bouamor, Behrang Mohit and Kemal Oflazer

Better Twitter Summaries?
Joel Judd and Jugal Kalita

Training MRF-Based Phrase Translation Models using Gradient Ascent
Jianfeng Gao and Xiaodong He

Automatic Morphological Enrichment of a Morphologically Underspecified Treebank
Sarah Alkuhlani, Nizar Habash and Ryan Roth

Monday, June 10, 2013 (continued)

A Beam-Search Decoder for Normalization of Social Media Text with Application to Machine Translation

Pidong Wang and Hwee Tou Ng

Parameter Estimation for LDA-Frames

Jiří Materna

Approximate PCFG Parsing Using Tensor Decomposition

Shay B. Cohen, Giorgio Satta and Michael Collins

Negative Deceptive Opinion Spam

Myle Ott, Claire Cardie and Jeffrey T. Hancock

Improving speech synthesis quality by reducing pitch peaks in the source recordings

Luisina Violante, Pablo Rodríguez Zivic and Agustín Gravano

Robust Systems for Preposition Error Correction Using Wikipedia Revisions

Aoife Cahill, Nitin Madnani, Joel Tetreault and Diane Napolitano

Supervised Bilingual Lexicon Induction with Multiple Monolingual Signals

Ann Irvine and Chris Callison-Burch

Creating Reverse Bilingual Dictionaries

Khang Nhut Lam and Jugal Kalita

Identification of Temporal Event Relationships in Biographical Accounts

Lucian Silcox and Emmett Tomai

Predicative Adjectives: An Unsupervised Criterion to Extract Subjective Adjectives

Michael Wiegand, Josef Ruppenhofer and Dietrich Klakow

Modeling Syntactic and Semantic Structures in Hierarchical Phrase-based Translation

Junhui Li, Philip Resnik and Hal Daumé III

Using Derivation Trees for Informative Treebank Inter-Annotator Agreement Evaluation

Seth Kulick, Ann Bies, Justin Mott, Mohamed Maamouri, Beatrice Santorini and Anthony Kroch

Monday, June 10, 2013 (continued)

Embracing Ambiguity: A Comparison of Annotation Methodologies for Crowdsourcing Word Sense Labels

David Jurgens

Compound Embedding Features for Semi-supervised Learning

Mo Yu, Tiejun Zhao, Daxiang Dong, Hao Tian and Dianhai Yu

On Quality Ratings for Spoken Dialogue Systems – Experts vs. Users

Stefan Ultes, Alexander Schmitt and Wolfgang Minker

Overcoming the Memory Bottleneck in Distributed Training of Latent Variable Models of Text

Yi Yang, Alexander Yates and Doug Downey

Processing Spontaneous Orthography

Ramy Eskander, Nizar Habash, Owen Rambow and Nadi Tomeh

Purpose and Polarity of Citation: Towards NLP-based Bibliometrics

Amjad Abu-Jbara, Jefferson Ezra and Dragomir Radev

Estimating effect size across datasets

Anders Søgaard

Systematic Comparison of Professional and Crowdsourced Reference Translations for Machine Translation

Rabih Zbib, Gretchen Markiewicz, Spyros Matsoukas, Richard Schwartz and John Makhoul

Down-stream effects of tree-to-dependency conversions

Jakob Elming, Anders Johannsen, Sigrid Klerke, Emanuele Lapponi, Hector Martinez Alonso and Anders Søgaard

6:00–6:30 Break

6:30–8:30 Poster and Demonstrations Session

Tuesday, June 11, 2013

9:15–9:25 Best paper awards

Best Short Paper

9:25–9:45 *The Life and Death of Discourse Entities: Identifying Singleton Mentions*
Marta Recasens, Marie-Catherine de Marneffe and Christopher Potts

IBM Best Student Paper

9:45–10:15 *Automatic Generation of English Respellings*
Bradley Hauer and Grzegorz Kondrak

10:15–10:45 Break

T1a: Machine Translation and Multilinguality

10:45–11:00 *A Simple, Fast, and Effective Reparameterization of IBM Model 2*
Chris Dyer, Victor Chahuneau and Noah A. Smith

11:00–11:15 *Phrase Training Based Adaptation for Statistical Machine Translation*
Saab Mansour and Hermann Ney

11:15–11:30 *Translation Acquisition Using Synonym Sets*
Daniel Andrade, Masaki Tsuchida, Takashi Onishi and Kai Ishikawa

11:30–11:45 *Supersense Tagging for Arabic: the MT-in-the-Middle Attack*
Nathan Schneider, Behrang Mohit, Chris Dyer, Kemal Oflazer and Noah A. Smith

11:45–12:00 *Zipfian corruptions for robust POS tagging*
Anders Søgaard

Tuesday, June 11, 2013 (continued)

T1b: Sentiment Analysis and Topic Modeling

- 10:45-11:00 *A Multi-Dimensional Bayesian Approach to Lexical Style*
Julian Brooke and Graeme Hirst
- 11:00-11:15 *Unsupervised Domain Tuning to Improve Word Sense Disambiguation*
Judita Preiss and Mark Stevenson
- 11:15-11:30 *What's in a Domain? Multi-Domain Learning for Multi-Attribute Data*
Mahesh Joshi, Mark Dredze, William W. Cohen and Carolyn P. Rosé
- 11:30-11:45 *An opinion about opinions about opinions: subjectivity and the aggregate reader*
Asad Sayeed
- 11:45-12:00 *An Examination of Regret in Bullying Tweets*
Jun-Ming Xu, Benjamin Burchfiel, Xiaojin Zhu and Amy Bellmore

T1c: Spoken Language Processing

- 10:45-11:00 *A Cross-language Study on Automatic Speech Disfluency Detection*
Wen Wang, Andreas Stolcke, Jiahong Yuan and Mark Liberman
- 11:00-11:15 *Distributional semantic models for the evaluation of disordered language*
Masoud Rouhizadeh, Emily Prud'hommeaux, Brian Roark and Jan van Santen
- 11:15-11:30 *Atypical Prosodic Structure as an Indicator of Reading Level and Text Difficulty*
Julie Medero and Mari Ostendorf
- 11:30-11:45 *Using Document Summarization Techniques for Speech Data Subset Selection*
Kai Wei, Yuzong Liu, Katrin Kirchhoff and Jeff Bilmes
- 11:45-12:00 *Semi-Supervised Discriminative Language Modeling with Out-of-Domain Text Data*
Arda Çelebi and Murat Saracclar
- 12:00–2:00 Lunch (and Business Meeting 1-2)

Tuesday, June 11, 2013 (continued)

T2a: Semantics

- 2:00-2:15 *More than meets the eye: Study of Human Cognition in Sense Annotation*
 Salil Joshi, Diptesh Kanojia and Pushpak Bhattacharyya
- 2:15-2:30 *Improving Lexical Semantics for Sentential Semantics: Modeling Selectional Preference and Similar Words in a Latent Variable Model*
 Weiwei Guo and Mona Diab
- 2:30-2:45 *Linguistic Regularities in Continuous Space Word Representations*
 Tomas Mikolov, Wen-tau Yih and Geoffrey Zweig
- 2:45-3:00 *TruthTeller: Annotating Predicate Truth*
 Amnon Lotan, Asher Stern and Ido Dagan
- 3:00-3:15 *PPDB: The Paraphrase Database*
 Juri Ganitkevitch, Benjamin Van Durme and Chris Callison-Burch

T2b: Information Extraction

- 2:00-2:15 *Exploiting the Scope of Negations and Heterogeneous Features for Relation Extraction: A Case Study for Drug-Drug Interaction Extraction*
 Md. Faisal Mahbub Chowdhury and Alberto Lavelli
- 2:15-2:30 *Graph-Based Seed Set Expansion for Relation Extraction Using Random Walk Hitting Times*
 Joel Lang and James Henderson
- 2:30-2:45 *Distant Supervision for Relation Extraction with an Incomplete Knowledge Base*
 Bonan Min, Ralph Grishman, Li Wan, Chang Wang and David Gondek
- 2:45-3:00 *Measuring the Structural Importance through Rhetorical Structure Index*
 Narine Kokhlikyan, Alex Waibel, Yuqi Zhang and Joy Ying Zhang
- 3:00-3:15 *Separating Fact from Fear: Tracking Flu Infections on Twitter*
 Alex Lamb, Michael J. Paul and Mark Dredze

Tuesday, June 11, 2013 (continued)

T2c: Discourse and Dialog

- 2:00-2:15 *Differences in User Responses to a Wizard-of-Oz versus Automated System*
Jesse Thomason and Diane Litman
- 2:15-2:30 *Improving the Quality of Minority Class Identification in Dialog Act Tagging*
Adinoyi Omuya, Vinodkumar Prabhakaran and Owen Rambow
- 2:30-2:45 *Discourse Connectors for Latent Subjectivity in Sentiment Analysis*
Rakshit Trivedi and Jacob Eisenstein
- 2:45-3:00 *Coherence Modeling for the Automated Assessment of Spontaneous Spoken Responses*
Xinhao Wang, Keelan Evanini and Klaus Zechner
- 3:00-3:15 *Disfluency Detection Using Multi-step Stacked Learning*
Xian Qian and Yang Liu
- 3:15–3:45 Break

T3a: Semantics

- 4:10-4:35 *Using Semantic Unification to Generate Regular Expressions from Natural Language*
Nate Kushman and Regina Barzilay
- 4:35-5:00 *Probabilistic Frame Induction*
Jackie Chi Kit Cheung, Hoifung Poon and Lucy Vanderwende
- 5:00–5:25 *A Quantum-Theoretic Approach to Distributional Semantics*
William Blacoe, Elham Kashefi and Mirella Lapata

Tuesday, June 11, 2013 (continued)

T3b: Information Extraction

- 3:45-4:10 *Answer Extraction as Sequence Tagging with Tree Edit Distance*
Xuchen Yao, Benjamin Van Durme, Chris Callison-Burch and Peter Clark
- 4:10-4:35 *Open Information Extraction with Tree Kernels*
Ying Xu, Mi-Young Kim, Kevin Quinn, Randy Goebel and Denilson Barbosa
- 4:35-5:00 *Finding What Matters in Questions*
Xiaoqiang Luo, Hema Raghavan, Vittorio Castelli, Sameer Maskey and Radu Florian
- 5:00-5:25 *A Just-In-Time Keyword Extraction from Meeting Transcripts*
Hyun-Je Song, Junho Go, Seong-Bae Park and Se-Young Park

T3c: Discourse

- 3:45-4:10 *Same Referent, Different Words: Unsupervised Mining of Opaque Coreferent Mentions*
Marta Recasens, Matthew Can and Daniel Jurafsky
- 4:10-4:35 *Global Inference for Bridging Anaphora Resolution*
Yufang Hou, Katja Markert and Michael Strube
- 4:35-5:00 *Classifying Temporal Relations with Rich Linguistic Knowledge*
Jennifer D'Souza and Vincent Ng
- 5:00-5:25 *Improved Information Structure Analysis of Scientific Documents Through Discourse and Lexical Constraints*
Yufan Guo, Roi Reichart and Anna Korhonen
- 7:00–9:30 Banquet

Wednesday, June 12, 2013

- 9:00–10:10 Invited talk by Kathleen McKeown – Natural Language Applications from Fact to Fiction
10:10–10:40 Break

W1a: Machine Translation

- 10:40-11:05 *Adaptation of Reordering Models for Statistical Machine Translation*
Boxing Chen, George Foster and Roland Kuhn
- 11:05-11:30 *Multi-Metric Optimization Using Ensemble Tuning*
Baskaran Sankaran, Anoop Sarkar and Kevin Duh
- 11:30-11:55 *Grouping Language Model Boundary Words to Speed K-Best Extraction from Hypergraphs*
Kenneth Heafield, Philipp Koehn and Alon Lavie
- 11:55-12:20 *A Systematic Bayesian Treatment of the IBM Alignment Models*
Yarin Gal and Phil Blunsom

W1b: Semantics

- 10:40-11:05 *Unsupervised Metaphor Identification Using Hierarchical Graph Factorization Clustering*
Ekaterina Shutova and Lin Sun
- 11:05-11:30 *Three Knowledge-Free Methods for Automatic Lexical Chain Extraction*
Steffen Remus and Chris Biemann
- 11:30-11:55 *Combining Heterogeneous Models for Measuring Relational Similarity*
Alisa Zhila, Wen-tau Yih, Christopher Meek, Geoffrey Zweig and Tomas Mikolov

Wednesday, June 12, 2013 (continued)

W1c: Social Media Processing

- 10:40-11:05 *Broadly Improving User Classification via Communication-Based Name and Location Clustering on Twitter*
Shane Bergsma, Mark Dredze, Benjamin Van Durme, Theresa Wilson and David Yarowsky
- 11:05-11:30 *To Link or Not to Link? A Study on End-to-End Tweet Entity Linking*
Stephen Guo, Ming-Wei Chang and Emre Kiciman
- 11:30-11:55 *A Latent Variable Model for Viewpoint Discovery from Threaded Forum Posts*
Minghui Qiu and Jing Jiang
- 11:55-12:20 *Identifying Intention Posts in Discussion Forums*
Zhiyuan Chen, Bing Liu, Meichun Hsu, Malu Castellanos and Riddhiman Ghosh
- 12:20–2:00 Lunch

W2a: Parsing and Syntax

- 2:25-2:50 *Dependency-based empty category detection via phrase structure trees*
Nianwen Xue and Yaqin Yang
- 2:50-3:15 *Target Language Adaptation of Discriminative Transfer Parsers*
Oscar Täckström, Ryan McDonald and Joakim Nivre

W2b: Dialog

- 2:00-2:25 *Emergence of Gricean Maxims from Multi-Agent Decision Theory*
Adam Vogel, Max Bodoia, Christopher Potts and Daniel Jurafsky
- 2:25-2:50 *Open Dialogue Management for Relational Databases*
Ben Hixon and Rebecca J. Passonneau
- 2:50-3:15 *A method for the approximation of incremental understanding of explicit utterance meaning using predictive models in finite domains*
David DeVault and David Traum

Wednesday, June 12, 2013 (continued)

W2c: Annotation and Language Resources

- 2:00-2:25 *Paving the Way to a Large-scale Pseudosense-annotated Dataset*
 Mohammad Taher Pilehvar and Roberto Navigli
- 2:25-2:50 *Labeling the Languages of Words in Mixed-Language Documents using Weakly Supervised Methods*
 Ben King and Steven Abney
- 2:50-3:15 *Learning Whom to Trust with MACE*
 Dirk Hovy, Taylor Berg-Kirkpatrick, Ashish Vaswani and Eduard Hovy
- 3:15–3:45 Break

W3a: Semantics and Syntax

- 3:45-4:10 *Supervised All-Words Lexical Substitution using Delexicalized Features*
 György Szarvas, Chris Biemann and Iryna Gurevych
- 4:10-4:35 *A Tensor-based Factorization Model of Semantic Compositionality*
 Tim Van de Cruys, Thierry Poibeau and Anna Korhonen

W3b: Summarization and Generation

- 3:45-4:10 *A Participant-based Approach for Event Summarization Using Twitter Streams*
 Chao Shen, Fei Liu, Fuliang Weng and Tao Li
- 4:10-4:35 *Towards Coherent Multi-Document Summarization*
 Janara Christensen, Mausam, Stephen Soderland and Oren Etzioni
- 4:35-5:00 *Generating Expressions that Refer to Visible Objects*
 Margaret Mitchell, Kees van Deemter and Ehud Reiter

Wednesday, June 12, 2013 (continued)

W3c: Morphology and Phonology

- 3:45-4:10 *Supervised Learning of Complete Morphological Paradigms*
 Greg Durrett and John DeNero
- 4:10-4:35 *Optimal Data Set Selection: An Application to Grapheme-to-Phoneme Conversion*
 Young-Bum Kim and Benjamin Snyder
- 4:35-5:00 *Knowledge-Rich Morphological Priors for Bayesian Language Models*
 Victor Chahuneau, Noah A. Smith and Chris Dyer

Model With Minimal Translation Units, But Decode With Phrases

Abstract

N-gram-based models co-exist with their phrase-based counterparts as an alternative SMT framework. Both techniques have pros and cons. While the N-gram-based framework provides a better model that captures both source and target contexts and avoids spurious phrasal segmentation, the ability to memorize and produce larger translation units gives an edge to the phrase-based systems during decoding, in terms of better search performance and superior selection of translation units. In this paper we combine N-gram-based modeling with phrase-based decoding, and obtain the benefits of both approaches. Our experiments show that using this combination not only improves the search accuracy of the N-gram model but that it also improves the BLEU scores. Our system outperforms state-of-the-art phrase-based systems (Moses and Phrasal) and N-gram-based systems by a significant margin on German, French and Spanish to English translation tasks.

1 Introduction

Statistical Machine Translation advanced from word-based models (Brown et al., 1993) towards more sophisticated models that take contextual information into account. Phrase-based (Och and Ney, 2004; Koehn et al., 2003) and N-gram-based (Mariño et al., 2006) models are two instances of such frameworks. While the two models have some common properties, they are substantially different.

Much of the work presented here was carried out while the first author was at the University of Stuttgart.

Phrase-based systems employ a simple and effective machinery by learning larger chunks of translation called phrases¹. Memorizing larger units enables the phrase-based model to learn local dependencies such as short reorderings, idioms, insertions and deletions, etc. The model however, has the following drawbacks: i) it makes independence assumptions over phrases ignoring the contextual information outside of phrases ii) it has issues handling long-distance reordering iii) it has the spurious phrasal segmentation problem which allows multiple derivations of a bilingual sentence pair having different model scores for each segmentation.

Modeling with minimal translation units helps address some of these issues. The N-gram-based SMT framework is based on tuples. Tuples are minimal translation units composed of source and target cepts². N-gram-based models are Markov models over sequences of tuples (Mariño et al., 2006; Crego and Mariño, 2006) or operations encapsulating tuples (Durrani et al., 2011). This mechanism has several useful properties. Firstly, no phrasal independence assumption is made. The model has access to both source and target context outside of phrases. Secondly the model learns a unique derivation of a bilingual sentence given its alignment, thus avoiding the spurious segmentation problem.

Using minimal translation units, however, results in a higher number of search errors because of i)

¹A phrase-pair in PBSMT is a sequence of source and target words that is translation of each other, and is not necessarily a linguistic constituent. Phrases are built by combining minimal translation units and ordering information.

²A cept is a group of words in one language that is translated as a minimal unit in one specific context (Brown et al., 1993).

poor translation selection, ii) inaccurate future-cost estimates and iii) incorrect early pruning of hypotheses that would produce better model scores if allowed to continue. In order to deal with these problems, search is carried out only on a graph of pre-calculated orderings, and ad-hoc reordering limits are imposed to constrain the search space (Crego et al., 2005; Crego and Mariño, 2006), or a higher beam size is used in decoding (Durrani et al., 2011). The ability to memorize and produce larger translation chunks during decoding, on the other hand, gives a distinct advantage to the phrase-based system during search. Phrase-based systems i) have access to uncommon translations, ii) do not require higher beam sizes, iii) have more accurate future-cost estimates because of the availability of phrase-internal language model context before search is started. To illustrate this consider the German-English phrase-pair “schoß ein Tor – scored a goal”, composed from the tuples (cept-pairs) “schoß – scored”, “ein – a” and “Tor – goal”. It is likely that the N-gram system does not have the tuple “schoß – scored” in its n-best translation options because “scored” is an uncommon translation for “schoß” outside the sports domain. Even if “schoß – scored” is hypothesized, it will be ranked quite low in the stack until “ein” and “Tor” are generated in the next steps. A higher beam is required to prevent it from getting pruned. Phrase-based systems, on the other hand, are likely to have access to the phrasal unit “schoß ein Tor – scored a goal” and can generate it in a single step. Moreover, a more accurate future-cost estimate can be computed because of the available context internal to the phrase.

In this work, we extend the N-gram model, based on operation sequences (Durrani et al., 2011), to use phrases during decoding. The main idea is to study whether a combination of modeling with minimal translation units and using phrasal information during decoding helps to solve the above-mentioned problems.

The remainder of this paper is organized as follows. The next two sections review phrase-based and N-gram-based SMT. Section 2 provides a comparison of phrase-based and N-gram-based SMT. Section 3 summarizes the operation sequence model (OSM), the main baseline for this work. Section 4 analyzes the search problem when decoding with

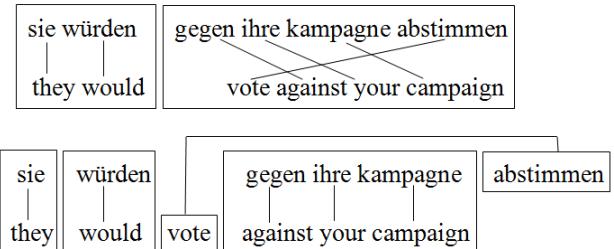

Figure 1: Different Segmentations of a Bilingual Sentence Pair

minimal units. Section 5 discusses how information available in phrases can be used to improve search performance. Section 6 presents the results of this work. We conducted experiments on the German-to-English and French-to-English translation tasks and found that using phrases in decoding improves both search accuracy and BLEU scores. Finally we compare our system with two state-of-the-art phrase-based systems (Moses and Phrasal) and two state-of-the-art N-gram-based systems (Ncode and OSM) on standard translation tasks.

2 Previous Work

Phrase-based and N-gram-based SMT are alternative frameworks for string-to-string translation. Phrase-based SMT segments a bilingual sentence pair into phrases that are continuous sequences of words (Och and Ney, 2004; Koehn et al., 2003) or discontinuous sequences of words (Galley and Manning, 2010). These phrases are then reordered through a lexicalized reordering model that takes into account the orientation of a phrase with respect to its previous phrase (Tillmann and Zhang, 2005) or block of phrases (Galley and Manning, 2008).

There are several drawbacks of the phrase-based model. Firstly it makes an independence assumption over phrases, according to which phrases are translated independently of each other, thus ignoring the contextual information outside of the phrasal boundary. This problem is corrected by the monolingual language model that takes context into account. But often the language model cannot compensate for the dispreference of the translation model for non-local dependencies. The second problem is that the model is unaware of the actual phrasal segmentation of a sentence during training. It therefore learns all possible ways of segmenting a bilingual sentence. Different segmentations of a bilingual sentence re-

sult in different probability scores for the translation and reordering models, causing spurious ambiguity in the model. See Figure 1. In the first segmentation, the model learns the lexical and reordering probabilities of the phrases “sie würden – they would” and “gegen ihre kampagne abstimmen – vote against your campaign”. In the second segmentation, the model learns the lexical and reordering probabilities of the phrases “sie – they” “würden – would”, “abstimmen – vote”, “gegen ihre kampagne – against your campaign”. Both segmentations result in different translation and reordering scores. This kind of ambiguity in the model subsequently results in the presence of many different equivalent segmentations in the search space. Also note that the two segmentations contain different information. From the first segmentation the model learns the dependency between the verb “abstimmen – vote” and the phrase “gegen ihre kampagne – against your campaign”. The second segmentation allows the model to capture the reordering of the complex verb predicate “würden – would” and “abstimmen – vote” by learning that the verb “abstimmen – vote” is discontinuous with respect to the auxiliary. This information cannot be captured in the first segmentation because of the phrasal independence assumption and stiff phrasal boundaries. The model loses one of the dependencies depending upon which segmentation it chooses during decoding.

N-gram-based SMT is an instance of a joint model that generates source and target strings together in bilingual translation units called tuples. Tuples are essentially phrases but they are atomic units that cannot be decomposed any further. This condition of atomicity results in a unique segmentation of the bilingual sentence pair given its alignments. The model does not make any phrasal independence assumption and generates a tuple by looking at a context of $n - 1$ previous tuples (or operations). This allows the N-gram model to model all the dependencies through a single derivation.

The main drawback of N-gram-based SMT is its poor search mechanism which is inherent from using minimal translation units during search. Decoding with tuples has problems with a high number of search errors caused by lower translation coverage, inaccurate future-cost estimation and pruning of correct hypotheses (see Section 4.2 for details).

Crego and Mariño (2006) proposed a way to couple reordering and search through POS-based rewrite rules. These rules are learned during training when units with crossing alignments are unfolded through source linearization to form minimal tuples. For example, in Figure 1, the N-gram-based MT will linearize the word sequence “gegen ihre kampagne abstimmen” to “abstimmen gegen ihre kampagne”, so that it is in the same order as the English words. It also learns a POS-rule “IN PRP NN VB → VB IN PRP NN”. The POS-based rewrite rules serve to precompute the orderings that are hypothesized during decoding. Coupling reordering and search allows the N-gram model to arrange hypotheses in 2^m stacks (for an m word source sentence), each containing hypotheses that cover exactly the same foreign words. This removes the need for future-cost estimation³. Secondly, memorizing POS-based rules enables phrase-based like reordering, however without lexical selection. There are three drawbacks of this approach. Firstly, lexical generation and reordering are decoupled. Search is only performed on a small number of reorderings, pre-calculated using the source side and completely ignoring the target-side. And lastly, the POS-based rules face data sparsity problems especially in the case of long distance reorderings.

Durrani et al. (2011) recently addressed these problems by proposing an operation sequence N-gram model which strongly couples translation and reordering, hypothesizes all possible reorderings and does not require POS-based rules. Representing bilingual sentences as a sequence of operations enables them to memorize phrases and lexical reordering triggers like PBSMT. However, using minimal units during decoding and searching over all possible reorderings means that hypotheses can no longer be arranged in 2^m stacks. The problem of inaccurate future-cost estimates resurfaces resulting in more search errors. A higher beam size of 500 is therefore used to produce translation units in comparison to phrase-based systems. This, however, still does not eliminate all search errors. This paper shows that using phrases instead of cepts in de-

³Using m stacks with future-cost estimation is a more efficient solution but is not used “due to the complexity of accurately computing these estimations in the N-gram architecture” (Crego et al., 2011).

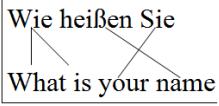

coding improves the search accuracy and translation quality. It also shows that using some phrasal information in cept-based decoding captures some of these improvements.

3 Operation Sequence Model

The N-gram model with integrated reordering models a *sequence of operations* obtained through the transformation of a bilingual sentence pair. An operation can either be to i) generate a sequence of source and target words, ii) to insert a gap as a placeholder for skipped words, iii) or to jump forward and backward in a sentence to translate words discontinuously. The translate operation $\text{Generate}(X, Y)$ encapsulates the translation tuple (X, Y) . It generates source and target translations simultaneously⁴. This is similar to N-gram-based SMT except that the tuples in the N-gram-based model are generated monotonically, whereas in this case lexical generation and reordering information is strongly coupled in an operation sequence.

Consider the phrase pair:

The model memorizes it through the sequence:

$\text{Generate}(\text{Wie}, \text{What is}) \rightarrow \text{Gap} \rightarrow \text{Generate}(\text{Sie}, \text{your}) \rightarrow \text{Jump Back (1)} \rightarrow \text{Generate}(\text{heissen}, \text{name})$

Let $O = o_1, \dots, o_{j-1}$ be a sequence of operations as hypothesized by the translator to generate the bilingual sentence pair $\langle F, E \rangle$ with an alignment function A . The translation model is defined as:

$$p(F, E, A) = p(o_1^J) = \prod_{j=1}^J p(o_j | o_{j-n+1}, \dots, o_{j-1})$$

where n indicates the amount of context used. The translation model is implemented as an N-gram model of operations using SRILM-Toolkit (Stolcke, 2002) with Kneser-Ney smoothing. A 9-gram model is used. Several count-based features such as gap and open gap penalties and distance-based features such as gap-width and reordering distance are added to the model, along with the lexical weighting and length penalty features in a standard log-linear framework (Durrani et al., 2011).

⁴The generation is carried out in the order of the target language E .

4 Search

4.1 Overview of Decoding Framework

The decoding framework used in the operation sequence model is based on Pharaoh (Koehn, 2004a). The decoder uses beam search to build up the translation from left to right. The hypotheses are arranged in m stacks such that stack i maintains hypotheses that have already translated i many foreign words. The ultimate goal is to find the best scoring hypothesis, that has translated all the words in the foreign sentence. The overall process can be roughly divided into the following steps: i) extraction of translation units ii) future-cost estimation, iii) hypothesis extension iv) recombination and pruning.

During the hypothesis extension each extracted phrase is translated into a sequence of operations. The reordering operations (gaps and jumps) are generated by looking at the position of the translator, the last foreign word generated etc. (Refer to Algorithm 1 in Durrani et al. (2011)). The probability of an operation depends on the $n - 1$ previous operations. The model backs-off to the smaller n-grams of operations if the full history is unknown. We use Kneser-Ney smoothing to handle back-off⁵.

4.2 Drawbacks of Cept-based Decoding

One of the main drawbacks of the operation sequence model is that it has a more difficult search problem than the phrase-based model. The operation model, although based on minimal translation units, can learn larger translation chunks by memorizing a sequence of operations. However, using cepts during decoding has the following drawbacks: i) the cept-based decoder does not have access to all the translation units that a phrase-based decoder uses as part of a larger phrase. ii) it requires a higher beam size to prevent early pruning of better hypotheses that lead toward higher model scores when allowed to continue and iii) it uses worse future-cost estimates than the phrase-based decoder.

Recall the example from the last section. For the cept-based decoder to generate the same phrasal translation, it requires three separate tuple translations “Wie – what is”, “Sie – your” and “heißen – name”. Here we are faced with three challenges.

⁵We also tried Witten-Bell and Good Turing methods of discounting and found Kneser-Ney smoothing to produce the best results.

Translation Coverage: The first problem is that the N-gram model does not have the same coverage of translation options. The English cepts “what is”, “your” and “name” are not good candidate translations for the German cepts “Wie”, “Sie” and “heißen”, respectively. When extracting tuple translations for these cepts from the Europarl data for our system, the tuple “Wie – what is” is ranked 124th, “heißen – name” is ranked 56th, and “Sie – your” is ranked 9th in the list of n-best translation candidates. Typically only the 20 best translation options are used, to reduce the decoding time, and such phrasal units with less frequent cept translations are never hypothesized in the N-gram-based systems. The phrase-based system on the other hand can extract the phrase “Wie heißen Sie – what is your name” even if it is observed only once during training. A similar problem is also reported in Costa-jussà et al. (2007). When trying to reproduce the sentences in the n-best translation output of the phrase-based system, the N-gram-based system was only able to produce 37.5% of the sentences in the Spanish-to-English and 37.2% in the English-to-Spanish translation tasks. In comparison the phrase-based system was able to reproduce 57.5% and 48.6% of the sentences in the n-best translation output of the Spanish-to-English and English-to-Spanish N-gram-based systems.

Larger Beam Size: A related problem is that a higher beam size is required in cept-based decoding to prevent uncommon translations from getting pruned. The phrase-based system can generate the phrase-pair “Wie heißen Sie – what is your name” in a single step placing it directly into the stack three words to the right. The cept-based decoder generates this phrase in three stacks with the tuple translations “Wie – What is”, “Sie – your” and “heißen – name”. A very large stack size is required during decoding to prevent the pruning of “Wie – What is” which is ranked quite low in the stack until the tuple “Sie – your” is hypothesized in the next stack. Costa-jussà et al. (2007) reports a significant drop in the performance of N-gram-based SMT when a beam size of 10 is used instead of 50 in their experiments. For the (cept-based) operation sequence model, Durrani et al. (2011) required a stack size of 500. In comparison, the translation quality achieved by phrase-based

SMT remains the same when varying the beam size between 5 and 50.

Future-Cost Estimation: A third problem is caused by inaccurate future-cost estimation. Using phrases helps phrase-based SMT to better estimate the future language model cost because of the larger context available, and allows the decoder to capture local (phrase-internal) reorderings in the future cost. In comparison the future cost for tuples is mostly unigram probabilities. The future-cost estimate for the phrase pair “Wie heißen Sie – What is your name” is estimated by calculating the cost of each feature. The language model cost, for example, is estimated in the phrase-based system as follows:

$$p_{lm} = p(\text{What}) \times p(\text{is}|\text{What}) \times p(\text{your}|\text{What is}) \\ \times p(\text{name}|\text{What is your})$$

The cost of the direct phrase translation probability, one of the features used in the phrase translation model, is estimated as:

$$p_{tm} = p(\text{What is your name}| \text{Wie heißen Sie})$$

Phrase-based SMT is aware during the preprocessing step that the words “Wie heißen Sie” may be translated as a phrase. This is helpful for estimating a more accurate future cost because the phrase-internal context is already available. The same is not true for the operation sequence model, to which only minimal units are available. The operation model does not have the information that “Wie heißen Sie” may be translated as a phrase during decoding. The future-cost estimate available to the operation model for the span covering “Wie heißen Sie” will have unigram probabilities for both the translation and language model:

$$p_{lm} = p(\text{What}) \times p(\text{is}|\text{What}) \times p(\text{your}) \times p(\text{name})$$

$$p_{tm} = p(\text{Generate(Wie, What is)}) \times p(\text{Generate(heißen, name)}) \\ \times p(\text{Generate(Sie, your)})$$

Thus the future-cost estimate in the operation model is much worse than that of the phrase-based model. The poor future-cost estimation leads to search errors, causing a drop in the translation quality. A more accurate future-cost estimate for the translation model cost would be:

$$\begin{aligned} P_{tm} = & p(\text{Generate(Wie,What is)}) \times p(\text{Insert Gap}|C) \\ & \times p(\text{Generate(Sie,your)}|C) \times p(\text{Jump Back(1)}|C) \\ & p(\text{Generate(hei\ss en,name)}|C) \end{aligned}$$

where C is the context, i.e., the $n-1$ previously generated operations. The future-cost estimates computed in this manner are much more accurate because they not only consider context, but also take the reordering operations into account.

5 N-gram Model with Phrase-based Decoding

In the last section we discussed the disadvantages of using cepts during search in a left-to-right decoding framework. We now define a method to empirically study the mentioned drawbacks and whether using information available in phrase-pairs during decoding can help improve search accuracy and translation quality.

5.1 Training

We extended the training steps in Durrani et al. (2011) to extract a phrase lexicon from the parallel data. We extract all phrase pairs of length 6 and below, that are consistent (Och et al., 1999) with the word alignments. Only continuous phrases as used in a traditional phrase-based system are extracted thus allowing only inside-out (Wu, 1997) type of alignments. The future cost of each feature component used in the log-linear model is calculated. The operation sequence required to hypothesize each phrase is generated and its future cost is calculated. The future costs of other features such as language models, lexicalized probability features, etc. are also estimated. The estimates of the count-based reordering penalties (gap penalty and open gap penalty) and the distance-based features (gap-width and reordering distance) could not be estimated previously with cepts but are available when using phrases.

5.2 Decoding

We extended the decoder developed by Durrani et al. (2011) and tried three ideas. In our primary experiments we enabled the decoder to use phrases instead of cepts. This allows the decoder to i) use phrase-internal context when computing the future-cost es-

timates, ii) hypothesize translation options not available to the cept-based decoder iii) cover multiple source words in a single step subsequently improving translation coverage and search. Note that using phrases instead of cepts during decoding, does not reintroduce the spurious phrasal segmentation problem as is present in the phrase-based system, because the model is built on minimal units which avoids segmentation ambiguity. Different compositions of the same phrasal unit lead to exactly the same model score. We therefore do not create any alternative compositions of the same phrasal unit during decoding. This option is not available in phrase-based decoding, because an alternative composition may lead towards a better model score.

In our secondary set of experiments, we used cept-based decoding but modified the decoder to use information available from the phrases extracted for the test sentences. Firstly, we used future-cost estimates from the extracted phrases (see system cept.500.fc in Table1). This however, leads to inconsistency in the cases where the future cost is estimated from some phrasal unit that cannot be generated through the available cept translations. For example, say the best cost to cover the sequence “Wie hei\ssen Sie” is given by the phrase “What is your name”. The 20-best translation options in cept-based system, however, do not have tuples “Wie – What” and “hei\ssen – name”. To remove this discrepancy, we add all such tuples that are used in the extracted phrases, to the list of extracted cepts (system cept.500.fc.t). We also studied how much gain we obtain by only adding tuples from phrases and using cept-based future-cost estimates (system cept.500.t).

5.3 Evaluation Method

To evaluate our modifications we apply a simple strategy. We hold the model constant and change the search to use the baseline decoder, which uses minimal translation units, or the modified decoders that use phrasal information during decoding. The model parameters are optimized by running MERT (minimum error rate training) for the baseline decoder on the dev set. After we have the optimized weights, we run the baseline decoder and our modifications on the test. Note that because all the decoding runs use the same feature vector, the model

stays constant, only search changes. This allows us to compare different decoding runs, obtained using the same parameters, but different search strategies, in terms of model scores. We compute a search accuracy and translation quality for each run.

Search accuracy is computed by comparing translation hypotheses from the different decoding runs. We form a collection of the best scoring hypotheses by traversing through all the runs and selecting the sentences with highest model score. For each input sentence we select a single best scoring hypothesis. The best scoring hypothesis can be contributed from several runs. In this case all these runs will be given a credit for that particular sentence when computing the search accuracy. The search accuracy of a decoding run is defined as the percentage of hypotheses that were contributed from this run, when forming a list of best scoring hypotheses. For example, for a test set of 1000 sentences, the accuracy of a decoding run would be 30% if it was able to produce the best scoring hypothesis for 300 sentences in the test set. Translation quality is measured through BLEU (Papineni et al., 2002).

6 Experimental Setup

We initially experimented with two language pairs: German-to-English (G-E) and French-to-English (F-E). We trained our system and the baseline systems on most of the data⁶ made available for the translation task of the *Fourth Workshop on Statistical Machine Translation*.⁷ We used 1M bilingual sentences, for the estimation of the translation model and 2M sentences from the monolingual corpus (news commentary) which also contains the English part of the bilingual corpus. Word alignments are obtained by running GIZA++ (Och and Ney, 2003) with the grow-diag-final-and (Koehn et al., 2005) symmetrization heuristic. We follow the training steps described in Durrani et al. (2011), consisting of i) post-processing the alignments to remove discontinuous and unaligned target cepts, ii) conversion of bilingual alignments into operation sequences, iii) estimation of the n-gram language models.

⁶We did not use all the available data due to scalability issues. The scores reported are therefore well below those obtained by the systems submitted to the WMT evaluation series.

⁷<http://www.statmt.org/wmt09/translation-task.html>

6.1 Search Accuracy Results

We divided our evaluation into two halves. In the first half we carried out experiments to measure search accuracy and translation quality of our decoders against the baseline cept-based OSM (cept.500) that uses minimal translation units with a stack size of 500. We used the version of the cept-based OSM system that does not allow discontinuous⁸ source cepts. To increase the speed of the system we used a hard reordering limit of 15⁹, in the baseline decoder and our modifications, disallowing jumps that are beyond 15 words from the first open gap. For each extracted cept or phrase 10-best translation options are extracted.

Using phrases in search reduces the decoding speed. In order to make a fair comparison, both the phrase-based and the baseline cept-based decoders should be allowed to run for the same amount of time. We therefore reduced the stack size in the phrase-based decoder so that it runs in the same amount of time as the cept-based decoder. We found that using a stack size of 200¹⁰ for the phrase-based decoder was comparable in speed to using a stack-size of 500 in the cept-based decoding.

We first tuned the baseline on dev¹¹ to obtain an optimized weight vector. We then ran the baseline and our decoders as discussed in Section 5.2 on the dev-test. Then we repeated this experiment by tuning the weights with our phrase-based decoder (using a stack size of 100) and ran all the decoders again using the new weights.

Table 1 shows the average search accuracies and BLEU scores of the two experiments. Using phrases during decoding in the G-E experiments resulted in a statistically significant¹² 0.69 BLEU points gain comparing our best system phrase.200 with the baseline system cept.500. We mark a result as sig-

⁸Discontinuous source-side units did not lead to any improvements in (Durrani et al., 2011) and increased the decoding times by multiple folds. We also found these to be less useful.

⁹Imposing a hard reordering limit significantly reduced the decoding time and also slightly increased the BLEU scores.

¹⁰Higher stack sizes leads to improvement in model scores for both German-English and French-English and slight improvement of BLEU in the case of the former.

¹¹We used news-dev2009a as dev and news-dev2009b as dev-test and tuned the weights with Z-MERT (Zaidan, 2009).

¹²We use bootstrap resampling (Koehn, 2004b) to test our results against the baseline result.

System	German		French	
	Acc.	BLEU	Acc.	BLEU
Baseline System cept.stack-size				
cept.50	25.95%	19.50	42.10%	21.44
cept.100	30.04%	19.79	47.32%	21.70
cept.200	35.17%	19.98	51.47%	21.82
cept.500	41.56%	20.14	54.93%	21.87
Our Cept-based Decoders				
cept.500.fc	48.44%	20.52*	54.73%	21.86
cept.500.t	52.24%	20.34	67.95%	22.00
cept.500.fc.t	61.81%	20.53*	67.76%	21.96
Our Phrase-based Decoders				
phrase.50	58.88%	20.58*	80.83%	22.04
phrase.100	69.85%	20.73*	88.34%	22.13
phrase.200	79.71%	20.83*	92.93%	22.17*

Table 1: Search Accuracies (Acc.) and BLEU scores of the Baseline and Our Decoders with different Stack Sizes (fc = Future Cost Estimated from Phrases, t = Cept Translation Options enriched from Phrases)

nificant if the improvement shown by our decoder over the baseline decoder (cept.500) is significant at the $p \leq 0.05$ level, in both the runs. All the outputs that show statistically significant improvements over the baseline decoder (cept.500) in Table 1 are marked with an asterisk.

The search accuracy of our best system (phrase.200), in G-E experiments is roughly 80%, which means that 80% of the times the phrase-based decoder (using stack size 200) was able to produce the same model score or a better model score than the cept-based decoders (using a stack size of 500). Our F-E experiments also showed improvements in BLEU and model scores. The search accuracy of our best system phrase.200 is roughly 93% as compared with 55% in the baseline decoder (cept.500) giving a BLEU point gain of +0.30 over the baseline.

Our modifications to the cept-based decoder also showed improvements. We found that extending the cept translation table (cept.500.t) using phrases helps both in G-E and F-E experiments by extending the list of n-best translation options by 18% and 18.30% respectively. Using future costs estimated from phrases (cept.500.fc) improved both search accuracy and BLEU scores in G-E experiments, but does not lead to any improvements in the F-E experiments, as both BLEU and model scores drop slightly. We looked at a few examples where the

model score dropped and found that in these cases, the best scoring hypotheses are ranked very low earlier in the decoding and make their way to the top gradually in subsequent steps. A slight difference in the future-cost estimate prunes these hypotheses in one or the other decoder. We found future cost to be more critical in G-E than F-E experiments. This can be explained by the fact that more reordering is required in G-E and it is necessary to account for the reordering operations and jump-based features (gap-based penalties, reordering distance and gap-width) in the future-cost estimation. F-E on the other hand is largely monotonic except for a few short distance reorderings such as flipping noun and adjective.

6.2 Comparison with other Baseline Systems

In the second half of our evaluation we compared our best system phrase.200 with the baseline system cept.500, and other state-of-the-art phrase-based and N-gram-based systems on German-to-English, French-to-English, and Spanish-to-English tasks¹³. We used the official evaluation data (news-test sets) from the Statistical Machine Translation Workshops 2009-2011 for all three language pairs (German, Spanish and French). The feature weights for all the systems are tuned using the dev set news-dev2009a. We separately tune the baseline system (cept.500) and the phrase-based system (phrase.200) and do not hold the lambda vector constant like before.

Baseline Systems: We also compared our system with i) Moses (Koehn et al., 2007), ii) Phrasal¹⁴ (Cer et al., 2010), and iii) Ncode (Crego et al., 2011).

We used the default stack sizes of 100 for Moses¹⁵, 200 for Phrasal, 25 for Ncode (with 2^m stacks). A 5-gram English language model is used. Both phrase-based systems use 20-best phrases for translation, Ncode uses 25-best tuple translations. The training and test data for Ncode was tagged using *TreeTagger* (Schmid, 1994). All the baseline systems used lexicalized reordering model. A hard reordering limit¹⁶ of 6 words is used as a default in

¹³We did not include the results of Spanish in the previous section due to space limitations but these are similar to those of the French-to-English translation task.

¹⁴Phrasal provides two extensions to Moses: i) hierarchical reordering model (Galley and Manning, 2008) and ii) discontinuous phrases (Galley and Manning, 2010).

¹⁵Using stacks sizes from 200–1000 did not improve results.

¹⁶We tried to increase the distortion limit in the baseline sys-

both the baseline phrase-based systems. Amongst the other defaults we retained the hard source gap penalty of 15 and a target gap penalty of 7 in Phrasal. We provide Moses and Ncode with the same post-edited alignments¹⁷ from which we removed target-side discontinuities. We feed the original alignments to Phrasal because of its ability to learn discontinuous source and target phrases. All the systems use MERT for the optimization of the weight vector.

	M_s	P_d	N_c	C_{500}	P_{200}
German-to-English					
MT09	18.73*	19.00*	18.37*	19.06*	19.66

Table 2: Comparison on 3-Test Sets – M_s = Moses, P_d = Phrasal (Discontinuous Phrases), N_c = Ncode, C_{500} = Cepet.500, P_{200} = Phrase.200

Table 2 compares the performance of our phrase-based decoder against the baselines. Our system shows an improvement over all the baseline systems for the G-E pair, in 11 out of 12 cases in the F-E pair and in 8 out of 12 cases in the S-E language pair. We mark a baseline with “*” to indicate that our decoder shows an improvement over this baseline result which is significant at the $p \leq 0.05$ level.

7 Conclusion and Future Work

We proposed a combination of using a model based on minimal units and decoding with phrases. Modeling with minimal units enables us to learn local and non-local dependencies in a unified manner and avoid spurious segmentation ambiguities. However, using minimal units also in the search presents a significant challenge because of the poor translation coverage, inaccurate future-cost estimates and

temts to 15 (in G-E experiments) as used in our systems but the results dropped significantly in case of Moses and slightly for Phrasal so we used the default limits for both decoders.

¹⁷Using post-processed alignments gave slightly better results than the original alignments for these baseline systems. Details are omitted due to space limitation.

the pruning of the correct hypotheses. Phrase-based SMT on the other hand overcomes these drawbacks by using larger translation chunks during search. However, the drawback of the phrase-based model is the phrasal independence assumption, spurious ambiguity in segmentation and a weak mechanism to handle non-local reorderings. We showed that combining a model based on minimal units with phrase-based decoding can improve both search accuracy and translation quality. We also showed that the phrasal information can be indirectly used in cept-based decoding with improved results. We tested our system against the state-of-the-art phrase-based and N-gram-based systems, for German-to-English, French-to-English, and Spanish-to-English for three standard test sets. Our system showed statistically significant improvements over all the baseline systems in most of the cases. We have shown the benefits of using phrase-based search with a model based on minimal units. In future work, we would like to study whether a phrase-based system like Moses or Phrasal can profit from an OSM-style or N-gram-style feature. Feng et al. (2010) previously showed that adding a linearized source-side language model in a phrase-based system helped. It would also be interesting to study whether the insight of using minimal units for modeling and phrase-based search would hold for hierarchical SMT. Vaswani et al. (2011) recently showed that a Markov model over the derivation history of minimal rules can obtain the same translation quality as using grammars formed with composed rules.

Abstract

Standard phrase-based translation models do not explicitly model context dependence between translation units. As a result, they rely on large phrase pairs and target language models to recover contextual effects in translation. In this work, we explore n-gram models over Minimal Translation Units (MTUs) to explicitly capture contextual dependencies across phrase boundaries in the channel model. As there is no single best direction in which contextual information should flow, we explore multiple decomposition structures as well as dynamic bidirectional decomposition. The resulting models are evaluated in an intrinsic task of lexical selection for MT as well as a full MT system, through n-best reranking. These experiments demonstrate that additional contextual modeling does indeed benefit a phrase-based system and that the direction of conditioning is important. Integrating multiple conditioning orders provides consistent benefit, and the most important directions differ by language pair.

1 Introduction

The translation procedure of a classical phrase-based translation model (Koehn et al., 2003) first divides the input sentence into a sequence of phrases, translates each phrase, explores reorderings of these translations, and then scores the resulting candidates with a linear combination of models. Conventional models include phrase-based channel models that effectively model each phrase as a large unigram, reordering models, and target language models. Of these models, only the target language model

This research was conducted during the author’s internship at Microsoft Research

(and, to some weak extent, the lexicalized reordering model) captures some lexical dependencies that span phrase boundaries, though it is not able to model information from the source side. Larger phrases capture more contextual dependencies within a phrase, but individual phrases are still translated almost independently.

To address this limitation, several researchers have proposed bilingual n-gram Markov models (Marino et al., 2006) to capture contextual dependencies between phrase pairs. Much of their work is limited by the requirement “that the source and target side of a tuple of words are synchronized, i.e. that they occur in the same order in their respective languages” (Crego and Yvon, 2010).

For language pairs with significant typological divergences, such as Chinese-English, it is quite difficult to extract a synchronized sequence of units; in the limit, the smallest synchronized unit may be the whole sentence. Other approaches explore incorporation into syntax-based MT systems or replacing the phrasal translation system altogether.

We investigate the addition of MTUs to a phrasal translation system to improve modeling of context and to provide more robust estimation of long phrases. However, in a phrase-based system there is no single synchronized traversal order; instead, we may consider the translation units in many possible orders: left-to-right or right-to-left according to either the source or the target are natural choices. Alternatively we consider translating a particularly unambiguous unit in the middle of the sentence and building outwards from there. We investigate both consistent and dynamic decomposition orders in several language pairs, looking at distinct orders in isolation and combination.

2 Related work

Marino et al. (2006) proposed a translation model using a Markov model of bilingual n-grams, demonstrating state-of-the-art performance compared to conventional phrase-based models. Crego and Yvon (2010) further explored factorized n-gram approaches, though both models considered rather large n-grams; this paper focuses on small units with asynchronous orders in source and target. Durrani et al. (2011) developed a joint model that captures translation of contiguous and gapped units as well as reordering. Two prior approaches explored similar models in syntax based systems. MTUs have been used in dependency translation models (Quirk and Menezes, 2006) to augment syntax directed translation systems. Likewise in target language syntax systems, one can consider Markov models over minimal rules, where the translation probability of each rule is adjusted to include context information from parent rules (Vaswani et al., 2011).

Most prior work tends to replace the existing probabilities rather than augmenting them. We believe that Markov rules provide an additional signal but are not a replacement. Their distributions should be more informative than the so-called “lexical weighting” models, and less sparse than relative frequency estimates, though potentially not as effective for truly non-compositional units. Therefore, we explore the inclusion of all such information. Also, unlike prior work, we explore combinations of multiple decomposition orders, as well as dynamic decompositions. The most useful context for translation differs by language pair, an important finding when working with many language pairs.

We build upon a standard phrase-based approach (Koehn et al., 2003). This acts as a proposal distribution for translations; the MTU Markov models provide additional signal as to which translations are correct.

3 MTU n-gram Markov models

We begin by defining Minimal Translation Units (MTUs) and describing how to identify them in word-aligned text. Next we define n-gram Markov models over MTUs, which requires us to define traversal orders over MTUs.

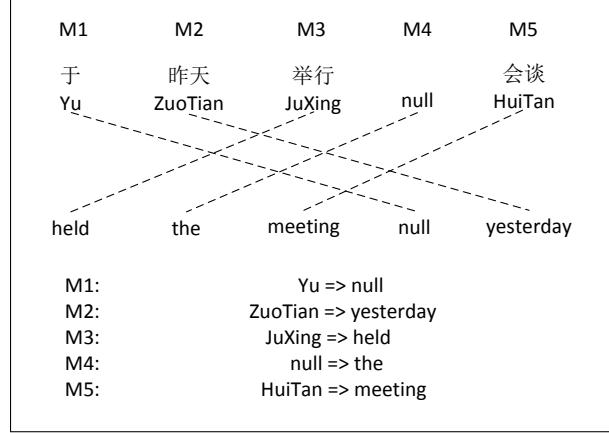

Figure 1: Word alignment and minimum translation units.

3.1 Definition of an MTU

Informally, the notion of a minimal translation unit is simple: it is a translation rule that cannot be broken down any further without violating the constraints of the rules. We restrict ourselves to *contiguous* MTUs. They are similar to small phrase pairs, though unlike phrase pairs we allow MTUs to have either an empty source or empty target side, thereby allowing insertion and deletion phrases. Conventional phrase pairs may be viewed as compositions of these MTUs up to a given size limit.

Consider a word-aligned sentence pair consisting of a sequence of source words $s = s_1 \dots s_m$, a sequence of target words $t = t_1 \dots t_n$, and a word alignment relation between the source and target words $\sim \subseteq \{1..m\} \times \{1..n\}$. A translation unit is a sequence of source words $s_i..s_j$ and a sequence of target words $t_k..t_l$ (one of which may be empty) such that for all aligned pairs $i' \sim k'$, we have $i \leq i' \leq j$ if and only if $k \leq k' \leq l$. This definition, nearly identical to that of a phrase pair (Koehn et al., 2003), relaxes the constraint that one aligned word must be present.

A set of translation units is a partition of the sentence pair if each source and target word is covered exactly once. *Minimal translation units* is the partition with the smallest average unit size, or, equivalently, the largest number of units. For example, Figure 1 shows a word-aligned sentence pair and its corresponding set of MTUs. We extract these minimal translation units with an algorithm similar to that of phrase extraction.

We train n-gram Markov models only over min-

imal rules for two reasons. First, the segmentation of the sentence pair is not unique under composed rules, which makes probability estimation complicated. Second, some phrase pairs are very large, which results in sparse data issues and compromises the model quality. Therefore, training an n-gram model over minimal translation units turns out to be a simple and clean choice: the resulting segmentation is unique, and the distribution is smooth. If we want to capture more context, we can simply increase the order of the Markov model.

Such Markov models address issues in large phrase-based translation approaches. Where standard phrase-based models rely upon large unigrams to capture contextual information, n-grams of minimal translation units allow a robust contextual model that is less constrained by segmentation.

3.2 MTU enumeration orders

When defining a joint probability distribution over MTUs of an aligned sentence pair, it is necessary to define a decomposition, or generation order for the sentence pair. For a single sequence in language modeling or synchronized sequences in channel modeling, the default enumeration order has been left-to-right.

Different decomposition orders have been used in part-of-speech tagging and named entity recognition (Tsuruoka and Tsujii, 2005). Intuitively, information from the left or right could be more useful for particular disambiguation choices. Our research on different decomposition orders was motivated by this work. When applying such ideas to machine translation, there are additional challenges and opportunities. The task exhibits much more ambiguity – the number of possible MTUs is in the millions. An opportunity arises from the reordering phenomenon in machine translation: while in POS tagging the natural decomposition orders to study are only left-to-right and right-to-left, in machine translation we can further distinguish source and target sentence orders.

We first define the source left-to-right and the target left-to-right orders of the aligned sets of MTUs. The definition is straightforward when there are no inserted or deleted word. To place the nulls corresponding to such word we use the following definition: the source position of the null for a target

inserted word is just after the position of the last source word aligned to the closest preceding non-null aligned target word. The target position for a null corresponding to a source deleted MTU is defined analogously. In Figure 1 we define the position of M4 to be right after M3 (because “the” is after “held” in left-to-right order on the target side).

The complete MTU sequence in source left-to-right order is M1-M2-M3-M4-M5. The sequence in target left-to-right order is M3-M4-M5-M1-M2. This illustrates that decomposition structure may differ significantly depending on which language is used to define the enumeration order.

Once a sentence pair is represented as a sequence of MTUs, we can define the probability of the sentence pair using a conventional n-gram Markov model (MM) over MTUs. For example, the 3-gram MM probability of the sentence pair in Figure 1 under the source left-to-right order is as follows:

$$P(M1) \cdot P(M2|M1) \cdot P(M3|M1, M2) \cdot P(M4|M2, M3) \cdot P(M5|M3, M4)$$

Different decomposition orders use different context for disambiguation and it is not clear apriori which would perform best. We compare all four decomposition orders (source order left-to-right and right-to-left, and target order left-to-right and right-to-left). Although the independence assumptions of left-to-right and right-to-left are the same, the resulting models may be different due to smoothing.

In addition to studying these four basic decomposition orders, we report performance of two cyclic orders: cyclic in source or target sentence order. These models are inspired by the cyclic dependency network model proposed for POS tagging (Toutanova et al., 2003) and also used as a baseline in previous work on dynamic decomposition orders (Tsuruoka and Tsujii, 2005).¹

The probability according to the cyclic orders is defined by conditioning each MTU on both its left and right neighbor MTUs. For example, the probability of the sentence pair in Figure 1 under the source cyclic order, using a 3-gram model is defined as:

$$P(M1|M2) \cdot P(M2|M1, M3) \cdot P(M3|M2, M4) \cdot P(M4|M3, M5) \cdot P(M5|M4)$$

All n-gram Markov models over MTUs are esti-

¹The correct application of such models requires sampling to find the highest scoring sequence, but we apply the max product approximation as done in previous work.

mated using Kneser-Ney smoothing. Each MTU is treated as an atomic unit in the vocabulary of the n-gram model. Counts of all n-grams are obtained from the parallel MT training data, using different MTU enumeration orders.

Note that if we use a target-order decomposition, the model provides a distribution over target sentences and the corresponding source sides of MTUs, albeit unordered. Likewise source order based models provide distributions over source sentences and unordered target sides of MTUs. We attempted to introduce reordering models to predict an order over the resulting MTU sequences using approaches similar to reordering models for phrases. Although these models produced gains in some language pairs when used without translation MTU MMs, there were no additional gains over a model using multiple translation MTU MMs.

4 Lexical selection

We perform an empirical evaluation of different MTU decomposition orders on a simplified machine translation task: lexical selection. In this task we assume that the source sentence segmentation into minimal translation units is given and that the order of the corresponding target sides of the minimal translation units is also given. The problem is to predict the target sides of the MTUs, called target MTUs for brevity (see Figure 2). The lexical selection task is thus similar to sequence tagging tasks like part-of-speech tagging, though much more difficult: the predicted variables are sequences of target language words with millions of possible outcomes.

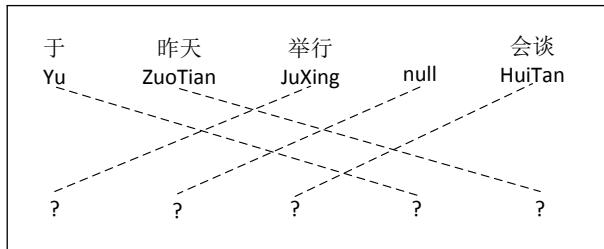

Figure 2: Lexical selection.

We use this constrained MT setting to evaluate the performance of models using different MTU decomposition orders and models using combinations of decomposition orders. The simplified setting allows

controlled experimentation while lessening the impact of complicating factors in a full machine translation setting (search error, reordering limits, phrase table pruning, interaction with other models).

To perform the tagging task, we use trigram MTU models. The four basic decomposition orders for MTU Markov models we use are left-to-right in target sentence order, right-to-left in target sentence order, left-to-right in source sentence order, and right-to-left in source sentence order. We also consider cyclic orders in source and target.

Regardless of the decomposition order used, we perform decoding using a beam search decoder, similar to ones used in phrase-based machine translation. The decoder builds target hypotheses in left-to-right target sentence order. At each step, it fills in the translation of the next source MTU, in the context of the already predicted MTUs to its left. The top scoring complete hypotheses covering the first m MTUs are maintained in a beam. When scoring with a target left-to-right MTU Markov model (L2RT), we can score each partial hypothesis exactly at each step. When scoring using a R2LT model or a source order model, we use lower-order approximations to the trigram MTU Markov model scores as future scores, since not all needed context is available for a hypothesis at the time of construction. As additional context becomes available, the exact score can be computed.²

4.1 Basic decomposition order combinations

We first introduce two methods of combining different decomposition orders: *product* and *system combination*.

The *product* method arises naturally in the machine translation setting, where probabilities from different models are multiplied together and further weighted to form the log-linear model for machine translation (Och and Ney, 2002). We define a similar scoring function using a set of MTU Markov models MM_1, \dots, MM_k for a hypothesis h as follows:

$$\text{Score}(h) = \lambda_1 \log P_{MM_1}(h) + \dots + \lambda_k \log P_{MM_k}(h)$$

²We apply hypothesis recombination, which can merge hypotheses that are indistinguishable with respect to future continuations. This is similar to recombination in a standard-phrase based decoder with the difference that it is not always the last two target MTUs that define the context needed by future extensions.

The weights λ of different models are trained on a development set using MER training to maximize the BLEU score of the resulting model. Note that this method of model combination was not considered in any of the previous works comparing different decompositions.

The *system combination* method is motivated by prior work in machine translation which combined left-to-right and right-to-left machine translation systems (Finch and Sumita, 2009). Similarly, we perform sentence-level system combination between systems using different MTU Markov models to come up with most likely translations. If we have k systems guessing hypotheses based on MM_1, \dots, MM_k respectively, we generate 1000-best lists from each system, resulting in a pool of up to $1000k$ possible distinct translations. Each of the candidate hypotheses from MM_i is scored with its Markov model log-probability $\log P_{MM_i}(h)$. We compute normalized probabilities for each system's n -best by exponentiating and normalizing: $P_i(h) \propto P_{MM_i}(h)$. If a hypothesis h is not in system i 's n -best list, we assume its probability is zero according to that system. The final scoring function for each hypothesis in the combined list of candidates is:

$$\text{Score}(h) = \lambda_1 P_1(h) + \dots + \lambda_k P_k(h)$$

The weights λ for the combination are tuned using MERT as for the product model.

4.2 Dynamic decomposition orders

A more complex combination method chooses the best possible decomposition order for each translation dynamically, using a set of constraints to define the possible decomposition orders, and a set of features to score the candidate decompositions. We term this method *dynamic combination*. The score of each translation is defined as its score according to the highest-scoring decomposition order for that translation.

This method is very similar to the bidirectional tagging approach of Tsuruoka and Tsujii (2005). For this approach we only explored combinations of target language orders (L2RT, CycT, and R2LT). If source language orders were included, the complexity of decoding would increase substantially.

Figure 3 shows two possible decompositions for a short MTU sequence. The structures displayed are

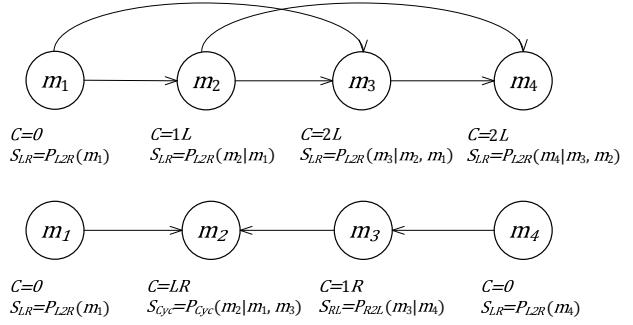

Figure 3: Different decompositions.

directed graphical models. They define the set of parents (context) used to predict each target MTU. The decomposition structures we consider are limited to acyclic graphs where each node can have one of the following parent configurations: no parents ($C = 0$ in the Figure), one left parent ($C = 1L$), one right parent ($C = 1R$), one left and one right parent ($C = LR$), two left parents ($C = 2L$), and two right parents ($C = 2R$). If all nodes have two left parents, we recover the left-to-right decomposition order, and if all nodes have two right parents, the right-to-left decomposition order. A mixture of parent configurations defines a mixed, dynamic decomposition order. The decomposition order chosen varies from translation to translation.

A directed graphical model defines the probability of an assignment of MTUs to the variable nodes as a product of local probabilities of MTUs given their parents. Here we extend this definition to scores of assignments by using a linear model with configuration features and log-probability features. The configuration features are indicators of which parent configuration is active at a node and the settings of these features for the decompositions in Figure 3 are shown as assignments to the C variables. The log-probability feature values are obtained by querying the appropriate n-gram model: L2RT, CycT, or R2LT. For a node with one or two left parents, the log-probability is computed according to the L2RT model. For a node with one or two right parents, the R2LT model is queried. The CycT model is used for nodes with one left and one right parent.

To find the best translation of a sentence the model now searches over hidden decomposition or-

ders in addition to assignments to target MTUs. The final score of a translation and decomposition is a linear combination of the two types of feature values – model log-probabilities and configuration types. There is one feature weight for each parent configuration (six configuration weights) and one feature weight for each component model (three model weights). The final score of the second decomposition and assignment in Figure 3 is:

$$\begin{aligned} \text{Score}(h) &= 2 * w_{C_0} + w_{C_{LR}} + w_{C_{1R}} \\ &+ w_{L2R} \log P_{LR}(m_1) + w_{Cyc} \log P_{Cyc}(m_2|m_1, m_3) \\ &+ w_{R2L} \log P_{RL}(m_3|m_4) + w_{L2R} \log P_{LR}(m_4) \end{aligned}$$

There are two main differences between our approach and that of Tsuruoka and Tsujii (2005): we perform beam search with hypothesis recombination instead of exact decoding (due to the larger size of the hypothesis set), and we use parameters to be able to globally weight the probabilities from different models and to develop preferences for using certain types of decompositions. For example, the model can learn to prefer right-to-left decompositions for one language pair, and left-to-right decompositions for another. An additional difference from prior work is the definition of the possible decomposition orders that are searched over.

Compared to the structures allowed in (Tsuruoka and Tsujii, 2005) for a trigram baseline model, our allowed structures are a subset; in (Tsuruoka and Tsujii, 2005) there are sixteen possible parent configurations (up to two left and two right parents), whereas we allow only six. We train and use only three n-gram Markov models to assign probabilities: L2RT, R2LT, and CycT, whereas the prior work used sixteen models. One could potentially see additional gains from considering a larger space of structures but the training time and runtime memory requirements might become prohibitive for the machine translation task.

Because of the maximization over decomposition structures, the score of a translation is not a simple linear function of the features, but rather a maximum over linear functions. The score of a translation for a fixed decomposition is a linear function of the features, but the score of a translation is a maximum of linear functions (over decompositions). Therefore,

if we define hypotheses as just containing translations, MERT training does not work directly for optimizing the weights of the dynamic combination method.³ We used a combination of approaches; we did MERT training followed by local simplex-method search starting from three starting points: the MERT solution, a weight vector that strongly prefers left-to-right decompositions, and a weight-vector that strongly prefers right-to-left decompositions. In the Experiments section, we report results for the weights that achieved the best development set performance.

5 N-best reranking

To evaluate the impact of these models in a full MT system, we investigate n-best reranking. We use a phrase-based MT system to output 1000-best candidate translations. For each candidate translation, we have access to the phrase pairs it used as well as the alignments inside each phrase pair. Thus, each source sentence and its candidate translation form a word-aligned parallel sentence pair. We can extract MTU sequences from this sentence pair and compute its probability according to MTU Markov models. These MTU MM log-probabilities are appended to the original MT features and used to rerank the 1000-best list. The weight vectors for systems using the original features along with one or more MTU Markov model log-probabilities are trained on the development set using MERT.

6 Experiments

We report experimental results on the lexical selection task and the reranking task on three language pairs. The datasets used for the different languages are described in detail in Section 6.2.

6.1 Lexical selection experiments

The data used for the lexical selection experiments consists of the training portion of the datasets used for MT. These training sets are split into three sections: - , for training MTU Markov models and extracting possible translations for each source

³If we include the decompositions in the hypotheses we could use MERT but then the n-best lists used for training might not contain much variety in terms of translation options. This is an interesting direction for future research.

Table 1: Lexical selection results for individual MTU Markov models.

MTU, - for tuning combination weights for systems using several MTU MMs, and - , for final evaluation results. The possible translations for each source MTU are defined as the most frequent 100 translations seen in - . The - sets contain 200 sentence pairs each and the - sets contains 1000 sentence pairs each. These development and test sets consist of equally spaced sentences taken from the full MT training sets.

We start by reporting BLEU scores of the six individual MTU MMs on the three language pairs in Table 1. The baseline predicts the most frequent target MTU for each source MTU (unigram MM not using context). The oracle looks at the correct translation and always chooses the correct target MTU if it is in the vocabulary of available MTUs.

We can see that there is a large difference between the baseline and oracle performance, underscoring the importance of modeling context for accurate prediction. The best decomposition order varies from language to language: right-to-left in source order is best for Chinese-English, right-to-left in target order is best for German-English and left-to-right or right-to-left in target order are best in English-Bulgarian. We computed statistical significance tests, testing the difference between the L2RT model (the standard in prior work) and models achieving higher test set performance. The models that are significantly better at significance $\alpha < 0.01$ are marked with a star in the table. We used a paired bootstrap test with 10,000 trials (Koehn, 2004).

Next we evaluate the methods for combining decomposition orders introduced in Sections 4.1 and 4.2. The results are reported in Table 2. The upper part of the table focuses on combining different

Model	Chs-En		Deu-En		En-Bgr	
	Dev	Test	Dev	Test	Dev	Test
Baseline-1	24.04	25.09	30.14	30.14	49.86	46.45
TgtProduct	25.27	25.84*	30.47	30.49	51.04	47.27*
TgtSysComb	24.49	25.27	30.20	30.15	50.46	46.31
TgtDynamic	24.07	25.10	30.60	30.41	49.99	46.52
Baseline-2	26.48	27.96	30.14	30.14	49.86	46.45
AllProduct	28.68	29.59*	31.54	31.36*	51.50	48.10*
AllSyscomb	27.02	28.30	30.20	30.17	50.90	46.53

Table 2: Lexical selection results for combinations of MTU Markov models.

target-order decompositions. The lower part of the table looks at combining all six decomposition orders. The baseline for the target order combinations, Baseline-1, is the best single target MTU Markov model from Table 1. Baseline-2 in the lower part of the table is the best individual model out of all six. We can see that the product models TgtProduct (a product of the three target-order MTU MMs) and AllProduct (a product of all six MTU MMs) are consistently best. The dynamic decomposition models TgtDynamic achieve slight but not significant gains over the baseline. The combination models that are statistically significantly better than corresponding baselines ($\alpha < 0.01$) are marked with a star.

Our takeaway from these experiments is that multiple decomposition orders are good, and thus taking a product (which encourages agreement among the models) is a good choice for this task. The dynamic decomposition method shows some promise, but it does not outperform the simpler product approach. Perhaps a larger space of decompositions would achieve better results, especially given a larger parameter set to trade off decompositions and better tuning for those parameters.

6.2 Datasets and reranking settings

For Chinese-English, the training corpus consists of 1 million sentence pairs from the FBIS and HongKong portions of the LDC data for the NIST MT evaluation. We used the union of the NIST 2002 and 2003 test sets as the development set and the NIST 2005 test set as our test set. The baseline phrasal system uses a 5-gram language model with modified Kneser-Ney smoothing (Kneser and Ney, 1995), trained on the Xinhua portion of the English Gigaword corpus (238M English words).

For German-English we used the dataset from

Language	Training	Dev	Test
Chs-En	1 Mln	NIST02+03	NIST05
Deu-En	751 K	WMT06dev	WMT06test
En-Bgr	4 Mln	1,497	2,498

Table 3: Data sets for different language pairs.

the WMT 2006 shared task on machine translation (Koehn and Monz, 2006). The parallel training set contains approximately 751K sentences. We also used the English monolingual data of around 1 million sentences for language model training. The development set contains 2000 sentences. The final test set (the in-domain test set for the shared task) also contains 2000 sentences. Two Kneser-Ney language models were used as separate features: a 4-gram LM trained on the parallel portion of the data, and a 5-gram LM trained on the monolingual corpus.

For English-Bulgarian we used a dataset containing sentences from several data sources: JRC-Acquis (Steinberger et al., 2006), TAUS⁴, and web-scraped data. The development set consists of 1,497 sentences, the English side from WMT 2009 news test data, and the Bulgarian side a human translation thereof. The test set comes from the same mixture of sources as the training set. For this system we used a single four-gram target language model trained on the target side of the parallel corpus.

All systems used phrase tables with a maximum length of seven words on either side and lexicalized reordering models. For the Chinese-English system we used GIZA++ alignments, and for the other two we used alignments by an HMM model augmented with word-based distortion (He, 2007). The alignments were symmetrized and then combined with the heuristics "grow-diag-final-and".⁵ We tune parameters using MERT (Och, 2003) with random restarts (Moore and Quirk, 2008) on the development set. Case-insensitive BLEU-4 is our evaluation metric (Papineni et al., 2002).

Table 4: Reranking with 3-gram and 5-gram MTU translation models on Chinese-English. Starred results on the test set indicate significantly better performance than the baseline.

6.3 MT reranking experiments

We first report detailed experiments on Chinese-English, and then verify our main conclusions on the other language pairs. Table 4 looks at the impact of individual 3-gram and 5-gram MTU Markov models and their combination. Amongst the decomposition orders tested (L2RT, R2LT, L2RS, and R2LS), each of the individual MTU MMs was able to achieve significant improvement over the baseline, around 1 BLEU point.⁶ The results achieved by the individual models differ, and the combination of four directions is better than the best individual direction, but the difference is not statistically significant.

We ran an additional experiment to test whether MTU MMs make effective use of context across phrase boundaries, or whether they simply provide better smoothed estimates of phrasal translation probabilities. The last row of the table reports the results achieved by a combination of MTU MMs that do not use context across the phrasal boundaries. Since an MTU MM limited to look only inside phrases can provide improved smoothing compared to whole phrase relative frequency counts, it is conceivable it could provide a large improvement. However, there is no improvement in practice for this language pair; the additional improvements from MTU MMs stem from modeling cross-phrase context.

⁴www.tausdata.org

⁵The combination heuristic was further refined to disallow crossing one-to-many alignments, which would result in the extraction of larger minimum translation units. We found that this further refinement on the combination heuristic consistently improved the BLEU scores by between 0.3 and 0.7.

⁶Here again we call a difference significant if the paired bootstrap p -value is less than 0.01.

Table 5 shows the test set results of individual 3-gram MTU Markov models and the combination of 3-gram and 5-gram models on the English-Bulgarian and German-English datasets. For English-Bulgarian all individual 3-gram Markov models achieve significant improvements of close to one point; their combination is better than the best individual model (but not significantly). The individual 5-gram models and their combination bring much larger improvement, for a total increase of 2.82 points over the baseline. We believe the 5-gram models were more effective in this setting because the larger training set allowed for successful training of models of larger capacity. Also the increased context size helps to resolve ambiguity in the forms of morphologically-rich Bulgarian words. For German-English we see a similar pattern, with the combination of models outperforming the individual ones, and the 5-gram models being better than the 3-gram. Here the individual 3-gram models are better than the baseline at significance level 0.02 and their combination is better than the baseline at our earlier defined threshold of 0.01. The within-phrase MTU MMs (results shown in the last two rows) improve upon the baseline slightly, but here again the improvements mostly stem from the use of context across phrase boundaries. Our final results on German-English are better than the best result of 27.30 from the shared task (Koehn and Monz, 2006).

Thanks to the reviewers for referring us to recent work by (Clark et al., 2011) that pointed out problems with significance tests for machine translation, where the randomness and local optima in the MERT weight tuning method lead to a large variance in development and test set performance across different runs of optimization (using a different random seed or starting point). (Clark et al., 2011) proposed a stratified approximate randomization statistical significance test, which controls for optimizer instability. Using this test, for the English-Bulgarian system, we confirmed that the combination of four 3-gram MMs and the combination of 5-gram MMs is better than the baseline ($p = .0001$ for both, using five runs of parameter tuning). We have not run the test for the other language pairs.

Model	En-Bgr	Deu-En
Baseline	45.75	27.92
L2RT 3-gram	47.07*	28.15

4 3-gram	47.17*	28.37*
4 5-gram	48.57*	28.47*
4 3-gram phrs	46.08	27.92
4 5-gram phrs	46.17*	27.93

Table 5: English-Bulgarian and German-English test set results: reranking with MTU translation models.

7 Conclusions

We introduced models of Minimal Translation Units for phrasal systems, and showed that they make a substantial and statistically significant improvement on three distinct language-pairs. Additionally we studied the importance of decomposition order when defining the probability of MTU sequences. In a simplified lexical selection task, we saw that there were large differences in performance among the different decompositions, with the best decompositions differing by language. We investigated multiple methods to combine decompositions and found that a simple product approach was most effective. Results in the lexical selection task were consistent with those obtained in a full MT system, although the differences among decompositions were smaller.

In future work, perhaps we would see larger gains by including additional decomposition orders (e.g., top-down in a dependency tree), and taking this idea deeper into the machine translation model, down to the word-alignment and language-modeling levels.

We were surprised to find n-best reranking so effective. We are incorporating the models into first pass decoding, in hopes of even greater gains.

Improved Reordering for Phrase-Based Translation using Sparse Features

Colin Cherry

National Research Council Canada

Colin.Cherry@nrc-cnrc.gc.ca

Abstract

There have been many recent investigations into methods to tune SMT systems using large numbers of sparse features. However, there have not been nearly so many examples of helpful sparse features, especially for phrase-based systems. We use sparse features to address reordering, which is often considered a weak point of phrase-based translation. Using a hierarchical reordering model as our baseline, we show that simple features coupling phrase orientation to frequent words or word-clusters can improve translation quality, with boosts of up to 1.2 BLEU points in Chinese-English and 1.8 in Arabic-English. We compare this solution to a more traditional maximum entropy approach, where a probability model with similar features is trained on word-aligned bitext. We show that sparse decoder features outperform maximum entropy handily, indicating that there are major advantages to optimizing reordering features directly for BLEU with the decoder in the loop.

1 Introduction

With the growing adoption of tuning algorithms that can handle thousands of features (Chiang et al., 2008; Hopkins and May, 2011), SMT system designers now face a choice when incorporating new ideas into their translation models. Maximum likelihood models can be estimated from large word-aligned bitexts, creating a small number of highly informative decoder features; or the same ideas can be incorporated into the decoder’s linear model directly. There are trade-offs to each approach. Maximum likelihood models can be estimated from millions of sentences of bitext, but optimize a mismatched objective, predicting events observed in

word aligned bitext instead of optimizing translation quality. Sparse decoder features have the opposite problem; with the decoder in the loop, we can only tune on small development sets,¹ but a translation error metric directly informs training.

We investigate this trade-off in the context of reordering models for phrase-based decoding. Starting with the intuition that most lexicalized reordering models do not smooth their orientation distributions intelligently for low-frequency phrase-pairs, we design features that track the first and last words (or clusters) of the phrases in a pair. These features are incorporated into a maximum entropy reordering model, as well as sparse decoder features, to see which approach best complements the now-standard relative-frequency lexicalized reordering model.

We also view our work as an example of strong sparse features for phrase-based translation. Features from hierarchical and syntax-based translation (Chiang et al., 2009) do not easily transfer to the phrase-based paradigm, and most work that has looked at large feature counts in the context of phrase-based translation has focused on the learning method, and not the features themselves (Hopkins and May, 2011; Cherry and Foster, 2012; Gimpeł and Smith, 2012). We show that by targeting reordering, large gains can be made with relatively simple features.

2 Background

Phrase-based machine translation constructs its target sentence from left-to-right, with each translation operation selecting a source phrase and appending its translation to the growing target sentence, until

¹Some systems tune for BLEU on much larger sets (Simianer et al., 2012; He and Deng, 2012), but these require exceptional commitments of resources and time.

all source words have been covered exactly once. The first phrase-based translation systems applied only a distortion penalty to model reordering (Koehn et al., 2003; Och and Ney, 2004). Any deviation from monotone translation is penalized, with a single linear weight determining how quickly the penalty grows.

2.1 Lexicalized Reordering

Implemented in a number of phrase-based decoders, the lexicalized reordering model (RM) uses word-aligned data to determine how each phrase-pair tends to be reordered during translation (Tillmann, 2004; Koehn et al., 2005; Koehn et al., 2007).

The core idea in this RM is to divide reordering events into three orientations that can be easily determined both during decoding and from word-aligned data. The orientations can be described in terms of the previously translated source phrase (*prev*) and the next source phrase to be translated (*next*):

- Monotone (M): *next* immediately follows *prev*.
- Swap (S): *prev* immediately follows *next*.
- Discontinuous (D): *next* and *prev* are not adjacent in the source.

Note that *prev* and *next* can be defined for constructing a translation from left-to-right or from right-to-left. Most decoders incorporate RMs for both directions; our discussion will generally only cover left-to-right, with the right-to-left case being implicit and symmetrical.

As the decoder extends its hypothesis by translating a source phrase, we can assess the implied orientations to determine if the resulting reordering makes sense. This is done using the probability of an orientation given the phrase pair $pp = [src, tgt]$ extending the hypothesis:²

$$P(o|pp) \approx \frac{cnt(o, pp)}{\sum_o cnt(o, pp)} \quad (1)$$

where $o \in \{M, S, D\}$, cnt uses simple heuristics on word-alignments to count phrase pairs and their orientations, and the \approx symbol allows for smoothing. The log of this probability is easily folded into the linear models that guide modern decoders. Better

² pp corresponds to the phrase pair translating *next* for the left-to-right model, and *prev* for right-to-left.

performance is achieved by giving each orientation its own log-linear weight (Koehn et al., 2005).

2.2 Hierarchical Reordering

Introduced by Galley and Manning (2008), the hierarchical reordering model (HRM) also tracks statistics over orientations, but attempts to increase the consistency of orientation assignments. To do so, they remove the emphasis on the previously translated phrase (*prev*), and instead determine orientation using a compact representation of the full translation history, as represented by a shift-reduce stack. Each source span is shifted onto the stack as it is translated; if the new top is adjacent to the span below it, then a reduction merges the two.

Orientations are determined in terms of the top of this stack,³ rather than the previously translated phrase *prev*. The resulting orientations are more consistent across different phrasal decompositions of the same translation, and more consistent with the statistics extracted from word aligned data. This results in a general improvement in performance. We assume the HRM as our baseline reordering model.

It is important to note that although our maximum entropy and sparse reordering solutions build on the HRM, the features in this paper can still be applied without a shift-reduce stack, by using the previously translated phrase where we use the top of the stack.

2.3 Maximum Entropy Reordering

One frequent observation regarding both the RM and the HRM is that the statistics used to grade orientations are very sparse. Each orientation prediction $P(o|pp)$ is conditioned on an entire phrase pair. Koehn et al. (2005) experiment with alternatives, such as conditioning on only the source or the target, but using the entire pair generally performs best. The vast majority of phrase pairs found in bitext with standard extraction heuristics are singletons (more than 92% in our Arabic-English bitext), and the corresponding $P(o|pp)$ estimates are based on a single observation. Because of these heavy tails, there have been several attempts to use maximum entropy to create more flexible distributions.

One straight-forward way to do so is to continue predicting orientations on phrases, but to use maxi-

³In the case of the right-to-left model, an approximation of the top of the stack is used instead.

mum entropy to consider features of the phrase pair. This is the approach taken by Xiong et al. (2006); their maximum entropy model chooses between M and S orientations, which are the only two options available in their chart-based ITG decoder. Nguyen et al. (2009) build a similar model for a phrase-based HRM, using syntactic heads and constituent labels to create a rich feature set. They show gains over an HRM baseline, albeit on a small training set.

A related approach is to build a reordering model over words, which is evaluated at phrase boundaries at decoding time. Zens and Ney (2006) propose one such model, with jumps between words binned very coarsely according to their direction and distance, testing models that differentiate only left jumps from right, as well as the cross-product of {left, right} \times {adjacent, discontinuous}. Their features consider word identity and automatically-induced clusters. Green et al. (2010) present a similar approach, with finer-grained distance bins, using word-identity and part-of-speech for features. Yahyaei and Monz (2010) also predict distance bins, but use much more context, opting to look at both sides of a reordering jump; they also experiment with hard constraints based on their model.

Tracking word-level reordering simplifies the extraction of complex models from word alignments; however, it is not clear if it is possible to enhance a word reordering model with the stack-based histories used by HRMs. In this work, we construct a phrase orientation maximum entropy model.

3 Methods

Our primary contribution is a comparison between the standard HRM and two feature-based alternatives. Since a major motivating concern is smoothing, we begin with a detailed description of our HRM baseline, followed by our maximum entropy HRM and our novel sparse reordering features.

3.1 Relative Frequency Model

The standard HRM uses relative frequencies to build smoothed maximum likelihood estimates of orientation probabilities. Orientation counts for phrase pairs are collected from bitext, using the method described by Galley and Manning (2008). The probability model $P(o|pp = [src, tgt])$ is estimated using

recursive MAP smoothing:

$$\begin{aligned} P(o|pp) &= \frac{cnt(o, pp) + \alpha_s P_s(o|src) + \alpha_t P_t(o|tgt)}{\sum_o cnt(o, pp) + \alpha_s + \alpha_t} \\ P_s(o|src) &= \frac{\sum_{tgt} cnt(o, src, tgt) + \alpha_g P_g(o)}{\sum_{o,tgt} cnt(o, src, tgt) + \alpha_g} \\ P_t(o|tgt) &= \frac{\sum_{src} cnt(o, src, tgt) + \alpha_g P_g(o)}{\sum_{o,src} cnt(o, src, tgt) + \alpha_g} \\ P_g(o) &= \frac{\sum_{pp} cnt(o, pp) + \alpha_u / 3}{\sum_{o,pp} cnt(o, pp) + \alpha_u} \end{aligned} \quad (2)$$

where the various α parameters can be tuned empirically. In practice, the model is not particularly sensitive to these parameters.⁴

3.2 Maximum Entropy Model

Next, we describe our implementation of a maximum entropy HRM. Our goal with this system is to benefit from modeling features of a phrase pair, while keeping the system architecture as simple and replicable as possible. To simplify training, we learn our model from the same orientation counts that power the relative-frequency HRM. To simplify decoder integration, we limit our feature space to information from a single phrase pair.

In a maximum entropy model, the probability of an orientation o given a phrase pair pp is given by a log-linear model:

$$P(o|pp) = \frac{\exp(w \cdot f(o, pp))}{\sum_{o'} \exp(w \cdot f(o', pp))} \quad (3)$$

where $f(o, pp)$ returns features of a phrase-pair, and w is the learned weight vector. We build two models, one for left-to-right translation, and one for right-to-left. As with the relative frequency model, we limit our discussion to the left-to-right model, with the other direction being symmetrical.

We construct a training example for each unique phrase-pair type (as opposed to token) found in our bitext. We use the orientation counts observed for a phrase pair pp_i to construct its example weight: $c_i = \sum_o cnt(o, pp_i)$. The same counts are used to construct a target distribution $\tilde{P}(o|pp_i)$, using the

⁴We use a historically good setting of $\alpha_* = 10$ throughout.

unsmoothed relative frequency estimate in Equation 1. We then train our weight vector to minimize:

$$\frac{1}{2} \|w\|^2 + C \sum_i c_i \begin{bmatrix} \log \sum_o \exp(w \cdot f(o, pp_i)) \\ - \sum_o \tilde{P}(o|pp_i) (w \cdot f(o, pp_i)) \end{bmatrix} \quad (4)$$

where C is a hyper-parameter that controls the amount of emphasis placed on minimizing loss versus regularizing w .⁵ Note that this objective is a departure from previous work, which tends to create an example for each phrase-pair token, effectively assigning $\tilde{P}(o|pp) = 1$ to a single gold-standard orientation. Instead, our model attempts to reproduce the target distribution \tilde{P} for the entire type, where the penalty c_i for missing this target is determined by the frequency of the phrase pair. The resulting model will tend to match unsmoothed relative frequency estimates for very frequent phrase pairs, and will smooth intelligently using features for less frequent phrase pairs.

All of the features returned by $f(o|pp)$ are derived from the phrase pair $pp = [src, tgt]$, with the goal of describing the phrase pair at a variety of granularities. Our features are described in Table 1, using the following notation: the operators *first* and *last* return the first and last words of phrases,⁶ while the operator *clust*₅₀ maps a word onto its corresponding cluster from an automatically-induced, deterministic 50-word clustering provided by `mkcls` (Och, 1999). Our use of words at the corners of phrases (as opposed to the syntactic head, or the last aligned word) follows Xiong et al. (2006), while our use of word clusters follows Zens and Ney (2006). Each feature has the orientation o appended onto it.

To help scale and to encourage smoothing, we only allow features that occur in at least 5 phrase pair

⁵Preliminary experiments indicated that the model is robust to the choice of C ; we use $C = 0.1$ throughout.

⁶*first = last* for a single-word phrase

tokens. Furthermore, to deal with the huge number of extracted phrase pairs (our Arabic system extracts roughly 88M distinct phrase pair types), we subsample pairs that have been observed only once, keeping only 10% of them. This reduces the number of training examples from 88M to 19M.

3.3 Sparse Reordering Features

The maximum entropy approach uses features to model the distribution of orientations found in word alignments. Alternatively, a number of recent tuning methods, such as MIRA (Chiang et al., 2008) or PRO (Hopkins and May, 2011), can handle thousands of features. These could be used to tune similar features to maximize BLEU directly.

Given the appropriate tuning architecture, the sparse feature approach is actually simpler in many ways than the maximum entropy approach. There is no need to scale to millions of training examples, and there is no question of how to integrate the trained model into the decoder. Instead, one simply implements the desired features in the decoder’s feature API and then tunes as normal. The challenge is to design features so that the model can be learned from small tuning sets.

The standard approach for sparse feature design in SMT is to lexicalize only on extremely frequent words, such as the top-80 words from each language (Chiang et al., 2009; Hopkins and May, 2011). We take that approach here, but we also use deterministic clusters to represent words from both languages, as provided by `mkcls`. These clusters mirror parts-of-speech quite effectively (Blunsom and Cohn, 2011), without requiring linguistic resources. They should provide useful generalization for reordering decisions. Inspired by recent successes in semi-supervised learning (Koo et al., 2008;

corpus	sentences	words (ar)	words (en)

mt09	1,313	40,684	46,813

Table 3: Arabic-English Corpus. For English dev and test sets, word counts are averaged across 4 references.

Lin and Wu, 2009), we cluster at two granularities (20 clusters and 50 clusters), and allow the discriminative tuner to determine how to best employ the various representations.

We add the sparse features in Table 2 to our decoder to help assess reordering decisions. As with the maximum entropy model, orientation is appended to each feature. Furthermore, each feature has a different version for each of our three word representations. Like the maximum entropy model, we describe the phrase pair being added to the hypothesis in terms of the first and last words of its phrases. Unlike the maximum entropy model, we make no attempt to use entire phrases or phrase-pairs as features, as they would be far too sparse for our small tuning sets. However, due to the sparse features’ direct decoder integration, we have access to a fair amount of extra context. We represent the current top of the stack (*top*) using its first and last source words (accessible from the HRM stack), and its last target word (accessible using language model context). Furthermore, for discontinuous (D) orientations, we can include an indicator for each source word between the current top of the stack and the phrase being added.

Because the sparse feature HRM has no access to phrase-pair or monolingual phrase features, and because it completely ignores our large supply of word-aligned training data, we view it as complementary to the relative frequency HRM. We always include both when tuning and decoding. Furthermore, we only include sparse features in the left-to-right translation direction, as the features already consider context (*top*) as well as the next phrase.

4 Experimental Design

We test our reordering models in Arabic to English and Chinese to English translation tasks. Both systems are trained on data from the NIST 2012 MT

corpus	sentences	words (ch)	words (en)

evaluation; the Arabic system is summarized in Table 3 and the Chinese in Table 4. The Arabic system’s development set is the NIST mt06 test set, and its test sets are mt08 and mt09. The Chinese system’s development set is taken from the NIST mt05 evaluation set, augmented with some material reserved from our NIST training corpora in order to better cover newsgroup and weblog domains. Its test sets are mt06 and mt08.

4.1 Baseline System

For both language pairs, word alignment is performed by GIZA++ (Och and Ney, 2003), with 5 iterations of Model 1, HMM, Model 3 and Model 4. Phrases are extracted with a length limit of 7 from alignments symmetrized using grow-diag-final-and (Koehn et al., 2003). Conditional phrase probabilities in both directions are estimated from relative frequencies, and from lexical probabilities (Zens and Ney, 2004). 4-gram language models are estimated from the target side of the bitext with Kneser-Ney smoothing. Relative frequency and maximum entropy RMs are represented with six features, with separate weights for M, S and D in both directions (Koehn et al., 2007). HRM orientations are determined using an unrestricted shift-reduce parser (Cherry et al., 2012). We also employ a standard distortion penalty incorporating the minimum completion cost described by Moore and Quirk (2007). Our multi-stack phrase-based decoder is quite similar to Moses (Koehn et al., 2007).

For all systems, parameters are tuned with a batch-lattice variant of hope-fear MIRA (Chiang et al., 2008; Cherry and Foster, 2012). Preliminary experiments suggested that the sparse reordering features have a larger impact when tuned with lattices as opposed to *n*-best lists.

4.2 Evaluation

We report lower-cased BLEU (Papineni et al., 2002), evaluated using the same English tokenization used in training. For our primary results, we perform random replications of parameter tuning, as suggested by Clark et al. (2011). Each replication uses a different random seed to determine the order in which MIRA visits tuning sentences. We test for significance using Clark et al.’s MultEval tool, which uses a stratified approximate randomization test to account for multiple replications.

5 Results

We begin with a comparison of the reordering models described in this paper: the hierarchical reordering model (**HRM**), the maximum entropy HRM (**Maxent HRM**) and our sparse reordering features (**Sparse HRM**). Results are shown in Table 5.

Our three primary points of comparison have been tested with 5 replications. We report BLEU scores averaged across replications as well as standard deviations, which indicate optimizer stability. We also provide unreplicated results for two systems, one using only the distortion penalty (**No RM**), and one using a non-hierarchical reordering model (**RM**). These demonstrate that our baseline already has quite mature reordering capabilities.

The Maxent HRM has very little effect on translation performance. We found this surprising; we expected large gains from improving the reordering distributions of low-frequency phrase-pairs. See §5.1 for further exploration of this result.

The Sparse HRM, on the other hand, performs very well. It produces significant BLEU score improvements on all test sets, with improvements ranging between 1 and 1.8 BLEU points. Even with millions of training sentences for our HRM, there is a large benefit in building HRM-like features that are tuned to optimize the decoder’s BLEU score on small tuning sets. We examine the impact of subsets of these features in §5.2.

The test sets’ standard deviations increase from 0.1 under the baseline to 0.3 under the Sparse HRM for Chinese-English, indicating a decrease in optimizer stability. With so many features trained on so few sentences, this is not necessarily surprising. Fortunately, looking at the actual replications (not

shown), we confirmed that if a replication produced low scores in one test, it also produced low scores in the other. This means that one should be able to outperform the average case by using a dev-test set to select among replications.

5.1 Maximum Entropy Analysis

The next two sections examine our two solutions in detail, starting with the Maxent HRM. To avoid excessive demands on our computing resources, all experiments report tuning with a single replication with the same seed. We select Arabic-English for our analysis, as this pair has high optimizer stability and fast decoding speeds.

Why does the Maxent HRM help so little? We begin by investigating some design decisions. One possibility is that our subsampling of frequency-1 training pairs (see §3.2) harmed performance. To test the impact of this decision, we train a Maxent HRM without subsampling, taking substantially longer. The resulting BLEU scores (not shown) are well within the projected standard deviations for optimizer instability (0.1 BLEU from Table 5). This indicates that subsampling is not the problem. To confirm our choice of hyperparameters, we conduct a grid search over the Maxent HRM’s regularization parameter C (see Equation 4), covering the set {1, 0.1, 0.01, 0.001}, where $C = 0.1$ is the value used throughout this paper. Again, the resulting BLEU scores (not shown) are all within 0.1 of the means reported in Table 5.

Another possibility is that the Maxent HRM has an inferior feature set. We selected features for our Maxent and Sparse HRMs to be similar, but also to play to the strengths of each method. To level the playing field, we train and test both systems with the feature set shown in Table 6, which is the intersection of the features from Tables 1 and 2. The resulting average BLEU scores are shown in Table 7. With

HRM (baseline)		—	44.2
Original	Maxent HRM	44.2	44.2
	Sparse HRM	45.4	46.0
Intersection	Maxent HRM	43.8	44.2
	Sparse HRM	45.2	46.0

Table 7: Arabic-English BLEU scores with each system’s original feature set versus the intersection of the two feature sets, with and without the relative frequency HRM. BLEU is averaged across mt08 and mt09.

the baseline HRM included, performance does not change for either system with the intersected feature set. Sparse features continue to help, while the maximum entropy model does not. Without the HRM, both systems degrade under the intersection, though the Sparse HRM still improves over the baseline.

Finally, we examine Maxent HRM performance as a function of the amount of word-aligned training data. To do so, we hold all aspects of our system constant, except for the amount of bitext used to train either the baseline HRM or the Maxent HRM. Importantly, the phrase table always uses the complete bitext. For our reordering training set, we hold out the final two thousand sentences of bitext to calculate perplexity. This measures the model’s surprise at reordering events drawn from previously unseen alignments; lower values are better. We proceed to subsample sentence pairs from the remaining bitext, in order to produce a series of training bitexts of increasing size. We subsample with the probability of accepting a sentence pair, P_a , set to $\{0.001, 0.01, 0.1, 1\}$. It is important to not confuse this subsampling of sentence pairs with the subsampling of low-frequency phrase pairs (see §3.2),

which is still carried out by the Maxent HRM for each training scenario.

Figure 1 shows how BLEU (averaged across both test sets) and perplexity vary as training data increases from 1.5K sentences to the full 1.5M. At $P_a < 0.1$, corresponding to less than 150K sentences, the maximum entropy model actually makes a substantial difference in terms of BLEU. However, these deltas narrow to nothing as we reach millions of training sentences. This is consistent with the results of Nguyen et al. (2009), who report that maximum entropy reordering outperforms a similar baseline, but using only 50K sentence pairs.

A related observation is that held-out perplexity does not seem to predict BLEU in any useful way. In particular, perplexity does not predict that the two systems will become similar as data grows, nor does it predict that maxent’s performance will level off. Predicting the orientations of unseen alignments is not the same task as predicting the orientation for a phrase during translation. We suspect that perplexity places too much emphasis on rare or previously unseen phrase pairs, due to phrase extraction’s heavy tails. Preliminary attempts to correct for this using absolute discounting on the test counts did not resolve these issues. Unfortunately, in maximizing (regularized or smoothed) likelihood, both maxent and relative frequency HRMs are chasing the perplexity objective, not the BLEU objective.

5.2 Sparse Feature Analysis

The results in Table 7 from §5.1 already provide us with a number of insights regarding the Sparse HRM. First, note that the intersected feature set uses only information found within a single phrase. The fact that the Sparse HRM performs so well with

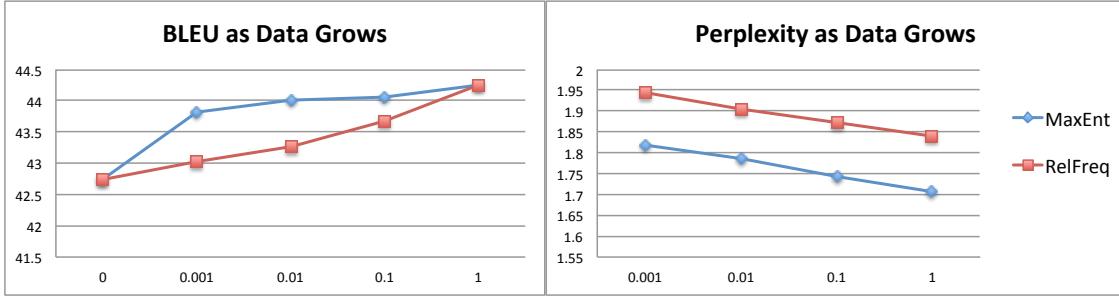

Figure 1: Learning curves for Relative Frequency and Maximum Entropy reordering models on Arabic-English.

Feature Group	Count	BLEU
No Sparse HRM	0	44.2
Between	312	44.4
Stack	1404	45.2
Phrase	1872	45.9
20 Clusters	506	45.4
50 Clusters	1196	45.8
80 Words	1886	45.8
Full Sparse HRM	3588	46.0

Table 8: Versions of the Sparse HRM built using organized subsets of the complete feature set for Arabic-English. Count is the number of distinct features, while BLEU is averaged over mt08 and mt09.

intersected features indicates that modeling context outside a phrase is not essential for strong performance. Furthermore, the **-HRM** portion of the table indicates that the sparse HRM does not require the baseline HRM to be present in order to outperform it. This is remarkable when one considers that the Sparse HRM uses less than 4k features to model phrase orientations, compared to the 530M probabilities⁷ maintained by the baseline HRM’s relative frequency model.

To determine which feature groups are most important, we tested the Sparse HRM on Arabic-English with a number of feature subsets. We report BLEU scores averaged over both test sets in Table 8. First, we break our features into three groups according to what part of the hypothesis is used to assess orientation. For each of these location groups, all forms of word representation (clusters or frequent words) are employed. The groups consist of **Be-**

tween: the words between the top of the stack and the phrase to be added; **Stack**: words describing the current top of the stack; and **Phrase**: words describing the phrase pair being added to the hypothesis. Each group was tested alone to measure its usefulness. This results in a clear hierarchy, with the phrase features being the most useful (nearly as useful as the complete system), and the between features being the least. Second, we break our features into three groups according to how words are represented. For each of these representation groups, all location groups (Between, Stack and Phrase) are employed. The groups are quite intuitive: **20 Clusters, 50 Clusters or 80 Words**. The differences between representations are much less dramatic than the location groups. All representations perform well on their own, with the finer-grained ones performing better. Including multiple representations provides a slight boost, but these experiments suggest that a leaner model could certainly drop one or two representations with little impact.

In its current implementation, the Sparse HRM is roughly 4 times slower than the baseline decoder. Our sparse feature infrastructure is designed for flexibility, not speed. To affect reordering, each sparse feature template is re-applied with each hypothesis extension. However, the intersected feature set from §5.1 is only 2 times slower, and could be made faster still. That feature set uses only within-phrase features to asses orientations; therefore, the total weight for each orientation for each phrase-pair could be pre-calculated, making its cost comparable to the baseline.

⁷88.4M phrase pairs \times 3 orientations (M, S and D) \times 2 translation directions (left-to-right and right-to-left).

+Sparse HRM	51.7	49.9	52.2

Table 9: The effect of Sparse HRMs on complex systems.

5.3 Impact on Competition-Grade SMT

Thus far, we have employed a baseline that has been designed for both translation quality and replicability. We now investigate the impact of our Sparse HRM on a far more complex baseline: our internal system used for MT competitions such as NIST.

The Arabic system uses roughly the same bilingual data as our original baseline, but also includes a 5-gram language model learned from the English Gigaword. The Chinese system adds the UN bitext as well as the English Gigaword. Both systems make heavy use of linear mixtures to create refined translation and language models, mixing across sources of corpora, genre and translation direction (Foster and Kuhn, 2007; Goutte et al., 2009). They also mix many different sources of word alignments, with the system adapting across alignment sources using either binary indicators or linear mixtures. Importantly, these systems already incorporate thousands of sparse features as described by Hopkins and May (2011). These provide additional information for each phrase pair through frequency bins, phrase-length bins, and indicators for frequent alignment pairs. Both systems include a standard HRM.

The result of adding the Sparse HRM to these systems is shown in Table 9. Improvements range from 0.4 to 1.1 BLEU, but importantly, all four test sets improve. The impact of these reordering features is reduced slightly in the presence of more carefully tuned translation and language models, but they remain a strong contributor to translation quality.

6 Conclusion

We have shown that sparse reordering features can improve the quality of phrase-based translations, even in the presence of lexicalized reordering models that track the same orientations. We have com-

pared this solution to a maximum entropy model, which does not improve our HRM baseline. Our analysis of the maximum entropy solution indicates that smoothing the orientation estimates is not a major concern in the presence of millions of sentences of bitext. This implies that our sparse features are achieving their improvement because they optimize BLEU with the decoder in the loop, side-stepping the objective mismatch that can occur when training on word-aligned data. The fact that this is possible with such small tuning corpora is both surprising and encouraging.

In the future, we would like to investigate how to incorporate useful future cost estimates for our sparse reordering features. Previous work has shown future distortion penalty estimates to be important for both translation speed and quality (Moore and Quirk, 2007; Green et al., 2010), but we have ignored future costs in this work. We would also like to investigate features inspired by transition-based parsing, such as features that look further down the reordering stack. Finally, as there is evidence that ideas from lexicalized reordering can help hierarchical phrase-based SMT (Huck et al., 2012), it would be interesting to explore the use of sparse RMs in that setting.

Abstract

Current word alignment models for statistical machine translation do not address morphology beyond merely splitting words. We present a two-level alignment model that distinguishes between words and morphemes, in which we embed an IBM Model 1 inside an HMM based word alignment model. The model jointly induces word and morpheme alignments using an EM algorithm. We evaluated our model on Turkish-English parallel data. We obtained significant improvement of BLEU scores over IBM Model 4. Our results indicate that utilizing information from morphology improves the quality of word alignments.

1 Introduction

All current state-of-the-art approaches to SMT rely on an automatically word-aligned corpus. However, current alignment models do not take into account the morpheme, the smallest unit of syntax, beyond merely splitting words. Since morphology has not been addressed explicitly in word alignment models, researchers have resorted to tweaking SMT systems by manipulating the content and the form of what should be the so-called “word”.

Since the word is the smallest unit of translation from the standpoint of word alignment models, the central focus of research on translating morphologically rich languages has been decomposition of morphologically complex words into tokens of the right granularity and representation for machine translation. Chung and Gildea (2009) and Naradowsky and Toutanova (2011) use unsupervised methods to find

word segmentations that create a one-to-one mapping of words in both languages. Al-Onaizan et al. (1999), Čmejrek et al. (2003), and Goldwater and McClosky (2005) manipulate morphologically rich languages by selective lemmatization. Lee (2004) attempts to learn the probability of deleting or merging Arabic morphemes for Arabic to English translation. Niessen and Ney (2000) split German compound nouns, and merge German phrases that correspond to a single English word. Alternatively, Yeniterzi and Oflazer (2010) manipulate words of the morphologically poor side of a language pair to mimic having a morphological structure similar to the richer side via exploiting syntactic structure, in order to improve the similarity of words on both sides of the translation.

We present an alignment model that assumes internal structure for words, and we can legitimately talk about words and their morphemes in line with the linguistic conception of these terms. Our model avoids the problem of collapsing words and morphemes into one single category. We adopt a two-level representation of alignment: the first level involves word alignment, the second level involves morpheme alignment in the scope of a given word alignment. The model jointly induces word and morpheme alignments using an EM algorithm.

We develop our model in two stages. Our initial model is analogous to IBM Model 1: the first level is a bag of words in a pair of sentences, and the second level is a bag of morphemes. In this manner, we embed one IBM Model 1 in the scope of another IBM Model 1. At the second stage, by introducing distortion probabilities at the word level, we develop an HMM extension of the initial model.

We evaluated the performance of our model on the

Turkish-English pair both on hand-aligned data and by running end-to-end machine translation experiments. To evaluate our results, we created gold word alignments for 75 Turkish-English sentences. We obtain significant improvement of AER and BLEU scores over IBM Model 4. Section 2.1 introduces the concept of morpheme alignment in terms of its relation to word alignment. Section 2.2 presents the derivation of the EM algorithm and Section 3 presents the results of our experiments.

2 Two-level Alignment Model (TAM)

2.1 Morpheme Alignment

Following the standard alignment models of Brown et al. (1993), we assume one-to-many alignment for both words and morphemes. A word alignment a_w (or only a) is a function mapping a set of word positions in a source language sentence to a set of word positions in a target language sentence. A morpheme alignment a_m is a function mapping a set of morpheme positions in a source language sentence to a set of morpheme positions in a target language sentence. A morpheme position is a pair of integers (j, k) , which defines a word position j and a relative morpheme position k in the word at position j . The alignments below are depicted in Figures 1 and 2.

$$a_w(1) = 1 \quad a_m(2, 1) = (1, 1) \quad a_w(2) = 1$$

Figure 1 shows a word alignment between two sentences. Figure 2 shows the morpheme alignment between same sentences. We assume that all unaligned morphemes in a sentence map to a special null morpheme.

A morpheme alignment a_m and a word alignment a_w are *compatible* if and only if they satisfy the following conditions: If the morpheme alignment a_m maps a morpheme of e to a morpheme of f , then the word alignment a_w maps e to f . If the word alignment a_w maps e to f , then the morpheme alignment a_m maps at least one morpheme of e to a morpheme of f . If the word alignment a_w maps e to null, then all of its morphemes are mapped to null. In sum, a morpheme alignment a_m and a word alignment a_w

are *compatible* if and only if:

$$\begin{aligned} & \forall j, k, m, n \in \mathbb{N}^+, \exists s, t \in \mathbb{N}^+ \\ & [a_m(j, k) = (m, n) \Rightarrow a_w(j) = m] \wedge \\ & [a_w(j) = m \Rightarrow a_m(j, s) = (m, t)] \wedge \\ & [a_w(j) = \text{null} \Rightarrow a_m(j, k) = \text{null}] \end{aligned} \quad (1)$$

Please note that, according to this definition of compatibility, ‘ $a_m(j, k) = \text{null}$ ’ does not necessarily imply ‘ $a_w(j) = \text{null}$ ’.

A word alignment induces a set of compatible morpheme alignments. However, a morpheme alignment induces a unique word alignment. Therefore, if a morpheme alignment a_m and a word alignment a_w are compatible, then the word alignment is a_w is recoverable from the morpheme alignment a_m .

The two-level alignment model (TAM), like IBM Model 1, defines an alignment between words of a sentence pair. In addition, it defines a morpheme alignment between the morphemes of a sentence pair.

The problem domain of IBM Model 1 is defined over alignments between words, which is depicted as the gray box in Figure 1. In Figure 2, the smaller boxes embedded inside the main box depict the new problem domain of TAM. Given the word alignments in Figure 1, we are presented with a new alignment problem defined over their morphemes. The new alignment problem is constrained by the given word alignment. We, like IBM Model 1, adopt a bag-of-morphemes approach to this new problem. We thus embed one IBM Model 1 into the scope of another IBM Model 1, and formulate a second-order interpretation of IBM Model 1.

TAM, like IBM Model 1, assumes that words and morphemes are translated independently of their context. The units of translation are both words and morphemes. Both the word alignment a_w and the morpheme alignment a_m are hidden variables that need to be learned from the data using the EM algorithm.

In IBM Model 1, $p(\mathbf{e}|\mathbf{f})$, the probability of translating the sentence \mathbf{f} into \mathbf{e} with any alignment is computed by summing over all possible word alignments:

$$p(\mathbf{e}|\mathbf{f}) = \sum_a p(a, \mathbf{e}|\mathbf{f})$$

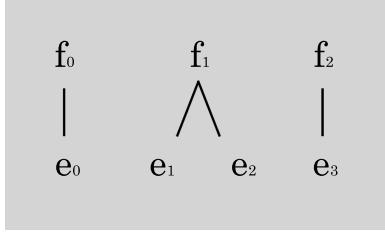

Figure 1: Word alignment

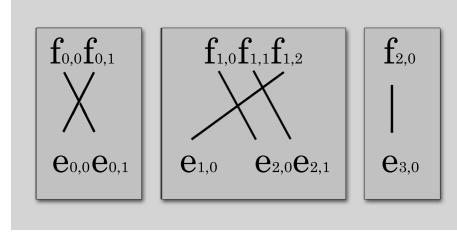

Figure 2: Morpheme alignment

In TAM, the probability of translating the sentence \mathbf{f} into \mathbf{e} with any alignment is computed by summing over all possible word alignments and all possible morpheme alignments that are compatible with a given word alignment a_w :

$$p(\mathbf{e}|\mathbf{f}) = \sum_{a_w} p(a_w, \mathbf{e}|\mathbf{f}) \sum_{a_m} p(a_m, \mathbf{e}|a_w, \mathbf{f}) \quad (2)$$

where a_m stands for a morpheme alignment. Since the morpheme alignment a_m is in the scope of a given word alignment a_w , a_m is constrained by a_w .

In IBM Model 1, we compute the probability of translating the sentence \mathbf{f} into \mathbf{e} by summing over all possible word alignments between the words of \mathbf{f} and \mathbf{e} :

$$p(\mathbf{e}|\mathbf{f}) = R(\mathbf{e}, \mathbf{f}) \prod_{j=1}^{|e|} \sum_{i=0}^{|f|} t(e_j | f_i) \quad (3)$$

where $t(e_j | f_i)$ is the word translation probability of e_j given f_i . $R(\mathbf{e}, \mathbf{f})$ substitutes $\frac{P(l_e | l_f)}{(l_f + 1)^{l_e}}$ for easy readability.¹

In TAM, the probability of translating the sentence \mathbf{f} into \mathbf{e} is computed as follows:

$$\begin{aligned} & \text{Word } \underline{\underline{\hspace{1cm}}} \\ & R(\mathbf{e}, \mathbf{f}) \prod_{j=1}^{|e|} \sum_{i=0}^{|f|} \left(t(e_j | f_i) \right. \\ & \quad \left. R(e_j, f_i) \prod_{k=1}^{|e_j|} \sum_{n=0}^{|f_i|} t(e_j^k | f_i^n) \right) \\ & \text{Morpheme } \underline{\underline{\hspace{1cm}}} \end{aligned}$$

where f_i^n is the n^{th} morpheme of the word at position i . The right part of this equation, the contribution of morpheme translation probabilities, is

¹ $l_e = |\mathbf{e}|$ is the number of words in sentence \mathbf{e} and $l_f = |\mathbf{f}|$.

in the scope of the left part. In the right part, we compute the probability of translating the word f_i into the word e_j by summing over all possible morpheme alignments between the morphemes of e_j and f_i . $R(e_j, f_i)$ is equivalent to $R(\mathbf{e}, \mathbf{f})$ except for the fact that its domain is not the set of sentences but the set of words. The length of words e_j and f_i in $R(e_j, f_i)$ are the number of morphemes of e_j and f_i .

The left part, the contribution of word translation probabilities alone, equals Eqn. 3. Therefore, canceling the contribution of morpheme translation probabilities reduces TAM to IBM Model 1. In our experiments, we call this reduced version of TAM ‘word-only’ (IBM). TAM with the contribution of both word and morpheme translation probabilities, as the equation above, is called ‘word-and-morpheme’. Finally, we also cancel out the contribution of word translation probabilities, which is called ‘morpheme-only’. In the ‘morpheme-only’ version of TAM, $t(e_j | f_i)$ equals 1. Below is the equation of $p(\mathbf{e}|\mathbf{f})$ in the morpheme-only model.

$$p(\mathbf{e}|\mathbf{f}) = R(\mathbf{e}, \mathbf{f}) \prod_{j=1}^{|e|} \sum_{i=0}^{|f|} \prod_{k=1}^{|e_j|} \sum_{n=0}^{|f_i|} R(e_j, f_i) t(e_j^k | f_i^n) \quad (4)$$

Please note that, although this version of the two-level alignment model does not use word translation probabilities, it is also a word-aware model, as morpheme alignments are restricted to correspond to a valid word alignment according to Eqn. 1. When presented with words that exhibit no morphology, the morpheme-only version of TAM is equivalent to IBM Model 1, as every single-morpheme word is itself a morpheme.

Deficiency and Non-Deficiency of TAM We present two versions of TAM, the word-and-

morpheme and the morpheme-only versions. The word-and-morpheme version of the model is deficient whereas the morpheme-only model is not.

The word-and-morpheme version is deficient, because some probability is allocated to cases where the morphemes generated by the morpheme model do not match the words generated by the word model. Moreover, although most languages exhibit morphology to some extent, they can be input to the algorithm without morpheme boundaries. This also causes deficiency in the word-and-morpheme version, as single morpheme words are generated twice, as a word and as a morpheme.

Nevertheless, we observed that the deficient version of TAM can perform as good as the non-deficient version of TAM, and sometimes performs better. This is not surprising, as deficient word alignment models such as IBM Model 3 or discriminative word alignment models work well in practice.

Goldwater and McClosky (2005) proposed a morpheme aware word alignment model for language pairs in which the source language words correspond to only one morpheme. Their word alignment model is:

$$P(e|f) = \prod_{k=0}^K P(e^k|f)$$

where e^k is the k^{th} morpheme of the word e . The morpheme-only version of our model is a generalization of this model. However, there are major differences in their and our implementation and experimentation. Their model assumes a fixed number of possible morphemes associated with any stem in the language, and if the morpheme e^k is not present, it is assigned a null value.

The null word on the source side is also a null morpheme, since every single morpheme word is itself a morpheme. In TAM, the null word is the null morpheme that all unaligned morphemes align to.

2.2 Second-Order Counts

In TAM, we collect counts for both word translations and morpheme translations. Unlike IBM Model 1, $R(e, f) = \frac{P(l_e|l_f)}{(l_f+1)^{l_e}}$ does not cancel out in the counts of TAM. To compute the conditional probability $P(l_e|l_f)$, we assume that the length of word e (the number of morphemes of word e) varies according

to a Poisson distribution with a mean that is linear with length of the word f .

$$\begin{aligned} P(l_e|l_f) &= F_{\text{Poisson}}(l_e, r \cdot l_f) \\ &= \frac{\exp(-r \cdot l_f)(r \cdot l_f)^{l_e}}{l_e!} \end{aligned}$$

$F_{\text{Poisson}}(l_e, r \cdot l_f)$ expresses the probability that there are l_e morphemes in e if the expected number of morphemes in e is $r \cdot l_f$, where $r = \frac{\mathbb{E}[l_e]}{\mathbb{E}[l_f]}$ is the rate parameter. Since l_f is undefined for null words, we omit $R(e, f)$ for null words.

We introduce $T(e|f)$, the translation probability of e given f with all possible morpheme alignments, as it will occur frequently in the counts of TAM:

$$T(e|f) = t(e|f)R(e, f) \prod_{k=1}^{|e|} \sum_{n=0}^{|f|} t(e^k|f^n)$$

The role of $T(e|f)$ in TAM is very similar to the role of $t(e|f)$ in IBM Model 1. In finding the Viterbi alignments, we do not take max over the values in the summation in $T(e|f)$.

2.2.1 Word Counts

Similar to IBM Model 1, we collect counts for word translations over all possible alignments, weighted by their probability. In Eqn. 5, the count function collects evidence from a sentence pair (\mathbf{e}, \mathbf{f}) as follows: For all words e_j of the sentence \mathbf{e} and for all word alignments $a_w(j)$, we collect counts for a particular input word f and an output word e iff $e_j = e$ and $f_{a_w(j)} = f$.

$$c_w(e|f; \mathbf{e}, \mathbf{f}, a_w) = \sum_{\substack{1 \leq j \leq |\mathbf{e}| \\ \text{s.t.} \\ e = e_j \\ f = f_{a_w(j)}}} \frac{T(e|f)}{\sum_{i=0}^{|f|} T(e|f_i)} \quad (5)$$

2.2.2 Morpheme Counts

As for morpheme translations, we collect counts over all possible word and morpheme alignments, weighted by their probability. The morpheme count function below collects evidence from a word pair (e, f) in a sentence pair (\mathbf{e}, \mathbf{f}) as follows: For all words e_j of the sentence \mathbf{e} and for all word alignments $a_w(j)$, for all morphemes e_j^k of the word e_j and for all morpheme alignments $a_m(j, k)$, we collect counts for a particular input morpheme g and an

output morpheme h iff $e_j = e$ and $f_{a_w(j)} = f$ and $h = e_j^k$ and $g = f_{a_m(j,k)}$.

$$c_m(h|g; \mathbf{e}, \mathbf{f}, a_w, a_m) = \sum_{\substack{1 \leq j \leq |\mathbf{e}| \\ \text{s.t.} \\ e=e_j \\ f=f_{a_w(j)}}} \sum_{\substack{1 \leq k \leq |e| \\ \text{s.t.} \\ h=e_j^k \\ g=f_{a_m(j,k)}}} \frac{T(e|f)}{\sum_{i=0}^{|\mathbf{f}|} T(e|f_i)} \frac{t(h|g)}{\sum_{i=1}^{|f|} t(h|f^i)}$$

The left part of the morpheme count function is the same as the word-counts in Eqn. 5. Since it does not contain h or g , it needs to be computed only once for each word. The right part of the equation is familiar from the IBM Model 1 counts.

2.3 HMM Extension

We implemented TAM with the HMM extension (Vogel et al., 1996) at the word level. We redefine $p(\mathbf{e}|\mathbf{f})$ as follows:

$$R(\mathbf{e}, \mathbf{f}) \sum_{a_w} \prod_{j=1}^{|e|} \left(p(s(j) | C(f_{a_w(j-1)})) t(e_j | f_{a_w(j)}) R(e_j, f_{a_w(j)}) \sum_{a_m} \prod_{k=1}^{|e_j|} t(e_j^k | f_{a_m(j,k)}) \right)$$

where the distortion probability depends on the relative jump width $s(j) = a_w(j-1) - a_w(j)$, as opposed to absolute positions. The distortion probability is conditioned on class of the previous aligned word $C(f_{a_w(j-1)})$. We used the `mkcls` tool in GIZA (Och and Ney, 2003) to learn the word classes.

We formulated the HMM extension of TAM only at the word level. Nevertheless, the morpheme-only version of TAM also has an HMM extension, as it is also a word-aware model. To obtain the HMM extension of the morpheme-only version, substitute $t(e_j | f_{a_w(j)})$ with 1 in the equation above.

For the HMM to work correctly, we must handle jumping to and jumping from null positions. We learn the probabilities of jumping to a null position from the data. To compute the jump probability from a null position, we keep track of the nearest previous source word that does not align to null, and use the position of the previous non-null word to calculate the jump width. For this reason, we use a total of

$2l_f - 1$ words for the HMM model, the positions $> l_f$ stand for null positions between the words of f (Och and Ney, 2003). We do not allow null to null jumps. In sum, we enforce the following constraints:

$$\begin{aligned} P(i + l_f + 1 | i') &= p(null | i') \\ P(i + l_f + 1 | i' + l_f + 1) &= 0 \\ P(i | i' + l_f + 1) &= p(i | i') \end{aligned}$$

In the HMM extension of TAM, we perform forward-backward training using the word counts in Eqn. 5 as the emission probabilities. We calculate the posterior word translation probabilities for each e_j and f_i such that $1 \leq j \leq l_e$ and $1 \leq i \leq 2l_f - 1$ as follows:

$$\gamma_j(i) = \frac{\alpha_j(i)\beta_j(i)}{\sum_{m=1}^{2l_f-1} \alpha_j(m)\beta_j(m)}$$

where α is the forward and β is the backward probabilities of the HMM. The HMM word counts, in turn, are the posterior word translation probabilities obtained from the forward-backward training:

$$c_w(e|f; \mathbf{e}, \mathbf{f}, a_w) = \sum_{\substack{1 \leq j \leq |\mathbf{e}| \\ \text{s.t.} \\ e=e_j \\ f=f_{a_w(j)}}} \gamma_j(a_w(j))$$

Likewise, we use the posterior probabilities in HMM morpheme counts:

$$c_m(h|g; \mathbf{e}, \mathbf{f}, a_w, a_m) = \sum_{\substack{1 \leq j \leq |\mathbf{e}| \\ \text{s.t.} \\ e=e_j \\ f=f_{a_w(j)}}} \sum_{\substack{1 \leq k \leq |e| \\ \text{s.t.} \\ h=e_j^k \\ g=f_{a_m(j,k)}}} \gamma_j(a_w(j)) \frac{t(h|g)}{\sum_{i=1}^{|f|} t(h|f^i)}$$

The complexity of the HMM extension of TAM is $O(n^3 m^2)$, where n is the number of words, and m is the number of morphemes per word.

2.4 Variational Bayes

Moore (2004) showed that the EM algorithm is particularly susceptible to overfitting in the case of rare words when training IBM Model 1. In order to prevent overfitting, we use the Variational Bayes extension of the EM algorithm (Beal, 2003). This

Figure 3: Turkish-English data examples

amounts to a small change to the M step of the original EM algorithm. We introduce Dirichlet priors α to perform an inexact normalization by applying the function $f(v) = \exp(\psi(v))$ to the expected counts collected in the E step, where ψ is the digamma function (Johnson, 2007).

$$\theta_{x|y} = \frac{f(E[c(x|y)] + \alpha)}{f(\sum_j E[c(x_j|y)] + \alpha)}$$

We set α to 10^{-20} , a very low value, to have the effect of anti-smoothing, as low values of α cause the algorithm to favor words which co-occur frequently and to penalize words that co-occur rarely.

3 Experimental Setup

3.1 Data

We trained our model on a Turkish-English parallel corpus of approximately 50K sentences, which have a maximum of 80 morphemes. Our parallel data consists mainly of documents in international relations and legal documents from sources such as the Turkish Ministry of Foreign Affairs, EU, etc. We followed a heavily supervised approach in morphological analysis. The Turkish data was first morphologically parsed (Oflazer, 1994), then disambiguated (Sak et al., 2007) to select the contextually salient interpretation of words. In addition, we removed morphological features that are not explicitly marked by an overt morpheme — thus each feature symbol beyond the root part-of-speech corresponds to a morpheme. Line (b) of Figure 3 shows an example of

a segmented Turkish sentence. The root is followed by its part-of-speech tag separated by a ‘+’. The derivational and inflectional morphemes that follow the root are separated by ‘–’s. In all experiments, we used the same segmented version of the Turkish data, because Turkish is an agglutinative language.

For English, we used the CELEX database (Baayen et al., 1995) to segment English words into morphemes. We created two versions of the data: a segmented version that involves both derivational and inflectional morphology, and an unsegmented POS tagged version. The CELEX database provides tags for English derivational morphemes, which indicate their function: the part-of-speech category the morpheme attaches to and the part-of-speech category it returns. For example, in ‘sparse+ity’ = ‘sparsity’, the morpheme *-ity* attaches to an adjective to the right and returns a noun. This behavior is represented as ‘N|A.’ in CELEX, where ‘.’ indicates the attachment position. We used these tags in addition to the surface forms of the English morphemes, in order to disambiguate multiple functions of a single surface morpheme.

The English sentence in line (d) of Figure 3 exhibits both derivational and inflectional morphology. For example, ‘author+ity+s’ = ‘authorities’ has both an inflectional suffix *-s* and a derivational suffix *-ity*, whereas ‘person+s’ has only an inflectional suffix *-s*.

For both English and Turkish data, the dashes in Figure 3 stand for morpheme boundaries, therefore the strings between the dashes are treated as indi-

	Words		Morphemes

Table 1: Data statistics

visible units. Table 1 shows the number of words, the number of morphemes and the respective vocabulary sizes. The average number of morphemes in segmented Turkish words is 2.69, and the average length of segmented English words is 1.57.

3.2 Experiments

We initialized our baseline word-only model with 5 iterations of IBM Model 1, and further trained the HMM extension (Vogel et al., 1996) for 5 iterations. We call this model ‘baseline HMM’ in the discussions. Similarly, we initialized the two versions of TAM with 5 iterations of the model explained in Section 2.2, and then trained the HMM extension of it as explained in Section 2.3 for 5 iterations.

To obtain BLEU scores for TAM models and our implementation of the word-only model, i.e. baseline-HMM, we bypassed GIZA++ in the Moses toolkit (Och and Ney, 2003). We also ran GIZA++ (IBM Model 1–4) on the data. We translated 1000 sentence test sets.

4 Results and Discussion

We evaluated the performance of our model in two different ways. First, we evaluated against gold word alignments for 75 Turkish-English sentences. Second, we used the word Viterbi alignments of our algorithm to obtain BLEU scores.

Table 2 shows the AER (Och and Ney, 2003) of the word alignments of the Turkish-English pair and the translation performance of the word alignments learned by our models. We report the grow-diag-final (Koehn et al., 2003) of the Viterbi alignments. In Table 2, results obtained with different versions of the English data are represented as follows: ‘Der’ stands for derivational morphology, ‘Inf’ for inflectional morphology, and ‘POS’ for part-of-speech

tags. ‘Der+Inf’ corresponds to the example sentence in line (d) in Figure 3, and ‘POS’ to line (e). ‘DIR’ stands for models with Dirichlet priors, and ‘NO DIR’ stands for models without Dirichlet priors. All reported results are of the HMM extension of respective models.

Table 2 shows that using Dirichlet priors hurts the AER performance of the word-and-morpheme model in all experiment settings, and benefits the morpheme-only model in the POS tagged experiment settings.

In order to reduce the effect of nondeterminism, we run Moses three times per experiment setting, and report the highest BLEU scores obtained. Since the BLEU scores we obtained are close, we did a significance test on the scores (Koehn, 2004). Table 2 visualizes the partition of the BLEU scores into statistical significance groups. If two scores within the same column have the same background color, or the border between their cells is removed, then the difference between their scores is not statistically significant. For example, the best BLEU scores, which are in bold, have white background. All scores in a given experiment setting without white background are significantly worse than the best score in that experiment setting, unless there is no border separating them from the best score.

In all experiment settings, the TAM Models perform better than the baseline-HMM. Our experiments showed that the baseline-HMM benefits from Dirichlet priors to a larger extent than the TAM models. Dirichlet priors help reduce the overfitting in the case of rare words. The size of the word vocabulary is larger than the size of the morpheme vocabulary. Therefore the number of rare words is larger for words than it is for morphemes. Consequently, baseline-HMM, using only the word vocab-

ulary, benefits from the use of Dirichlet priors more than the TAM models.

In four out of eight experiment settings, the morpheme-only model performs better than the word-and-morpheme version of TAM. However, please note that our extensive experimentation with TAM models revealed that the superiority of the morpheme-only model over the word-and-morpheme model is highly dependent on segmentation accuracy, degree of segmentation, and morphological richness of languages.

Finally, we treated morphemes as words and trained IBM Model 4 on the morpheme segmented versions of the data. To obtain BLEU scores, we had to unsegment the translation output: we concatenated the prefixes to the morpheme to the right, and suffixes to the morpheme to the left. Since this process creates malformed words, the BLEU scores obtained are much lower than the scores obtained by IBM Model 4, the baseline and the TAM Models.

5 Conclusion

We presented two versions of a two-level alignment model for morphologically rich languages. We ob-

served that information provided by word translations and morpheme translations interact in a way that enables the model to be receptive to the partial information in rarely occurring words through their frequently occurring morphemes. We obtained significant improvement of BLEU scores over IBM Model 4. In conclusion, morphologically aware word alignment models prove to be superior to their word-only counterparts.

Multi-faceted Event Recognition with Bootstrapped Dictionaries

Abstract

Identifying documents that describe a specific type of event is challenging due to the high complexity and variety of event descriptions. We propose a *multi-faceted event recognition* approach, which identifies documents about an event using event phrases as well as defining characteristics of the event. Our research focuses on civil unrest events and learns civil unrest expressions as well as phrases corresponding to potential agents and reasons for civil unrest. We present a bootstrapping algorithm that automatically acquires event phrases, agent terms, and purpose (reason) phrases from unannotated texts. We use the bootstrapped dictionaries to identify civil unrest documents and show that multi-faceted event recognition can yield high accuracy.

1 Introduction

Many people are interested in following news reports about events. Government agencies are keenly interested in news about civil unrest, acts of terrorism, and disease outbreaks. Companies want to stay on top of news about corporate acquisitions, high-level management changes, and new joint ventures. The general public is interested in articles about crime, natural disasters, and plane crashes. We will refer to the task of identifying documents that describe a specific type of event as *event recognition*.

It is tempting to assume that event keywords are sufficient to identify documents that discuss instances of an event. But event words are rarely reliable on their own. For example, consider the challenge of finding documents about civil unrest. The

words “*strike*”, “*rally*”, and “*riot*” refer to common types of civil unrest, but they frequently refer to other things as well. A strike can refer to a military event or a sporting event (e.g., “*air strike*”, “*bowling strike*”), a rally can be a race or a spirited exchange (e.g., “*car rally*”, “*tennis rally*”), and a riot can refer to something funny (e.g., “*she’s a riot*”). Event keywords also appear in general discussions that do not mention a specific event (e.g., “*37 states prohibit teacher strikes*” or “*The fine for inciting a riot is \$1,000*”). Furthermore, many relevant documents are not easy to recognize because events can be described with complex expressions that do not include event keywords. For example, “*took to the streets*”, “*walked off their jobs*” and “*stormed parliament*” often describe civil unrest.

The goal of our research is to recognize event descriptions in text by identifying event expressions as well as defining characteristics of the event. We propose that *agents* and *purpose* are characteristics of an event that are essential to distinguish one type of event from another. The agent responsible for an action often determines how we categorize the action. For example, natural disasters, military operations, and terrorist attacks can all produce human casualties and physical destruction. But the agent of a natural disaster must be a natural force, the agent of a military incident must be military personnel, and the agent of a terrorist attack is never a natural force and rarely military personnel. There may be other important factors as well, but the agent is often an essential part of an event definition.

The purpose of an event is also a crucial factor in distinguishing between event types. For exam-

ple, civil unrest events and sporting events both involve large groups of people amassing at a specific site. But the purpose of civil unrest gatherings is to protest against socio-political problems, while sporting events are intended as entertainment. As another example, terrorist events and military incidents can both cause casualties, but the purpose of terrorism is to cause widespread fear, while the purpose of military actions is to protect national security interests.

Our research explores the idea of *multi-faceted event recognition*: using event expressions as well as facets of the event (agents and purpose) to identify documents about a specific type of event. We present a bootstrapping framework to automatically create event phrase, agent, and purpose dictionaries. The learning process uses unannotated texts, a few event keywords, and seed terms for common agents and purpose phrases associated with the event type.

Our bootstrapping algorithm exploits the observation that event expressions, agents, and purpose phrases often appear together in sentences that introduce an event. In the first step, we extract event expressions based on dependency relations with an agent and purpose phrase. The harvested event expressions are added to an event phrase dictionary. In the second step, new agent terms are extracted from sentences containing an event phrase and a purpose phrase, and new purpose phrases are harvested from sentences containing an event phrase and an agent. These harvested terms are added to agent and purpose dictionaries. The bootstrapping algorithm ricochets back and forth, alternately learning new event phrases and learning new agent/purpose phrases, in an iterative process.

We explore several ways of using these bootstrapped dictionaries. We conclude that finding at least two different types of event information produces high accuracy (88% precision) with good recall (71%) on documents that contain an event keyword. We also present experiments with documents that do not contain event keywords, and obtain 74% accuracy when matching all three types of event information.

2 Related Work

Event recognition has been studied in several different contexts. There has been a lot of research

on event extraction, where the goal is to extract facts about events from text (e.g., (ACE Evaluations, 2006; Appelt et al., 1993; Riloff, 1996; Yangarber et al., 2000; Chieu and Ng, 2002; Califf and Mooney, 2003; Sudo et al., 2003; Stevenson and Greenwood, 2005; Sekine, 2006)). Although our research does not involve extracting facts, event extraction systems can also be used to identify stories about a specific type of event. For example, the MUC-4 evaluation (MUC-4 Proceedings, 1992) included “text filtering” results that measured the performance of event extraction systems at identifying event-relevant documents. The best text filtering results were high (about 90% F score), but relied on hand-built event extraction systems. More recently, some research has incorporated event region detectors into event extraction systems to improve extraction performance (Gu and Cercone, 2006; Patwardhan and Riloff, 2007; Huang and Riloff, 2011).

There has been recent work on event detection from social media sources (Becker et al., 2011; Popescu et al., 2011). Some research identifies specific types of events in tweets, such as earthquakes (Sakaki et al., 2010) and entertainment events (Benson et al., 2011). There has also been work on event trend detection (Lampos et al., 2010; Mathioudakis and Koudas, 2010) and event prediction through social media, such as predicting elections (Tumasjan et al., 2010; Conover et al., 2011) or stock market indicators (Zhang et al., 2010). (Ritter et al., 2012) generated a calendar of events mentioned on twitter. (Metzler et al., 2012) proposed structured retrieval of historical event information over microblog archives by distilling high quality event representations using a novel temporal query expansion technique.

Some text classification research has focused on event categories. (Riloff and Lehnert, 1994) used an information extraction system to generate *relevancy signatures* that were indicative of different event types. This work originally relied on manually labeled patterns and a hand-crafted semantic dictionary. Later work (Riloff and Lorenzen, 1999) eliminated the need for the dictionary and labeled patterns, but still assumed the availability of relevant/irrelevant training texts.

Event recognition is also related to Topic Detection and Tracking (TDT) (Allan et al., 1998; Allan,

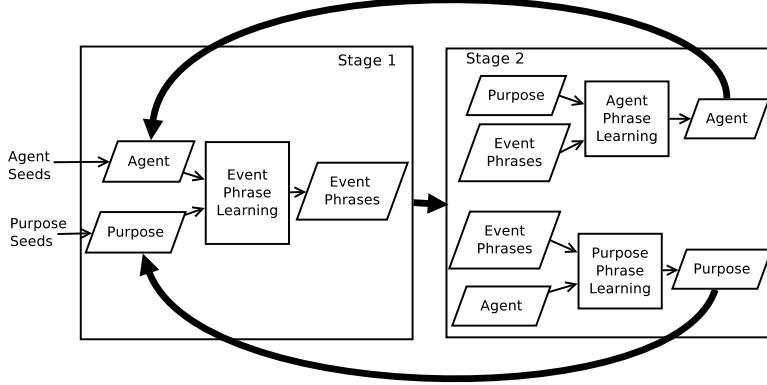

Figure 1: Bootstrapped Learning of Event Dictionaries

2002) which addresses event-based organization of a stream of news stories. Event recognition is similar to New Event Detection, also called First Story Detection, which is considered the most difficult TDT task (Allan et al., 2000a). Typical approaches reduce documents to a set of features, either as a word vector (Allan et al., 2000b) or a probability distribution (Jin et al., 1999), and compare the incoming stories to stories that appeared in the past by computing similarities between their feature representations. Recently, event paraphrases (Petrovic et al., 2012) have been explored to deal with the diversity of event descriptions. However, the New Event Detection task differs from our event recognition task because we want to find all stories describing a certain type of event, not just new events.

3 Bootstrapped Learning of Event Dictionaries

Our bootstrapping approach consists of two stages of learning as shown in Figure 1. The process begins with a few agent seeds, purpose phrase patterns, and unannotated articles selected from a broad-coverage corpus using event keywords. In the first stage, event expressions are harvested from the sentences that have both an agent and a purpose phrase in specific syntactic positions. In the second stage, new purpose phrases are harvested from sentences that contain both an event phrase and an agent, while new agent terms are harvested from sentences that contain both an event phrase and a purpose phrase. The new terms are added to growing event dictionaries, and the bootstrapping process repeats. Our work

focuses on civil unrest events.

3.1 Stage 1: Event Phrase Learning

We first extract potential civil unrest stories from the English Gigaword corpus (Parker et al., 2011) using six civil unrest keywords. As explained in Section 1, event keywords are not sufficient to obtain relevant documents with high precision, so the extracted stories are a mix of relevant and irrelevant articles. Our algorithm first selects sentences to use for learning, and then harvests event expressions from them.

3.1.1 Event Sentence Identification

The input in stage 1 consists of a few agent terms and purpose patterns for seeding. The agent seeds are single nouns, while the purpose patterns are verbs in infinitive or present participle forms. Table 1 shows the agent terms and purpose phrases used in our experiments. The agent terms were manually selected by inspecting the most frequent nouns in the documents with civil unrest keywords. The purpose patterns are the most common verbs that describe the reason for a civil unrest event. We identify *probable event sentences* by extracting all sentences that contain at least one agent term and one purpose phrase.

Agents	protesters, activists, demonstrators, students, groups, crowd, workers, palestinians, supporters, women
Purpose Phrases	demanding, to demand, protesting, to protest

Table 1: Agent and Purpose Phrases Used for Seeding

3.1.2 Harvesting Event Expressions

To constrain the learning process, we require event expressions and purpose phrases to match certain syntactic structures. We apply the Stanford dependency parser (Marneffe et al., 2006) to the probable event sentences to identify verb phrase candidates and to enforce syntactic constraints between the different types of event information.

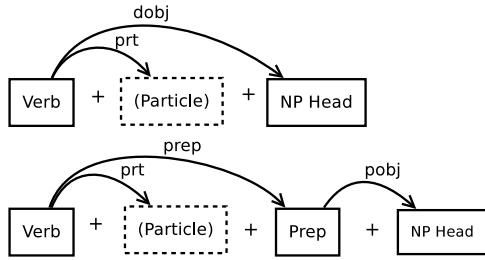

Figure 2: Phrasal Structure of Event & Purpose Phrases

Figure 2 shows the two types of verb phrases that we learn. One type consists of a verb paired with the head noun of its direct object. For example, event phrases can be “*stopped work*” or “*occupied offices*”, and purpose phrases can be “*show support*” or “*condemn war*”. The second type consists of a verb and an attached prepositional phrase, retaining only the head noun of the embedded noun phrase. For example, “*took to street*” and “*scuffled with police*” can be event phrases, while “*call for resignation*” and “*press for wages*” can be purpose phrases. In both types of verb phrases, a particle can optionally follow the verb.

Event expressions, agents, and purpose phrases must appear in specific dependency relations, as illustrated in Figure 3. An agent must be the syntactic subject of the event phrase. A purpose phrase must be a complement of the event phrase, specifically, we require a particular dependency relation, “xcomp”¹, between the two verb phrases. For example, in the sentence “*Leftist activists took to the streets in the Nepali capital Wednesday protesting higher fuel prices.*”, the dependency relation

¹In the dependency parser, “xcomp” denotes a general relation between a VP or an ADJP and its open clausal complement. For example, in the sentence “*He says that you like to swim.*”, the “xcomp” relation will link “like” (head) and “swim” (dependent). With our constraints on the verb phrase forms, the dependent verb phrase in this construction tends to describe the purpose of the verb phrase.

“xcomp” links “*took to the streets*” with “*protesting higher fuel prices*”.

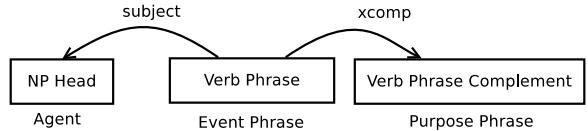

Figure 3: Syntactic Dependencies between Agents, Event Phrases, and Purpose Phrases

Given the syntactic construction shown in Figure 3, with a known agent and purpose phrase, we extract the head verb phrase of the “xcomp” dependency relation as an event phrase candidate. The event phrases that co-occur with at least two unique agent terms and two unique purposes phrases are saved in our event phrase dictionary.

3.2 Stage 2: Learning Agent and Purpose Phrases

In the second stage of bootstrapping, we learn new agent terms and purpose phrases. Our rationale is that if a sentence contains an event phrase and one other important facet of the event (agent or purpose), then the sentence probably describes a relevant event. We can then look for additional facets of the event in the same sentence. We learn both agent and purpose phrases simultaneously in parallel learning processes. As before, we first identify probable event sentences and then harvest agent and purpose phrases from these sentences.

3.2.1 Event Sentence Identification

We identify probable event sentences by extracting sentences that contain at least one event phrase (based on the dictionary produced in the first stage of bootstrapping) and an agent term or a purpose phrase. As before, the event information must occur in the sentential dependency structures shown in Figure 3.

3.2.2 Harvesting Agent and Purpose Phrases

The sentences that contain an event phrase and an agent are used to harvest more purpose phrases, while the sentences that contain an event phrase and a purpose phrase are used to harvest more agent terms. Purpose phrases are extracted from the phrasal structures shown in Figure 2. In the learning process for agents, if a sentence has an event

phrase as the head of the “xcomp” dependency relation and a purpose phrase as the dependent clause of the “xcomp” dependency relation, then the head noun of the syntactic subject of the event phrase is harvested as a candidate agent term. We also record the modifiers appearing in all of the noun phrases headed by an agent term. Agent candidates that co-occur with at least two unique event phrases and at least two different modifiers of known agent terms are selected as new agent terms.

The learning process for purpose phrases is analogous. If the syntactic subject of an event phrase is an agent and the event phrase is the head of the “xcomp” dependency relation, then the dependent clause of the “xcomp” dependency relation is harvested as a candidate purpose phrase. Purpose phrase candidates that co-occur with at least two different event phrases are selected as purpose phrases.

The bootstrapping process then repeats, ricocheting back and forth between learning event phrases and learning agent and purpose phrases.

3.3 Domain Relevance Criteria

To avoid domain drift during bootstrapping, we use two additional criteria to discard phrases that are not necessarily associated with the domain.

For each event phrase and purpose phrase, we estimate its *domain-specificity* as the ratio of its prevalence in domain-specific texts compared to broad-coverage texts. The goal is to discard phrases that are common across many types of documents, and therefore not specific to the domain. We define the domain-specificity of phrase p as:

$$\text{domain-specificity}(p) = \frac{\text{frequency of } p \text{ in domain-specific corpus}}{\text{frequency of } p \text{ in broad-coverage corpus}}$$

We randomly sampled 10% of the Gigaword texts that contain a civil unrest event keyword to create the “domain-specific” corpus, and randomly sampled 10% of the remaining Gigaword texts to create the “broad-coverage” corpus.² Keyword-based sampling is an approximation to domain-relevance, but gives us a general idea about the prevalence of a phrase in different types of texts.

For agent terms, our goal is to identify people who participate as agents of civil unrest events. Other types of people may be commonly mentioned in civil unrest stories too, as peripheral characters. For

²The random sampling was simply for efficiency reasons.

example, police may provide security and reporters may provide media coverage of an event, but they are not the agents of the event. We estimate the *event-specificity* of each agent term as the ratio of the phrase’s prevalence in event sentences compared to all the sentences in the domain-specific corpus. We define an event sentence as one that contains both a learned event phrase and a purpose phrase, based on the dictionaries at that point in time. Therefore, the number of event sentences increases as the bootstrapped dictionaries grow. We define the event-specificity of phrase p as:

$$\text{event-specificity}(p) = \frac{\text{frequency of } p \text{ in event sentences}}{\text{frequency of } p \text{ in all sentences}}$$

In our experiments we required event and purpose phrases to have *domain-specificity* $\geq .33$ and agent terms to have *event-specificity* $\geq .01$.³

4 Evaluation

4.1 Data

We conducted experiments to evaluate the performance of our bootstrapped event dictionaries for recognizing civil unrest events. Civil unrest is a broad term typically used by the media or law enforcement to describe a form of public disturbance that involves a group of people, usually to protest or promote a cause. Civil unrest events include strikes, protests, occupations, rallies, and similar forms of obstructions or riots. We chose six *event keywords* to identify potential civil unrest documents: “protest”, “strike”, “march”, “rally”, “riot” and “occupy”. We extracted documents from the English Gigaword corpus (Parker et al., 2011) that contain at least one of these event keywords, or a morphological variant of a keyword.⁴ This process extracted nearly one million documents, which we will refer to as our *event-keyword corpus*.

We randomly sampled 400 documents⁵ from the event-keyword corpus and asked two annotators to determine whether each document mentioned a civil

³This value is so small because we simply want to filter phrases that virtually never occur in the event sentences, and we can recognize very few event sentences in the early stages of bootstrapping.

⁴We used “marched” and “marching” as keywords but did not use “march” because it often refers to a month.

⁵These 400 documents were excluded from the unannotated data used for dictionary learning.

unrest event. We defined annotation guidelines and conducted an inter-annotator agreement study on 100 of these documents. The annotators achieved a κ score of .82. We used these 100 documents as our *tuning set*. Then each annotator annotated 150 more documents to create our *test set* of 300 documents.

4.2 Baselines

The first row of Table 2 shows event recognition accuracy when only the event keywords are used. All of our documents were obtained by searching for a keyword, but only 101 of the 300 documents in our test set were labeled as relevant by the annotators (i.e., 101 describe a civil unrest event). This means that using only the event keywords to identify civil unrest documents yields about 34% precision. In a second experiment, **KeywordTitle**, we required the event keyword to be in the title (headline) of the document. The KeywordTitle approach produced better precision (66%), but only 33% of the relevant documents had a keyword in the title.

Method	Recall	Precision	F
<i>Keyword Accuracy</i>			
Keyword	-	34	-
KeywordTitle	33	66	44
<i>Supervised Learning</i>			
Unigrams	62	66	64
Unigrams+Bigrams	55	71	62
<i>Bootstrapped Dictionary Lookup</i>			
Event Phrases (EV)	60	79	69
Agent Phrases (AG)	98	42	59
Purpose Phrases (PU)	59	67	63
All Pairs	71	88	79

Table 2: Experimental Results

The second section of Table 2 shows the results of two supervised classifiers based on 10-fold cross validation with our test set. Both classifiers were trained using support vector machines (SVMs) (Joachims, 1999) with a linear kernel (Keerthi and DeCoste, 2005). The first classifier used unigrams as features, while the second classifier used both unigrams and bigrams. All the features are binary. The evaluation results show that the unigram classifier has an F-score of .64. Using both unigram and bigram features increased precision to 71% but recall fell by 7%, yielding a slightly lower F-score of .62.

4.3 Event Recognition with Bootstrapped Dictionaries

Next, we used our bootstrapped dictionaries for event recognition. The bootstrapping process ran for 8 iterations and then stopped because no more phrases could be learned. The quality of bootstrapped data often degrades as bootstrapping progresses, so we used the tuning set to evaluate the dictionaries after each iteration. The best performance⁶ on the tuning set resulted from the dictionaries produced after four iterations, so we used these dictionaries for our experiments. Table 3 shows the

	Event Phrases	Agent Terms	Purpose Phrases
Iter #1	145	67	124
Iter #2	410	106	356
Iter #3	504	130	402
Iter #4	623	139	569

Table 3: Dictionary Sizes after Several Iterations

number of event phrases, agents and purpose phrases learned after each iteration. All three lexicons were significantly enriched after each iteration. The final bootstrapped dictionaries contain 623 event phrases, 569 purpose phrases and 139 agent terms. Table 4 shows samples from each event dictionary.

Event Phrases: went on strike, took to street, chanted slogans, gathered in capital, formed chain, clashed with police, staged rally, held protest, walked off job, burned flags, set fire, hit streets, marched in city, blocked roads, carried placards
Agent Terms: employees, miners, muslims, unions, protestors, journalists, refugees, prisoners, immigrants, inmates, pilots, farmers, followers, teachers, drivers
Purpose Phrases: accusing government, voice anger, press for wages, oppose plans, urging end, defying ban, show solidarity, mark anniversary, calling for right, condemning act, pressure government, mark death, push for hike, call attention, celebrating withdrawal

Table 4: Examples of Dictionary Entries

The third section of Table 2 shows the results when using the bootstrapped dictionaries for event recognition. We used a simple dictionary look-up approach that searched for dictionary entries in each document. Our phrases were generated based on

⁶Based on the performance for the **All Pairs** approach.

syntactic analysis and only head words were retained for generality. But we wanted to match dictionary entries without requiring syntactic analysis of new documents. So we used an approximate matching scheme that required each word to appear within 5 words of the previous word. For example, “held protest” would match “held a large protest” and “held a very large political protest”. In this way, we avoid the need for syntactic analysis when using the dictionaries for event recognition.

First, we labeled a document as relevant if it contained any Event Phrase (EV) in our dictionary. The event phrases achieved better performance than all of the baselines, yielding an F-score of 69%. The best baseline was the unigram classifier, which was trained with supervised learning. The bootstrapped event phrase dictionary produced much higher precision (79% vs. 66%) with only slightly lower recall (60% vs. 62%), and did not require annotated texts for training. Statistical significance testing shows that the Event Phrase lookup approach works significantly better than the unigram classifier ($p < 0.05$, paired bootstrap (Berg-Kirkpatrick et al., 2012)).

For the sake of completeness, we also evaluated the performance of dictionary look-up using our bootstrapped Agent (AG) and Purpose (PU) dictionaries, individually. The agents terms produced 42% precision with 98% recall, demonstrating that the learned agent list has extremely high coverage but (unsurprisingly) does not achieve high precision on its own. The purpose phrases achieved a better balance of recall and precision, producing an F-score of 63%, which is nearly the same as the supervised unigram classifier.

Our original hypothesis was that a single type of event information is not sufficient to accurately identify event descriptions. Our goal was high-accuracy event recognition by requiring that a document contain multiple clues pertaining to different facets of an event (*multi-faceted event recognition*). The last row of Table 2 (**All Pairs**) shows the results when requiring matches from at least two different bootstrapped dictionaries. Specifically, we labeled a document as relevant if it contained at least one phrase from each of two different dictionaries and these phrases occurred in the same sentence. Table 2 shows that multi-faceted event recognition achieves 88% precision with reasonably good recall of 71%, yielding an

F-score of 79%. This multi-faceted approach with simple dictionary look-up outperformed all of the baselines, and each dictionary used by itself. Statistical significance testing shows that the All Pairs approach works significantly better than the unigram classifier ($p < 0.001$, paired bootstrap). The All Pairs approach is significantly better than the Event Phrase (EV) lookup approach at the $p < 0.1$ level.

Method	Recall	Precision	F-score
EV + PU	14	100	24
EV + AG	47	94	62
AG + PU	50	85	63
All Pairs	71	88	79

Table 5: Analysis of Dictionary Combinations

Table 5 takes a closer look at how each pair of dictionaries performed. The first row shows that requiring a document to have an event phrase and a purpose phrase produces the best precision (100%) but with low recall (14%). The second row reveals that requiring a document to have an event phrase and an agent term yields better recall (47%) and high precision (94%). The third row shows that requiring a document to have a purpose phrase and an agent term produces the best recall (50%) but with slightly lower precision (85%). Finally, the last row of Table 5 shows that taking the union of these results (i.e., any combination of dictionary pairs is sufficient) yields the best recall (71%) with high precision (88%), demonstrating that we get the best coverage by recognizing multiple combinations of event information.

Lexicon	Recall	Precision	F-score
Seeds	13	87	22
Iter #1	50	88	63
Iter #2	63	89	74
Iter #3	68	88	77
Iter #4	71	88	79

Table 6: **All Pairs** Lookup Results using only Seeds and the Lexicons Learned after each Iteration, on the Test Set

Table 6 shows the performance of the lexicon lookup approach using the **All Pairs** criteria during the bootstrapping process. The first row shows the results using only 10 agent seeds and 4 purpose seeds as shown in Table 1. The following four rows in the table show the performance of **All Pairs** using

the lexicons learned after each bootstrapping iteration. We can see that the recall increases steadily and that precision is maintained at a high level throughout the bootstrapping process.

Event recognition can be formulated as an information retrieval (IR) problem. As another point of comparison, we ran an existing IR system, Terrier (Ounis et al., 2007), on our test set. We used Terrier to rank these 300 documents given our set of event keywords as the query⁷, and then generated a recall/precision curve (Figure 4) by computing the precisions at different levels of recall, ranging from 0 to 1 in increments of .10. Terrier was run with the

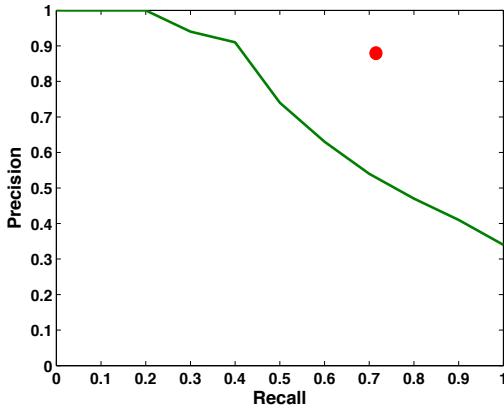

Figure 4: Comparison with the Terrier IR system

parameter PL2 which refers to an advanced Divergence From Randomness weighting model (Amati and Van Rijsbergen, 2002). In addition, Terrier used automatic query expansion. We can see that Terrier identified the first 60 documents (20% recall) with 100% precision. But precision dropped sharply after that. The circle in Figure 4 shows the performance of our bootstrapped dictionaries using the **All Pairs** approach. At comparable level of precision (88%), Terrier achieved about 45% recall versus 71% recall produced with the bootstrapped dictionaries.

4.4 Supervised Classifiers with Bootstrapped Dictionaries

We also explored the idea of using the bootstrapped dictionaries as features for a classifier to see if a supervised learner could make better use of the dic-

⁷We gave Terrier one query with all of the event keywords.

tionaries. We created five SVM classifiers and performed 10-fold cross validation on the test set.

Method	Recall	Precision	F-score

PairSets	68	84	75
AllSets	70	84	76

Table 7: Supervised classifiers using the dictionaries

Table 7 shows the results for the five classifiers. **TermLex** encodes a binary feature for every phrase in any of our dictionaries. **PairLex** encodes a binary feature for each pair of phrases from two different dictionaries and requires them to occur in the same sentence. The TermLex classifier achieves good performance (74% F-score), but is not as effective as our All Pairs dictionary look-up approach (79% F-score). The PairLex classifier yield higher precision but very low recall, undoubtedly due to sparsity issues in matching specific pairs of phrases.

One of the strengths of our bootstrapping method is that it creates dictionaries from large volumes of unannotated documents. A limitation of supervised learning with lexical features is that the classifier can not benefit from terms in the bootstrapped dictionaries that do not appear in its training documents. To address this issue, we also tried encoding the dictionaries as set-based features. The **TermSets** classifier encodes three binary features, one for each dictionary. A feature gets a value of 1 if a document contains any word in the corresponding dictionary. The **PairSets** classifier also encodes three binary features, but each feature represents a different pair of dictionaries (EV+AG, EV+PU, or AG+PU). A feature gets a value of 1 if a document contains at least one term from each of the two dictionaries in the same sentence. The **AllSets** classifier encodes 7 set-based features: the previous six features and one additional feature that requires a sentence to contain at least one entry from all three dictionaries.

The **All Sets** classifier yields the best performance with an F-score of 76%. However, our straightforward dictionary look-up approach still performs better (79% F-score), and does not require annotated documents for training.

4.5 Finding Articles with no Event Keyword

The learned event dictionaries have the potential to recognize event-relevant documents that do not contain any human-selected event keywords. This can happen in two ways. First, 378 of the 623 learned event phrases do not contain any of the original event keywords. Second, we expect that some event descriptions will contain a known agent and purpose phrase, even if the event phrase is unfamiliar.

We performed an additional set of experiments with documents in the Gigaword corpus that contain no human-selected civil unrest keyword. Following our multi-faceted approach to event recognition, we collected all documents that contain a sentence that matches phrases in at least two of our bootstrapped event dictionaries. This process retrieved 178,197 documents. The first column of Table 8 shows the number of documents that had phrases found in two different dictionaries (EV+AG, EV+PU, AG+PU) or in all three dictionaries (EV+AG+PU).

	Total	Samples	Accuracy
EV+AG	67,796	50	44%
EV+PU	2,375	50	54%
AG+PU	101,173	50	18%
EV+AG+PU	6,853	50	74%

Table 8: Evaluation of articles with no event keyword

We randomly sampled 50 documents from each category and had them annotated. The accuracies are shown in the third column. Finding all three types of phrases produced the best accuracy, 74%. Furthermore, we found over 6,800 documents that had all three types of event information using our learned dictionaries. This result demonstrates that the bootstrapped dictionaries can recognize many event descriptions that would have been missed by searching only with manually selected keywords. This experiment also confirms that multi-faceted event recognition using all three learned dictionaries achieves good accuracy even for documents that do not contain the civil unrest keywords.

5 Conclusions

We proposed a *multi-faceted* approach to event recognition and presented a bootstrapping technique to learn event phrases as well as agent terms and

purpose phrases associated with civil unrest events. Our results showed that *multi-faceted event recognition* using the learned dictionaries achieved high accuracy and performed better than several other methods. The bootstrapping approach can be easily trained for new domains since it requires only a large collection of unannotated texts and a few event keywords, agent terms, and purpose phrases for the events of interest. Furthermore, although the training phase requires syntactic parsing to learn the event dictionaries, the dictionaries can then be used for event recognition without needing to parse the documents.

An open question for future work is to investigate whether the same multi-faceted approach to event recognition will work well for other types of events. Our belief is that many different types of events have characteristic agent terms, but additional types of facets will need to be defined to cover a broad array of event types. The syntactic constructions used to harvest dictionary items may also vary depending on the types of event information that must be learned. In future research, we plan to explore these issues in more depth to design a more general multi-faceted event recognition system, and we plan to investigate new ways to use these event dictionaries for event extraction as well.

Abstract

Different languages contain complementary cues about entities, which can be used to improve Named Entity Recognition (NER) systems. We propose a method that formulates the problem of exploring such signals on unannotated bilingual text as a simple Integer Linear Program, which encourages entity tags to agree via bilingual constraints. Bilingual NER experiments on the large OntoNotes 4.0 Chinese-English corpus show that the proposed method can improve strong baselines for both Chinese and English. In particular, Chinese performance improves by over 5% absolute F₁ score. We can then annotate a large amount of bilingual text (80k sentence pairs) using our method, and add it as up-training data to the original monolingual NER training corpus. The Chinese model retrained on this new combined dataset outperforms the strong baseline by over 3% F₁ score.

1 Introduction

Named Entity Recognition (NER) is an important task for many applications, such as information extraction and machine translation. State-of-the-art supervised NER methods require large amounts of annotated data, which are difficult and expensive to produce manually, especially for resource-poor languages.

A promising approach for improving NER performance without annotating more data is to exploit unannotated bilingual text (bitext), which are relatively easy to obtain for many language pairs, borrowing from the resources made available by statis-

tical machine translation research.¹ Different languages contain complementary cues about entities. For example, in Figure 1, the word “本 (Ben)” is common in Chinese but rarely appears as a translated foreign name. However, its aligned word on the English side (“Ben”) provides a strong clue that this is a person name. Judicious use of this type of bilingual cues can help to recognize errors a monolingual tagger would make, allowing us to produce more accurately tagged bitext. Each side of the tagged bitext can then be used to expand the original monolingual training dataset, which may lead to higher accuracy in the monolingual taggers.

Previous work such as Li et al. (2012) and Kim et al. (2012) demonstrated that bilingual corpus annotated with NER labels can be used to improve monolingual tagger performance. But a major drawback of their approaches are the need for manual annotation efforts to create such corpora. To avoid this requirement, Burkett et al. (2010) suggested a “multi-view” learning scheme based on re-ranking. Noisy output of a “strong” tagger is used as training data to learn parameters of a log-linear re-ranking model with additional bilingual features, simulated by a “weak” tagger. The learned parameters are then reused with the “strong” tagger to re-rank its own outputs for unseen inputs. Designing good “weak” taggers so that they complement the “view” of bilingual features in the log-linear re-ranker is crucial to the success of this algorithm. Unfortunately there is no principled way of designing such “weak” taggers.

In this paper, we would like to explore a conceptually much simpler idea that can also take advantage

¹opus.lingfil.uu.se

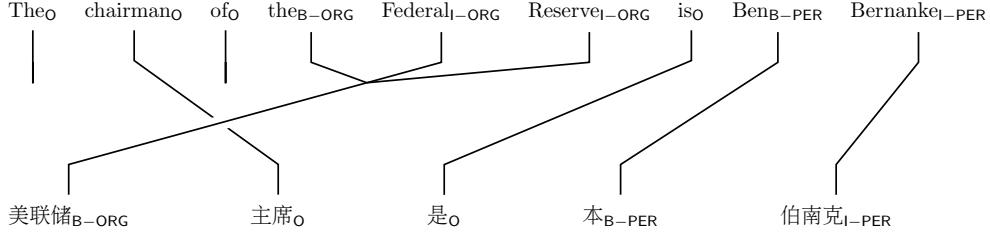

Figure 1: Example of NER labels between two word-aligned bilingual parallel sentences.

of the large amount of unannotated bitext, without complicated machinery. More specifically, we introduce a joint inference method that formulates the bilingual NER tagging problem as an Integer Linear Program (ILP) and solves it during decoding. We propose a set of intuitive and effective bilingual constraints that encourage NER results to agree across the two languages.

Experimental results on the OntoNotes 4.0 named entity annotated Chinese-English parallel corpus show that the proposed method can improve the strong Chinese NER baseline by over 5% F₁ score and also give small improvements over the English baseline. Moreover, by adding the automatically tagged data to the original NER training corpus and retraining the monolingual model using an up-training regimen (Petrov et al., 2010), we can improve the monolingual Chinese NER performance by over 3% F₁ score.

2 Constraint-based Monolingual NER

NER is a sequence labeling task where we assign a named entity tag to each word in an input sentence. One commonly used tagging scheme is the BIO scheme. The tag B-X (Begin) represents the first word of a named entity of type X, for example, PER (Person) or LOC (Location). The tag I-X (Inside) indicates that a word is part of an entity but not first word. The tag O (Outside) is used for all non-entity words.² See Figure 1 for an example tagged sentence.

Conditional Random Fields (CRF) (Lafferty et al., 2001) is a state-of-the-art sequence labeling model widely used in NER. A first-order linear-chain CRF

defines the following conditional probability:

$$P_{CRF}(\mathbf{y}|\mathbf{x}) = \frac{1}{Z(\mathbf{x})} \prod_i M_i(y_i, y_{i-1}|\mathbf{x}) \quad (1)$$

where \mathbf{x} and \mathbf{y} are the input and output sequences, respectively, $Z(\mathbf{x})$ is the partition function, and M_i is the clique potential for edge clique i . Decoding in CRF involves finding the most likely output sequence that maximizes this objective, and is commonly done by the Viterbi algorithm.

Roth and Yih (2005) proposed an ILP inference algorithm, which can capture more task-specific and global constraints than the vanilla Viterbi algorithm. Our work is inspired by Roth and Yih (2005). But instead of directly solving the shortest-path problem in the ILP formulation, we re-define the conditional probability as:

$$P_{MAR}(\mathbf{y}|\mathbf{x}) = \prod_i P(y_i|\mathbf{x}) \quad (2)$$

where $P(y_i|\mathbf{x})$ is the marginal probability given by an underlying CRF model computed using *forward-backward* inference. Since the early HMM literature, it has been well known that using the marginal distributions at each position works well, as opposed to Viterbi MAP sequence labeling (Mérialdo, 1994). Our experimental results also supports this claim, as we will show in Section 6. Our objective is to find an optimal NER tag sequence:

$$\begin{aligned} \hat{\mathbf{y}} &= \arg \max_{\mathbf{y}} P_{MAR}(\mathbf{y}|\mathbf{x}) \\ &= \arg \max_{\mathbf{y}} \sum_i \log P(y_i|\mathbf{x}) \end{aligned} \quad (3)$$

Then an ILP can be used to solve the inference problem as classification problem with constraints.

²While the performance of NER is measured at the entity level (not the tag level).

The objective function is:

$$\max \sum_{i=1}^{|x|} \sum_{y \in Y} z_i^y \log P_i^y \quad (4)$$

where Y is the set of all possible named entity tags. $P_i^y = P(y_i = y | \mathbf{x})$ is the CRF marginal probability that the i^{th} word is tagged with y , and z_i^y is an indicator that equals 1 iff the i^{th} word is tagged y ; otherwise, z_i^y is 0.

If no constraints are identified, then Eq. (4) achieves maximum when all z_i^y are assigned to 1, which violates the condition that each word should only be assigned a single entity tag. We can express this with constraints:

$$\forall i : \sum_{y \in Y} z_i^y = 1 \quad (5)$$

After adding the constraints, the probability of the sequence is maximized when each word is assigned the tag with highest probability. However, some invalid results may still exist. For example a tag O may be wrongly followed by a tag I-X, although a named entity cannot start with I-X. Therefore, we can add the following constraints:

$$\forall i, \forall X : z_{i-1}^{B-X} + z_{i-1}^{I-X} - z_i^{I-X} \geq 0 \quad (6)$$

which specifies that when the i^{th} word is tagged with I-X ($z_i^{I-X} = 1$), then the previous word can only be tagged with B-X or I-X ($z_{i-1}^{B-X} + z_{i-1}^{I-X} \geq 1$).

3 NER with Bilingual Constraints

This section demonstrates how to jointly perform NER for two languages with bilingual constraints. We assume sentences have been aligned into pairs, and the word alignment between each pair of sentences is also given.

3.1 Hard Bilingual Constraints

We first introduce the simplest *hard* constraints, i.e., each word alignment pair should have the same named entity tag. For example, in Figure 1, the Chinese word “美联储” was aligned with the English words “the”, “Federal” and “Reserve”. Therefore, they have the same named entity tags ORG.³

³The prefix B- and I- are ignored.

Similarly, “本” and “Ben” as well as “伯南克” and “Bernanke” were all tagged with the tag PER.

The objective function for bilingual NER can be expressed as follows:

$$\max \sum_{i=1}^{|x_c|} \sum_{y \in Y} z_i^y \log P_i^y + \sum_{j=1}^{|x_e|} \sum_{y \in Y} z_j^y \log P_j^y \quad (7)$$

where P_i^y and P_j^y are the probabilities of the i^{th} Chinese word and j^{th} English word to be tagged with y , respectively. \mathbf{x}_c and \mathbf{x}_e are respectively the Chinese and English sentences.

Similar to monolingual constrained NER (Section 2), monolingual constraints are added for each language as shown in Eqs. (8) and (9):

$$\forall i : \sum_{y \in Y} z_i^y = 1; \forall j : \sum_{y \in Y} z_j^y = 1 \quad (8)$$

$$\begin{aligned} \forall i, \forall X : z_i^{B-X} + z_i^{I-X} - z_{i+1}^{B-X} &\geq 0 \\ \forall j, \forall X : z_j^{B-X} + z_j^{I-X} - z_{j+1}^{B-X} &\geq 0 \end{aligned} \quad (9)$$

Bilingual constraints are added in Eq. (10):

$$\forall (i, j) \in A, \forall X : z_i^{B-X} + z_i^{I-X} = z_j^{B-X} + z_j^{I-X} \quad (10)$$

where $A = \{(i, j)\}$ is the word alignment pair set, i.e., the i^{th} Chinese word and the j^{th} English word were aligned together. Chinese word i is tagged with a named entity type X ($z_i^{B-X} + z_i^{I-X} = 1$), iff English word j is tagged with X ($z_j^{B-X} + z_j^{I-X} = 1$). Therefore, these *hard* bilingual constraints guarantee that when two words are aligned, they are tagged with the same named entity tag.

However, in practice, aligned word pairs do not always have the same tag because of the difference in annotation standards across different languages. For example, in Figure 2(a), the Chinese word “开发区” is a location. However, it is aligned to the words, “development” and “zone”, which are not named entities in English. Word alignment error is another serious problem that can cause violation of hard constraints. In Figure 2(b), the English word “Agency” is wrongly aligned with the Chinese word “电 (report)”. Thus, these two words cannot be assigned with the same tag.

To address these two problems, we present a probabilistic model for bilingual NER which can lead to

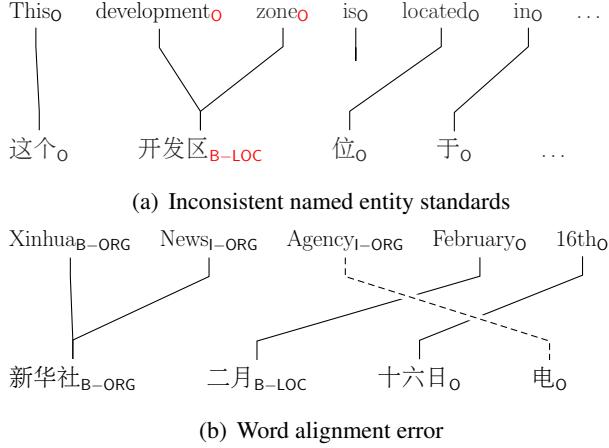

Figure 2: Errors of hard bilingual constraints method.

an optimization problem with two *soft* bilingual constraints:

- 1) allow word-aligned pairs to have different named entity tags; 2) consider word alignment probabilities to reduce the influence of wrong word alignments.

3.2 Soft Constraints with Tag Uncertainty

The new probabilistic model for bilingual NER is:

$$\begin{aligned} P(\mathbf{y}_c, \mathbf{y}_e | \mathbf{x}_c, \mathbf{x}_e, A) &= \frac{P(\mathbf{y}_c, \mathbf{y}_e, \mathbf{x}_c, \mathbf{x}_e, A)}{P(\mathbf{x}_c, \mathbf{x}_e, A)} \\ &= \frac{P(\mathbf{y}_c, \mathbf{x}_c, \mathbf{x}_e, A)}{P(\mathbf{x}_c, \mathbf{x}_e, A)} \cdot \frac{P(\mathbf{y}_e, \mathbf{x}_c, \mathbf{x}_e, A)}{P(\mathbf{x}_c, \mathbf{x}_e, A)} \\ &\quad \cdot \frac{P(\mathbf{y}_c, \mathbf{y}_e, \mathbf{x}_c, \mathbf{x}_e, A)P(\mathbf{x}_c, \mathbf{x}_e, A)}{P(\mathbf{y}_c, \mathbf{x}_c, \mathbf{x}_e, A)P(\mathbf{y}_e, \mathbf{x}_c, \mathbf{x}_e, A)} \end{aligned} \quad (11)$$

$$\approx P(\mathbf{y}_c | \mathbf{x}_c)P(\mathbf{y}_e | \mathbf{x}_e) \frac{P(\mathbf{y}_c, \mathbf{y}_e | A)}{P(\mathbf{y}_c | A)P(\mathbf{y}_e | A)} \quad (12)$$

where \mathbf{y}_c and \mathbf{y}_e respectively denotes Chinese and English named entity output sequences. A is the set of word alignment pairs.

If we assume that named entity tag assignments in Chinese is only dependent on the observed Chinese sentence, then we can drop the A and \mathbf{x}_e term in the first factor of Eq. (11), and arrive at the first factor of Eq. (12); similarly we can use the same assumption to derive the second factor in Eq. (12) for English; alternatively, if we assume the named entity tag assignments are only dependent on the cross-lingual word associations via word alignment, then we can drop \mathbf{x}_c and \mathbf{x}_e terms in the third factor of Eq. (11)

and arrive at the third factor of Eq. (12). These factors represent the two major sources of information in the model: monolingual surface observation, and cross-lingual word associations.

The first two factors of Eq. (12) can be further decomposed into the product of probabilities of all words in each language sentence like Eq. (2).

Assuming that the tags are independent between different word alignment pairs, then the last factor of Eq. (12) can be decomposed into:

$$\begin{aligned} \frac{P(\mathbf{y}_c, \mathbf{y}_e | A)}{P(\mathbf{y}_c | A)P(\mathbf{y}_e | A)} &= \prod_{a \in A} \frac{P(y_{ca} y_{ea})}{P(y_{ca})P(y_{ea})} \\ &= \prod_{a \in A} \lambda_a^{y_c y_e} \end{aligned} \quad (13)$$

where y_{ca} and y_{ea} respectively denotes Chinese and English named entity tags in a word alignment pair a . $\lambda^{y_c y_e} = \frac{P(y_c y_e)}{P(y_c)P(y_e)}$ is the pointwise mutual information (PMI) score between a Chinese named entity tag y_c and an English named entity tag y_e . If $y_c = y_e$, then the score will be high; otherwise the score will be low. A number of methods for calculating the scores are provided at the end of this section.

We use ILP to maximize Eq. (12). The new objective function is expressed as follow:

$$\begin{aligned} \max \sum_{i=1}^{|\mathbf{x}_c|} \sum_{y \in Y} z_i^y \log P_i^y + \sum_{j=1}^{|\mathbf{x}_e|} \sum_{y \in Y} z_j^y \log P_j^y \\ + \sum_{a \in A} \sum_{y_c \in Y} \sum_{y_e \in Y} z_a^{y_c y_e} \log \lambda_a^{y_c y_e} \end{aligned} \quad (14)$$

where $z_a^{y_c y_e}$ is an indicator that equals 1 iff the Chinese and English named entity tags are y_c and y_e respectively, given a word alignment pair a ; otherwise, $z_a^{y_c y_e}$ is 0.

Monolingual constraints such as Eqs. (8) and (9) need to be added. In addition, one and only one possible named entity tag pair exists for a word alignment pair. This condition can be expressed as the following constraints:

$$\forall a \in A : \sum_{y_c \in Y} \sum_{y_e \in Y} z_a^{y_c y_e} = 1 \quad (15)$$

When the tag pair of a word alignment pair is determined, the corresponding monolingual named en-

ity tags can also be identified. This rule can be expressed by the following constraints:

$$\forall a = (i, j) \in A : z_a^{y_c y_e} \leq z_i^{y_c}, z_a^{y_c y_e} \leq z_j^{y_e} \quad (16)$$

Thus, if $z_a^{y_c y_e} = 1$, then $z_i^{y_c}$ and $z_j^{y_e}$ must be both equal to 1. Here, the i^{th} Chinese word and the j^{th} English word are aligned together.

In contrast to hard bilingual constraints, inconsistent named entity tags for an aligned word pair are allowed in soft bilingual constraints, but are given lower $\lambda^{y_c y_e}$ scores.

To calculate the $\lambda^{y_c y_e}$ score, an annotated bilingual NER corpus is consulted. We count from all word alignment pairs the number of times y_c and y_e occur together ($C(y_c y_e)$) and separately ($C(y_c)$ and $C(y_e)$). Afterwards, $\lambda^{y_c y_e}$ is calculated with maximum likelihood estimation as follows:

$$\lambda^{y_c y_e} = \frac{P(y_c y_e)}{P(y_c)P(y_e)} = \frac{N \times C(y_c y_e)}{C(y_c)C(y_e)} \quad (17)$$

where N is the total number of word alignment pairs.

However, in this paper, we assume that no named entity annotated bilingual corpus is available. Thus, the above method is only used as `Oracle`. A realistic method for calculating the $\lambda^{y_c y_e}$ score requires the use of two initial monolingual NER models, such as baseline CRF, to predict named entity tags for each language on an unannotated bitext. We count from this automatically tagged corpus the statistics mentioned above. This method is henceforth referred to as `Auto`.

A simpler approach is to manually set the value of $\lambda^{y_c y_e}$: if $y_c = y_e$ then we assign a larger value to $\lambda^{y_c y_e}$; else we assign an ad-hoc smaller value. In fact, if we set $\lambda^{y_c y_e} = 1$ iff $y_c = y_e$; otherwise, $\lambda^{y_c y_e} = 0$, then the soft constraints backs off to hard constraints. We refer to this set of soft constraints as `Soft-tag`.

3.3 Constraints with Alignment Uncertainty

So far, we assumed that a word alignment set A is known. In practice, only the word alignment probability P_a for each word pair a is provided. We can set a threshold θ for P_a to tune the set A : $a \in A$ iff $P_a \geq \theta$. This condition can be regarded as a kind of *hard word alignment*. However, the following problem exists: the smaller the θ , the noisier the

word alignments are; the larger the θ , the more possible word alignments are lost. To ameliorate this problem, we introduce another set of soft bilingual constraints.

We can re-express Eq. (13) as follows:

$$\prod_{a \in A} \lambda_a^{y_c y_e} = \prod_{a \in \mathcal{A}} (\lambda_a^{y_c y_e})^{I_a} \quad (18)$$

where \mathcal{A} is the set of all word pairs between two languages. $I_a = 1$ iff $P_a \geq \theta$; otherwise, $I_a = 0$.

We can then replace the hard indicator I_a with the word alignment probability P_a , Eq. (14) is then transformed into the following equation:

$$\max \sum_{i=1}^{|W_c|} \sum_{y \in Y} z_i^y \log P_i^y + \sum_{j=1}^{|W_e|} \sum_{y \in Y} z_j^y \log P_j^y \\ + \sum_{a \in \mathcal{A}} \sum_{y_c \in Y} \sum_{y_e \in Y} z_a^{y_c y_e} P_a \log \lambda_a^{y_c y_e} \quad (19)$$

We name the set of constraints above `Soft-align`, which has the same constraints as `Soft-tag`, i.e., Eqs. (8), (9), (15) and (16).

4 Experimental Setup

We conduct experiments on the latest OntoNotes 4.0 corpus (LDC2011T03). OntoNotes is a large, manually annotated corpus that contains various text genres and annotations, such as part-of-speech tags, named entity labels, syntactic parse trees, predicate-argument structures and co-references (Hovy et al., 2006). Aside from English, this corpus also contains several Chinese and Arabic corpora. Some of these corpora contain bilingual parallel documents. We used the Chinese-English parallel corpus with named entity labels as our development and test data. This corpus includes about 400 document pairs (chtb_0001-0325, ectb_1001-1078). We used odd-numbered documents as development data and even-numbered documents as test data. We used all other portions of the named entity annotated corpus as training data for the monolingual systems. There were a total of ~ 660 Chinese documents ($\sim 16k$ sentences) and $\sim 1,400$ English documents ($\sim 39k$ sentences). OntoNotes annotates 18 named entity types, such as person, location, date and money. In this paper, we selected the four most common named entity types, i.e., `PER` (Person), `LOC` (Location),

Chinese NER Templates
00: 1 (class bias param)

Bigram Features
$y_{i-1} \circ y_i \circ 00 - 08$

Table 1: Basic features of Chinese NER.

ORG (Organization) and GPE (Geo-Political Entities), and discarded the others.

Since the bilingual corpus is only aligned at the document level, we performed sentence alignment using the Champollion Tool Kit (CTK).⁴ After removing sentences with no aligned sentence, a total of 8,249 sentence pairs were retained.

We used the BerkeleyAligner,⁵ to produce word alignments over the sentence-aligned datasets. BerkeleyAligner also gives posterior probabilities P_a for each aligned word pair.

We used the CRF-based Stanford NER tagger (using Viterbi decoding) as our baseline monolingual NER tool.⁶ English features were taken from Finkel et al. (2005). Table 1 lists the basic features of Chinese NER, where \circ means string concatenation and y_i is the named entity tag of the i^{th} word w_i . Moreover, $\text{shape}(w_i)$ is the shape of w_i , such as date and number. $\text{prefix}/\text{suffix}(w_i, k)$ denotes the k -characters prefix/suffix of w_i . $\text{radical}(w_i, k)$ denotes the radical of the k^{th} Chinese character of w_i .⁷ $\text{len}(w_i)$ is the number of Chinese characters in w_i .

To make the baseline CRF taggers stronger, we added word clustering features to improve generalization over unseen data for both Chinese and English. Word clustering features have been successfully used in several English tasks, including

⁴champollion.sourceforge.net

⁵code.google.com/p/berkeleyaligner

⁶nlp.stanford.edu/software/CRF-NER.shtml, which has included our English and Chinese NER implementations.

⁷The radical of a Chinese character can be found at: www.unicode.org/charts/unihan.html

NER (Miller et al., 2004) and dependency parsing (Koo et al., 2008). To our knowledge, this work is the first use of word clustering features for Chinese NER. A C++ implementation of the Brown word clustering algorithms (Brown et al., 1992) was used to obtain the word clusters (Liang, 2005).⁸ Raw text was obtained from the fifth edition of Chinese Gigaword (LDC2011T13). One million paragraphs from Xinhua news section were randomly selected, and the Stanford Word Segmente with LDC standard was applied to segment Chinese text into words.⁹ About 46 million words were obtained which were clustered into 1,000 word classes.

5 Threshold Tuning

During development, we tuned the word alignment probability thresholds to find the best value. Figure 3 shows the performance curves.

When the word alignment probability threshold θ is set to 0.9, the hard bilingual constraints perform well for both Chinese and English. But as the thresholds value gets smaller, and more noisy word alignments are introduced, we see the hard bilingual constraints method starts to perform badly.

In Soft-tag setting, where inconsistent tag assignments within aligned word pairs are allowed but penalized, different languages have different optimal threshold values. For example, Chinese has an optimal threshold of 0.7, whereas English has 0.2. Thus, the optimal thresholds for different languages need to be selected with care when Soft-tag is applied in practice.

Soft-align eliminates the need for careful tuning of word alignment thresholds, and therefore can be more easily used in practice. Experimental results of Soft-align confirms our hypothesis – the performance of both Chinese and English NER systems improves with decreasing threshold. However, we can still improve efficiency by setting a low threshold to prune away very unlikely word alignments. We set the threshold to 0.1 for Soft-align to increase speed, and we observed very minimal performance lost when doing so.

We also found that automatically estimated bilingual tag PMI scores (Auto) gave comparable results

⁸github.com/percyliang/brown-cluster

⁹nlp.stanford.edu/software/segmenter.shtml

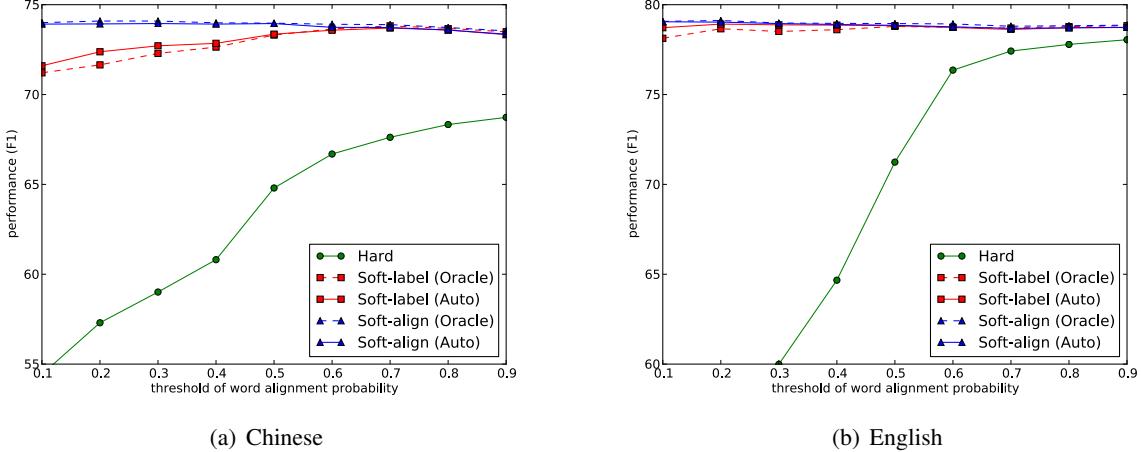

Figure 3: Performance curves of different bilingual constraints methods on development set.

to Oracle. Therefore this technique is effective for computing the PMI scores, avoiding the need of manually annotating named entity bilingual corpus.

6 Bilingual NER Results

The main results on Chinese and English test sets with the optimal word alignment threshold for each method are shown in Table 2.

The CRF-based Chinese NER with and without word clustering features are compared here. The word clustering features significantly ($p < 0.01$) improved the performance of Chinese NER,¹⁰ giving us a strong Chinese NER baseline.¹¹ The effectiveness of word clustering for English NER has been proved in previous work.

The performance of ILP with only monolingual constraints is quite comparable with the CRF results, especially on English. The greater ILP performance on English is probably due to more accurate marginal probabilities estimated by the English CRF model.

The ILP model with hard bilingual constraints gives a slight performance improvement on Chinese, but affects performance negatively on English. Once we introduced tagging uncertainties into the Soft-tag bilingual constraints, we see a very sig-

¹⁰We use paired bootstrap resampling significance test (Efron and Tibshirani, 1993).

¹¹To the best of our knowledge, there was no performance report of state-of-the-art NER results on the latest OntoNotes dataset.

nificant ($p < 0.01$) performance boost on Chinese. This method also improves the recall on English, with a smaller decrease in precision. Overall, it improves English F₁ score by about 0.4%, which is unfortunately not statistically significant.

Compared with Soft-tag, the final Soft-align method can further improve performance on both Chinese and English. This is likely to be because: 1) Soft-align includes more word alignment pairs, thereby improving recall; and 2) uses probabilities to cut wrong word alignments, thereby improving precision. In particular, compared with the strong CRF baseline, the gain on Chinese side is almost 5.5% in absolute F₁ score.

Decoding/inference efficiency of different methods are shown in the last column of Table 2.¹² Compared with Viterbi decoding in CRF, monolingual ILP decoding is about 2.3 times slower. Bilingual ILP decoding, with either hard or soft constraints, is significantly slower than the monolingual methods. The reason is that the number of monolingual ILP constraints doubles, and there are additionally many more bilingual constraints. The difference in speed between the Soft-tag and Soft-align methods is attributed to the difference in number of word alignment pairs.

Since each sentence pair can be decoded indepen-

¹²CPU: Intel Xeon E5-2660 2.20GHz. And the speed calculation of ILP inference methods exclude the time needed to obtain marginal probabilities from the CRF models.

	Chinese			English			Speed #sent/s
	P	R	F ₁	P	R	F ₁	
CRF (No Cluster)	74.74	56.17	64.13	—	—	—	—
CRF (Word Cluster)	76.90	63.32	69.45	82.95	76.67	79.68	317.3
Monolingual ILP	76.20	63.06	69.01	82.88	76.68	79.66	138.0
Hard	74.38	65.78	69.82	82.66	75.36	78.84	21.1
Soft-tag (Auto)	77.37	71.14	74.13	81.36	78.74	80.03	5.9
Soft-align (Auto)	77.71	72.51	75.02	81.94	78.35	80.10	1.5

Table 2: Results on bilingual parallel test set.

dently, parallelization the decoding process can result in significant speedup.

7 Semi-supervised NER Results

The above results show the usefulness of our method in a bilingual setting, where we are presented with sentence aligned data, and are tagging both languages at the same time. To have a greater impact on general monolingual NER systems, we employ a semi-supervised learning setting. First, we tag a large amount of unannotated bitext with our bilingual constraint-based NER tagger. Then we mix the automatically tagged results with the original monolingual Chinese training data to train a new model.

Our bitext is derived from the Chinese-English part of the Foreign Broadcast Information Service corpus (FBIS, LDC2003E14). The best performing bilingual model Soft-align with threshold $\theta = 0.1$ was used under the same experimental setting as described in Section 4

Method	#sent	P	R	F ₁
CRF	~16k	76.90	63.32	69.45
Semi	10k	77.60	66.51	71.62
	20k	77.28	67.26	71.92
	40k	77.40	67.81	72.29
	80k	77.44	68.64	72.77

Table 3: Semi-supervised results on Chinese test set.

Table 3 shows that the performance of the semi-supervised method improves with more additional data. We simply appended these data to the original training data. We also have done the experiments to down weight the additional training data by duplicating the original training data. There was some slight improvements, but not very significant. Finally, when we add 80k sentences, the F₁

score is improved by 3.32%, which is significantly ($p < 0.01$) better than the baseline, and most of the contribution comes from recall improvement.

Before the end of experimental section, let us summarize the usage of different kinds of data resources used in our experiments, as shown in Table 4, where ✓ and × denote whether the corresponding resources are required. In the bilingual case, during training, only the monolingual named entity annotated data (NE-mono) is necessary to train a monolingual NER tagger. During the test, unannotated bitext (Bitext) is required by the word aligner and our bilingual NER tagger. Named entity annotated bitext (NE-bitext) is used to evaluate our bilingual model. In the semi-supervised case, besides the original NE-mono data, the Bitext is used as input to our bilingual NER tagger to product additional training data. To evaluate the final NER model, only NE-mono is needed.

		NE-mono	Bitext	NE-bitext
Bilingual	train	✓	✗	✗
	test	✗	✓	✓
Semi	train	✓	✓	✗
	test	✓	✗	✗

8 Related Work

Previous work explored the use of bilingual corpora to improve existing monolingual analyzers. Huang et al. (2009) proposed methods to improve parsing performance using bilingual parallel corpus. Li et al. (2012) jointly labeled bilingual named entities with a cyclic CRF model, where approximate inference was done using loopy belief propagation. These methods require manually annotated bilingual

corpora, which are expensive to construct, and hard to obtain. Kim et al. (2012) proposed a method of labeling bilingual corpora with named entity labels automatically based on Wikipedia. However, this method is restricted to topics covered by Wikipedia.

Similar to our work, Burkett et al. (2010) also assumed that annotated bilingual corpora are scarce. Beyond the difference discussed in Section 1, their re-ranking strategy may lose the correct named entity results if they are not included in the top-N outputs. Furthermore, we consider the word alignment probabilities in our method which can reduce the influence of word alignment errors. Finally, we test our method on a large standard publicly available corpus (8,249 sentences), while they used a much smaller (200 sentences) manually annotated bilingual NER corpus for results validation.

In addition to bilingual corpora, bilingual dictionaries are also useful resources. Huang and Vogel (2002) and Chen et al. (2010) proposed approaches for extracting bilingual named entity pairs from unannotated bitext, in which verification is based on bilingual named entity dictionaries. However, large-scale bilingual named entity dictionaries are difficult to obtain for most language pairs.

Yarowsky and Ngai (2001) proposed a projection method that transforms high-quality analysis results of one language, such as English, into other languages on the basis of word alignment. Das and Petrov (2011) applied the above idea to part-of-speech tagging with a more complex model. Fu et al. (2011) projected English named entities onto Chinese by carefully designed heuristic rules. Although this type of method does not require manually annotated bilingual corpora or dictionaries, errors in source language results, wrong word alignments and inconsistencies between the languages limit application of this method.

Constraint-based monolingual methods by using ILP have been successfully applied to many natural language processing tasks, such as Semantic Role Labeling (Punyakanok et al., 2004), Dependency Parsing (Martins et al., 2009) and Textual Entailment (Berant et al., 2011). Zhuang and Zong (2010) proposed a joint inference method for bilingual semantic role labeling with ILP. However, their approach requires training an alignment model with a manually annotated corpus.

9 Conclusions

We proposed a novel ILP based inference algorithm with bilingual constraints for NER. This method can jointly infer bilingual named entities without using any annotated bilingual corpus. We investigate various bilingual constraints: hard and soft constraints. Our empirical study on large-scale OntoNotes Chinese-English parallel NER data showed that Soft-align method, which allows inconsistent named entity tags between two aligned words and considers word alignment probabilities, can significantly improve over the performance of a strong Chinese NER baseline. Our work is the first to evaluate performance on a large-scale standard dataset. Finally, we can also improve monolingual Chinese NER performance significantly, by combining the original monolingual training data with new data obtained from bitext tagged by our method. The final ILP-based bilingual NER tagger with soft constraints is publicly available at: github.com/carfly/bi_ilp

Future work could apply the bilingual constraint-based method to other tasks, such as part-of-speech tagging and relation extraction.

Abstract

We propose a minimally supervised method for multilingual paraphrase extraction from definition sentences on the Web. Hashimoto et al. (2011) extracted paraphrases from Japanese definition sentences on the Web, assuming that definition sentences defining the same concept tend to contain paraphrases. However, their method requires manually annotated data and is language dependent. We extend their framework and develop a minimally supervised method applicable to multiple languages. Our experiments show that our method is comparable to Hashimoto et al.’s for Japanese and outperforms previous unsupervised methods for English, Japanese, and Chinese, and that our method extracts 10,000 paraphrases with 92% precision for English, 82.5% precision for Japanese, and 82% precision for Chinese.

1 Introduction

Automatic paraphrasing has been recognized as an important component for NLP systems, and many methods have been proposed to acquire paraphrase knowledge (Lin and Pantel, 2001; Barzilay and McKeown, 2001; Shinyama et al., 2002; Barzilay and Lee, 2003; Dolan et al., 2004; Callison-Burch, 2008; Hashimoto et al., 2011; Fujita et al., 2012).

We propose a minimally supervised method for multilingual paraphrase extraction. Hashimoto et al. (2011) developed a method to extract paraphrases from definition sentences on the Web, based on their observation that definition sentences defining the same concept tend to contain many paraphrases. Their method consists of two steps; they extract definition sentences from the Web, and extract phrasal

- (1) a. Paraphrasing is the use of your own words to express the author’s ideas without changing the meaning.
b. Paraphrasing is defined as a process of transforming an expression into another while keeping its meaning intact.
- (2) a. 言い換えとは、ある表現をその意味内容を変えずに別の表現に置き換えることを言います。(Paraphrasing refers to the replacement of an expression into another without changing the semantic content.)
b. 言い換えとは、ある言語表現ができるだけ意味や内容を保ったまま同一言語の別の表現に変換する処理である。(Paraphrasing is a process of transforming an expression into another of the same language while preserving the meaning and content as much as possible.)
- (3) a. 意译是指译者在不改变原文意思的前提下，完全改变原文的句子结构。(Paraphrasing refers to the transformation of sentence structure by the translator without changing the meaning of original text.)
b. 意译是指只保持原文内容，不保持原文形式的翻译方法。(Paraphrasing is a translation method of keeping the content of original text but not keeping the expression.)

Figure 1: Multilingual definition pairs on “paraphrasing.”

paraphrases from the definition sentences. Both steps require supervised classifiers trained by manually annotated data, and heavily depend on their target language. However, the basic idea is actually language-independent. Figure 1 gives examples of definition sentences on the Web that define the same concept in English, Japanese, and Chinese (with English translation). As indicated by underlines, each definition pair has a phrasal paraphrase.

We aim at extending Hashimoto et al.’s method to a minimally supervised method, thereby enabling acquisition of phrasal paraphrases within one language, but in different languages without manually annotated data. The first contribution of our work is to develop a minimally supervised method for multilingual definition extraction that uses a classifier distinguishing definition from non-definition. The classifier is learnt from the first sentences in

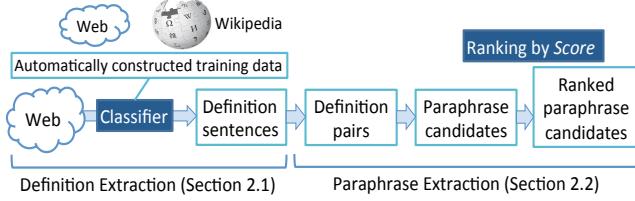

Figure 2: Overall picture of our method.

Wikipedia articles, which can be regarded as the definition of the title of Wikipedia article (Kazama and Torisawa, 2007) and hence can be used as positive examples. Our method relies on a POS tagger, a dependency parser, a NER tool, noun phrase chunking rules, and frequency thresholds for each language, in addition to Wikipedia articles, which can be seen as a manually annotated knowledge base. However, our method needs no additional manual annotation particularly for this task and thus we categorize our method as a minimally supervised method. On the other hand, Hashimoto et al.’s method heavily depends on the properties of Japanese like the assumption that characteristic expressions of definition sentences tend to appear at the end of sentence in Japanese. We show that our method is applicable to English, Japanese, and Chinese, and that its performance is comparable to state-of-the-art supervised methods (Navigli and Velardi, 2010). Since the three languages are very different we believe that our definition extraction method is applicable to any language as long as Wikipedia articles of the language exist.

The second contribution of our work is to develop a minimally supervised method for multilingual paraphrase extraction from definition sentences. Again, Hashimoto et al.’s method utilizes a supervised classifier trained with annotated data particularly prepared for this task. We eliminate the need for annotation and instead introduce a method that uses a novel similarity measure considering the occurrence of phrase fragments in global contexts. Our paraphrase extraction method is mostly language-independent and, through experiments for the three languages, we show that it outperforms unsupervised methods (Paşca and Dienes, 2005; Koehn et al., 2007) and is comparable to Hashimoto et al.’s supervised method for Japanese.

Previous methods for paraphrase (and entailment)

extraction can be classified into a distributional similarity based approach (Lin and Pantel, 2001; Gefet and Dagan, 2005; Bhagat et al., 2007; Szpektor and Dagan, 2008; Hashimoto et al., 2009) and a parallel corpus based approach (Barzilay and McKeown, 2001; Shinyama et al., 2002; Barzilay and Lee, 2003; Dolan et al., 2004; Callison-Burch, 2008). The former can exploit large scale monolingual corpora, but is known to be unable to distinguish paraphrase pairs from antonymous pairs (Lin et al., 2003). The latter rarely mistakes antonymous pairs for paraphrases, but preparing parallel corpora is expensive. As with Hashimoto et al. (2011), our method is a kind of parallel corpus approach in that it uses definition pairs as a parallel corpus. However, our method does not suffer from a high labor cost of preparing parallel corpora, since it can automatically collect definition pairs from the Web on a large scale. The difference between ours and Hashimoto et al.’s is that our method requires no manual labeling of data and is mostly language-independent.

2 Proposed Method

Our method first extracts definition sentences from the Web, and then extracts paraphrases from the definition sentences, as illustrated in Figure 2.

2.1 Definition Extraction

2.1.1 Automatic Construction of Training Data

Our method learns a classifier that classifies sentences into definition and non-definition using automatically constructed training data, $TrDat$. $TrDat$ ’s positive examples, Pos , are the first sentences of Wikipedia articles and the negative examples, Neg , are randomly sampled Web sentences. The former can be seen as definition, while the chance that the sentences in the latter are definition is quite small.

Our definition extraction not only distinguishes definition from non-definition but also identifies the defined term of a definition sentence, and in the paraphrase extraction step our method couples two definition sentences if their defined terms are identical. For example, the defined terms of (1a) and (1b) in Figure 1 are both “Paraphrasing” and thus the two definition sentences are coupled. For Pos , we mark up the title of Wikipedia article as the defined term. For Neg , we randomly select a noun phrase in a sen-

N-gram definition pattern		N-gram non-definition pattern	
(A)	^ [term] is the [term] is a type of	[term] may be [term] is not	
Subsequence definition pattern		Subsequence non-definition pattern	
(B)	[term] is * which is located [term] is a * in the	you may * [term] was [term] *, who is	
Subtree definition pattern		Subtree non-definition pattern	
(C)	[term] is defined as the NP	[term] will not be	

Table 1: Examples of English patterns.

tence and mark it up as a (false) defined term. Any marked term is uniformly replaced with [term].

2.1.2 Feature Extraction and Learning

As features, we use patterns that are characteristic of definition (definition patterns) and those that are unlikely to be a part of definition (non-definition patterns). Patterns are either *N-grams*, *subsequences*, or *dependency subtrees*, and are mined automatically from *TrDat*. Table 1 shows examples of patterns mined by our method. In (A) of Table 1, “^” is a symbol representing the beginning of a sentence. In (B), “*” represents a wildcard that matches any number of arbitrary words. Patterns are represented by either their words’ surface form, base form, or POS. (Chinese words do not inflect and thus we do not use the base form for Chinese.)

We assume that definition patterns are frequent in *Pos* but are infrequent in *Neg*, and non-definition patterns are frequent in *Neg* but are infrequent in *Pos*. To see if a given pattern ϕ is likely to be a definition pattern, we measure ϕ ’s probability rate $Rate(\phi)$. If the probability rate of ϕ is large, ϕ tends to be a definition pattern. The probability rate of ϕ is:

$$Rate(\phi) = \frac{freq(\phi, Pos)/|Pos|}{freq(\phi, Neg)/|Neg|}, \text{ if } freq(\phi, Neg) \neq 0.$$

Here, $freq(\phi, Pos) = |\{s \in Pos : \phi \subseteq s\}|$ and $freq(\phi, Neg) = |\{s \in Neg : \phi \subseteq s\}|$. We write $\phi \subseteq s$ if sentence s contains ϕ . If $freq(\phi, Neg) = 0$, $Rate(\phi)$ is set to the largest value of all the patterns’ *Rate* values. Only patterns whose *Rate* is more than or equal to a *Rate* threshold ρ_{pos} and whose $freq(\phi, Pos)$ is more than or equal to a frequency threshold are regarded as definition patterns. Similarly, we check if ϕ is likely to be a non-definition pattern. Only patterns whose *Rate* is less or equal

		English		Japanese		Chinese	
Type	Representation	Pos	Neg	Pos	Neg	Pos	Neg
N-gram	Surface	120	400	30	100	20	100
	Base	120	400	30	100	—	—
	POS	2,000	4,000	500	500	100	400
Subsequence	Surface	120	400	30	100	20	40
	Base	120	400	30	100	—	—
	POS	2,000	2,000	500	500	200	400
Subtree	Surface	5	10	5	10	5	5
	Base	5	10	5	10	—	—
	POS	25	50	25	50	25	50

Table 2: Values of frequency threshold.

to a *Rate* threshold ρ_{neg} and whose $freq(\phi, Neg)$ is more than or equal to a frequency threshold are regarded as non-definition patterns. The probability rate is based on the growth rate (Dong and Li, 1999).

ρ_{pos} and ρ_{neg} are set to 2 and 0.5, while the frequency threshold is set differently according to languages, pattern types (N-gram, subsequence, and subtree), representation (surface, base, and POS), and data (*Pos* and *Neg*), as in Table 2. The thresholds in Table 2 were determined manually, but not really arbitrarily. Basically they were determined according to the frequency of each pattern in our data (e.g. how frequently the surface N-gram of English appears in English positive training samples (*Pos*)).

Below, we detail how patterns are acquired. First, we acquire N-gram patterns. Then, subsequence patterns are acquired using the N-gram patterns as input. Finally, subtree patterns are acquired using the subsequence patterns as input.

N-gram patterns We collect N-gram patterns from *TrDat* with *N* ranging from 2 to 6. We filter out N-grams using thresholds on the *Rate* and frequency, and regard those that are kept as definition or non-definition N-grams.

Subsequence patterns We generate subsequence patterns as ordered combinations of N-grams with the wild card “*” inserted between them (we use two or three N-grams for a subsequence). Then, we check each of the generated subsequences and keep it if there exists a sentence in *TrDat* that contains the subsequence and whose root node is contained in the subsequence. For example, subsequence “[term] is a * in the” is kept if a term-marked sentence like “[term] is a baseball player in the Dominican Republic.” exists in *TrDat*. Then, patterns are filtered

out using thresholds on the *Rate* and frequency as we did for N-grams.

Subtree patterns For each definition and non-definition subsequence, we retrieve all the term-marked sentences that contain the subsequence from *TrDat*, and extract a minimal dependency subtree that covers all the words of the subsequence from each retrieved sentence. For example, assume that we retrieve a term-marked sentence “[term] is usually defined as the way of life of a group of people.” for subsequence “[term] is * defined as the”. Then we extract from the sentence the minimal dependency subtree in the left side of (C) of Table 1. Note that all the words of the subsequence are contained in the subtree, and that in the subtree a node (“way”) that is not a part of the subsequence is replaced with its dependency label (“NP”) assigned by the dependency parser. The patterns are filtered out using thresholds on the *Rate* and frequency.

We train a SVM classifier¹ with a linear kernel, using binary features that indicate the occurrence of the patterns described above in a target sentence.

In theory, we could feed all the features to the SVM classifier and let the classifier pick informative features. But we restricted the feature set for practical reasons: the number of features would become tremendously large. There are two reasons for this. First, the number of sentences in our automatically acquired training data is huge (2,439,257 positive sentences plus 5,000,000 negative sentences for English, 703,208 positive sentences plus 1,400,000 negative sentences for Japanese and 310,072 positive sentences plus 600,000 negative sentences for Chinese). Second, since each subsequence pattern is generated as a combination of two or three N-gram patterns and one subsequence pattern can generate one or more subtree patterns, using all possible features leads to a combinatorial explosion of features. Moreover, since the feature vector will be highly sparse with a huge number of infrequent features, SVM learning becomes very time consuming. In preliminary experiments we observed that when using all possible features the learning process took more than one week for each language. We therefore introduced the current feature selection method, in which the learning process finished in one day but

Original Web sentence: Albert Pujols is a baseball player.

Term-marked sentence 1: [term] is a baseball player.

Term-marked sentence 2: Albert Pujols is a [term].

Figure 3: Term-marked sentences from a Web sentence.

still obtains good results.

2.1.3 Definition Extraction from the Web

We extract a large amount of definition sentences by applying this classifier to sentences in our Web archive. Because our classifier requires term-marked sentences (sentences in which the term being defined is marked) as input, we first have to identify all such defined term candidates for each sentence. For example, Figure 3 shows a case where a Web sentence has two NPs (two candidates of defined term). Basically we pick up NPs in a sentence by simple heuristic rules. For English, NPs are identified using TreeTagger (Schmid, 1995) and two NPs are merged into one when they are connected by “for” or “of”. After applying this procedure recursively, the longest NPs are regarded as candidates of defined terms and term-marked sentences are generated. For Japanese, we first identify nouns that are optionally modified by adjectives as NPs, and allow two NPs connected by “の” (of), if any, to form a larger NP. For Chinese, nouns that are optionally modified by adjectives are considered as NPs.

Then, each term-marked sentence is given a feature vector and classified by the classifier. The term-marked sentence whose SVM score (the distance from the hyperplane) is the largest among those from the same original Web sentence is chosen as the final classification result for the original Web sentence.

2.2 Paraphrase Extraction

We use all the Web sentences classified as definition and all the sentences in *Pos* for paraphrase extraction. First, we couple two definition sentences whose defined term is the same. We filter out definition sentence pairs whose cosine similarity of content word vectors is less than or equal to threshold C , which is set to 0.1. Then, we extract phrases from each definition sentence, and generate all possible phrase pairs from the coupled sentences. In this study, phrases are restricted to predicate phrases that consist of at least one dependency relation and in which all the constituents are consecutive in a

¹<http://svmlight.joachims.org>.

f_1	The ratio of the number of words shared between two candidate phrases to the number of all of the words in the two phrases. Words are represented by either their surface form ($f_{1,1}$), base form ($f_{1,2}$) or POS ($f_{1,3}$).
f_2	The identity of the leftmost word (surface form ($f_{2,1}$), base form ($f_{2,2}$) or POS ($f_{2,3}$)) between two candidate phrases.
f_3	The same as f_2 except that we use the rightmost word. There are three corresponding subfunctions ($f_{3,1}$ to $f_{3,3}$).
f_4	The ratio of the number of words that appear in a candidate phrase segment of a definition sentence s_1 and in a segment that is NOT a part of the candidate phrase of another definition sentence s_2 to the number of all the words of s_1 's candidate phrase. Words are in their base form ($f_{4,1}$).
f_5	The reversed ($s_1 \leftrightarrow s_2$) version of $f_{4,1}$ ($f_{5,1}$).
f_6	The ratio of the number of words (the surface form) of a shorter candidate phrase to that of a longer one ($f_{6,1}$).
f_7	Cosine similarity between two definition sentences from which two candidate phrases are extracted. Only content words in the base form are used ($f_{7,1}$).
f_8	The ratio of the number of parent dependency subtrees that are shared by two candidate phrases to the number of all the parent dependency subtrees. The parent dependency subtrees are adjacent to the candidate phrases and represented by their surface form ($f_{8,1}$), base form ($f_{8,2}$), or POS ($f_{8,3}$).
f_9	The same as f_8 except that we use child dependency subtrees. There are 3 subfunctions ($f_{9,1}$ to $f_{9,3}$) of f_9 type.
f_{10}	The ratio of the number of context N-grams that are shared by two candidate phrases to the number of all the context N-grams of both candidate phrases. The context N-grams are adjacent to the candidate phrases and represented by either the surface form, the base form, or POS. The N ranges from 1 to 3, and the context is either left-side or right-side. Thus, there are 18 subfunctions ($3 \times 3 \times 2$).

Table 3: Local similarity subfunctions, $f_{1,1}$ to $f_{10,18}$.

sentence. Accordingly, if two definition sentences that are coupled have three such predicate phrases respectively, we get nine phrase pairs, for instance. A phrase pair extracted from a definition pair is a paraphrase candidate and is given a score that indicates the likelihood of being a paraphrase, *Score*. It consists of two similarity measures, *local similarity* and *global similarity*, which are detailed below.

Local similarity Following Hashimoto et al., we assume that two candidate phrases (p_1, p_2) tend to be a paraphrase if they are similar enough and/or their surrounding contexts are sufficiently similar. Then, we calculate the local similarity (*localSim*) of (p_1, p_2) as the weighted sum of 37 similarity subfunctions that are grouped into 10 types (Table 3.). For example, the f_1 type consists of three subfunctions, $f_{1,1}$, $f_{1,2}$, and $f_{1,3}$. The 37 subfunctions are inspired by Hashimoto et al.'s features. Then, *localSim* is defined as:

$$localSim(p_1, p_2) = \max_{(d_l, d_m) \in DP(p_1, p_2)} ls(p_1, p_2, d_l, d_m).$$

Here, $ls(p_1, p_2, d_l, d_m) = \sum_{i=1}^{10} \sum_{j=1}^{k_i} \frac{w_{i,j} \times f_{i,j}(p_1, p_2, d_l, d_m)}{k_i}$. $DP(p_1, p_2)$ is the set of all definition sentence pairs that contain (p_1, p_2). (d_l, d_m) is a definition sentence pair containing (p_1, p_2). k_i is the number of subfunctions of f_i type. $w_{i,j}$ is the weight for $f_{i,j}$. $w_{i,j}$ is uniformly set to 1 except for $f_{4,1}$ and $f_{5,1}$, whose weight is set to -1 since they indicate the unlikelihood of (p_1, p_2)'s being a paraphrase. As the formula indicates, if there is more than one definition sentence pair that contains (p_1, p_2), *localSim* is calculated from the definition sentence pair that gives the maximum value of $ls(p_1, p_2, d_l, d_m)$. *localSim* is local in the sense that it is calculated based on only one definition pair from which (p_1, p_2) are extracted.

Global similarity The global similarity (*globalSim*) is our novel similarity function. We decompose a candidate phrase pair (p_1, p_2) into *Comm*, the common part between p_1 and p_2 , and *Diff*, the difference between the two. For example, *Comm* and *Diff* of ("keep the meaning intact", "preserve the meaning") is ("the meaning") and ("keep, intact", "preserve"). *globalSim* measures the semantic similarity of the *Diff* of a phrase pair. It is proposed based on the following intuition: phrase pair (p_1, p_2) tend to be a paraphrase if their surface difference (i.e. *Diff*) have the same meaning. For example, if "keep, intact" and "preserve" mean the same, then ("keep the meaning intact", "preserve the meaning") is a paraphrase.

globalSim considers the occurrence of *Diff* in global contexts (i.e., all the paraphrase candidates from all the definition pairs). The *globalSim* of a given phrase pair (p_1, p_2) is measured by basically counting how many times the *Diff* of (p_1, p_2) appears in all the candidate phrase pairs from all the definition pairs. The assumption is that *Diff* tends to share the same meaning if it appears repeatedly in paraphrase candidates from all definition sentence pairs, i.e., our parallel corpus. Each occurrence of *Diff* is weighted by the *localSim* of the phrase pair in which *Diff* occurs. Precisely, *globalSim* is defined as:

Threshold	The frequency threshold of Table 2 (Section 2.1.2).
NP rule	Rules for identifying NPs in sentences (Section 2.1.3).
POS list	The list of content words' POS (Section 2.2).
Tagger/parser	POS taggers, dependency parsers and NER tools.

Table 4: Language-dependent components.

$$globalSim(p_1, p_2) = \sum_{(p_i, p_j) \in PP(p_1, p_2)} \frac{localSim(p_i, p_j)}{M}.$$

$PP(p_1, p_2)$ is the set of candidate phrase pairs whose $Diff$ is the same as (p_1, p_2) .² M is the number of similarity subfunction types whose weight is 1, i.e. $M = 8$ (all the subfunction types except f_4 and f_5). It is used to normalize the value of each occurrence of $Diff$ to $[0, 1]$.³ $globalSim$ is global in the sense that it considers all the definition pairs that have a phrase pair with the same $Diff$ as a target candidate phrase pair (p_1, p_2) .

The final score for a candidate phrase pair is:

$$Score(p_1, p_2) = localSim(p_1, p_2) + \ln globalSim(p_1, p_2).$$

The way of combining the two similarity functions has been determined empirically after testing several other ways of combining them. This ranks all the candidate phrase pairs.

Finally, we summarize language-dependent components that we fix manually in Table 4.

3 Experiments

3.1 Experiments of Definition Extraction

We show that our unsupervised definition extraction method is competitive with state-of-the-art supervised methods for English (Navigli and Velardi, 2010), and that it extracts a large number of definitions reasonably accurately for English (3,216,121 definitions with 70% precision), Japanese (651,293 definitions with 62.5% precision), and Chinese (682,661 definitions with 67% precision).

²If there are more than one (p_i, p_j) in a definition pair, we use only one of them that has the largest $localSim$ value.

³Although we claim that our idea of using $globalSim$ is effective, we do not claim that the above formula for calculating is the optimal way to implement the idea. Currently we are investigating a more mathematically well-motivated model.

3.1.1 Preparing Corpora

First we describe Pos , Neg , and the Web corpus from which definition sentences are extracted. As the source of Pos , we used the English Wikipedia of April 2011 (3,620,149 articles), the Japanese Wikipedia of October 2011 (830,417 articles), and the Chinese Wikipedia of August 2011 (365,545 articles). We removed category articles, template articles, list articles and so on from them. Then the number of sentences of Pos was 2,439,257 for English, 703,208 for Japanese, and 310,072 for Chinese. We verified our assumption that Wikipedia first sentences can mostly be seen as definition by manually checking 200 random samples from Pos . 96.5% of English Pos , 100% of Japanese Pos , and 99.5% of Chinese Pos were definitions.

As the source of Neg , we used 600 million Japanese Web pages (Akamine et al., 2010) and the ClueWeb09 corpus for English (about 504 million pages) and Chinese (about 177 million pages).⁴ From each Web corpus, we collected the sentences satisfying following conditions: 1) they contain 5 to 50 words and at least one verb, 2) less than half of their words are numbers, and 3) they end with a period. Then we randomly sampled sentences from the collected sentences as Neg so that $|Neg|$ was about twice as large as $|Pos|$: 5,000,000 for English, 1,400,000 for Japanese, and 600,000 for Chinese.

In Section 3.1.3, we use 10% of the Web corpus as the input to the definition classifier. The number of sentences are 294,844,141 for English, 245,537,860 for Japanese, and 68,653,130 for Chinese.

All the sentences were POS-tagged and parsed. We used TreeTagger and MSTParser (McDonald et al., 2006) for English, JUMAN (Kurohashi and Kawahara, 2009a) and KNP (Kurohashi and Kawahara, 2009b) for Japanese, MMA (Kruengkrai et al., 2009) and CNP (Chen et al., 2009) for Chinese.

3.1.2 Comparison with Previous Methods

We compared our method with the state-of-the-art supervised methods proposed by Navigli and Velardi (2010), using their WCL datasets v1.0 (<http://lcl.uniroma1.it/wcl/>), definition and non-definition datasets for English (Navigli et al., 2010). Specifically, we used its training data ($TrDat_{wcl}$, hereafter), which consisted of 1,908 definition and

⁴<http://lemurproject.org/clueweb09.php>

Method	Precision	Recall	F1	Accuracy
<i>Proposed_{def}</i>	86.79	86.97	86.88	89.18
<i>WCL-1</i>	99.88	42.09	59.22	76.06
<i>WCL-3</i>	98.81	60.74	75.23	83.48

Table 5: Definition classification results on $TrDat_{wcl}$.

2,711 non-definition sentences, and compared the following three methods. *WCL-1* and *WCL-3* are methods proposed by Navigli and Velardi (2010). They were trained and tested with 10 fold cross validation using $TrDat_{wcl}$. *Proposed_{def}* is our method, which used $TrDat$ for acquiring patterns (Section 2.1.2) and training. We tested *Proposed_{def}* on each of $TrDat_{wcl}$'s 10 folds and averaged the results. Note that, for *Proposed_{def}*, we removed sentences in $TrDat_{wcl}$ from $TrDat$ in advance for fairness. Table 5 shows the results. The numbers for *WCL-1* and *WCL-3* are taken from Navigli and Velardi (2010). *Proposed_{def}* outperformed both methods in terms of recall, F1, and accuracy. Thus, we conclude that *Proposed_{def}* is comparable to *WCL-1/WCL-3*.

We conducted ablation tests of our method to investigate the effectiveness of each type of pattern. When using only N-grams, F1 was 85.41. When using N-grams and subsequences, F1 was 86.61. When using N-grams and subtrees, F1 was 86.85. When using all the features, F1 was 86.88. The results show that each type of patterns contribute to the performance, but the contributions of subsequence patterns and subtree patterns do not seem very significant.

3.1.3 Experiments of Definition Extraction

We extracted definitions from 10% of the Web corpus. We applied *Proposed_{def}* to the corpus of each language, and the state-of-the-art supervised method for Japanese (Hashimoto et al., 2011) (*Hashi_{def}*, hereafter) to the Japanese corpus. *Hashi_{def}* was trained on their training data that consisted of 2,911 sentences, 61.1% of which were definitions. Note that we removed sentences in $TrDat$ from 10% of the Web corpus in advance, while we did not remove Hashimoto et al.'s training data from the corpus. This means that, for *Hashi_{def}*, the training data is included in the test data.

For each method, we filtered out its positive outputs whose defined term appeared more than 1,000 times in 10% of the Web corpus, since those terms

tend to be too vague to be a defined term or refer to an entity outside the definition sentence. For example, if “the college” appears more than 1,000 times in 10% of the corpus, we filter out sentences like “The college is one of three colleges in the Coast Community College District and was founded in 1947.” For *Proposed_{def}*, the number of remaining positive outputs is 3,216,121 for English, 651,293 for Japanese, and 682,661 for Chinese. For *Hashi_{def}*, the number of positive outputs is 523,882.

For *Proposed_{def}* of each language, we randomly sampled 200 sentences from the remaining positive outputs. For *Hashi_{def}*, we first sorted its output by the SVM score in descending order and then randomly sampled 200 from the top 651,293, i.e., the same number as the remaining positive outputs of *Proposed_{def}* of Japanese, out of all the remaining sentences of *Hashi_{def}*.

For each language, after shuffling all the samples, two human annotators evaluated each sample. The annotators for English and Japanese were not the authors, while one of the Chinese annotators was one of the authors. We regarded a sample as a definition if it was regarded as a definition by both annotators. Cohen's kappa (Cohen, 1960) was 0.55 for English (moderate agreement (Landis and Koch, 1977)), 0.73 for Japanese (substantial agreement), and 0.69 for Chinese (substantial agreement).

For English, *Proposed_{def}* achieved 70% precision for the 200 samples. For Japanese, *Proposed_{def}* achieved 62.5% precision for the 200 samples, while *Hashi_{def}* achieved 70% precision for the 200 samples. For Chinese, *Proposed_{def}* achieved 67% precision for the 200 samples. From these results, we conclude that *Proposed_{def}* can extract a large number of definition sentences from the Web moderately well for the three languages.

Although the precision is not very high, our experiments in the next section show that we can still extract a large number of paraphrases with high precision from these definition sentences, due mainly to our similarity measures, *localSim* and *globalSim*.

3.2 Experiments of Paraphrase Extraction

We show (1) that our paraphrase extraction method outperforms unsupervised methods for the three languages, (2) that *globalSim* is effective, and (3) that our method is comparable to the state-of-the-art su-

- Proposed_{Score}:** Our method. Outputs are ranked by *Score*.
- Proposed_{local}:** This is the same as *Proposed_{Score}* except that it ranks outputs by *localSim*. The performance drop from *Proposed_{Score}* shows *globalSim*'s effectiveness.
- Hashi_{sup}:** Hashimoto et al.'s supervised method. Training data is the same as Hashimoto et al. Outputs are ranked by the SVM score (the distance from the hyperplane). This is for Japanese only.
- Hashi_{uns}:** The unsupervised version of *Hashi_{sup}*. Outputs are ranked by the sum of feature values. Japanese only.
- SMT:** The phrase table construction method of Moses (Koehn et al., 2007). We assume that Moses should extract a set of two phrases that are paraphrases of each other, if we input monolingual parallel sentence pairs like our definition pairs. We used default values for all the parameters. Outputs are ranked by the product of two phrase translation probabilities of both directions.
- P&D:** The distributional similarity based method by Paşa and Dienes (2005) (their “N-gram-Only” method). Outputs are ranked by the number of contexts two phrases share. Following Paşa and Dienes (2005), we used the parameters $LC = 3$ and $MaxP = 4$, while $MinP$, which was 1 in Paşa and Dienes (2005), was set to 2 since our target was phrasal paraphrases.

Table 6: Evaluated paraphrase extraction methods.

pervised method for Japanese.

3.2.1 Experimental Setting

We extracted paraphrases from definition sentences in *Pos* and those extracted by *Proposed_{def}* in Section 3.1.3. First we coupled two definition sentences whose defined term was the same. The number of definition pairs was 3,208,086 for English, 742,306 for Japanese, and 457,233 for Chinese.

Then we evaluated six methods in Table 6.⁵ All the methods except *P&D* took the same definition pairs as input, while *P&D*'s input was 10% of the Web corpus. The input can be seen as the same for all the methods, since the definition pairs were derived from that 10% of the Web corpus. In our experiments *Exp1* and *Exp2* below, all evaluation samples were shuffled so that human annotators could not know which sample was from which method. Annotators were the same as those who conducted the evaluation in Section 3.1.3. Cohen's kappa (Cohen, 1960) was 0.83 for English, 0.88 for Japanese,

⁵We filtered out phrase pairs in which one phrase contained a named entity but the other did not contain the named entity from the output of *Proposed_{Score}*, *Proposed_{local}*, *SMT*, and *P&D*, since most of them were not paraphrases. We used Stanford NER (Finkel et al., 2005) for English named entity recognition (NER), KNP for Japanese NER, and BaseNER (Zhao and Kit, 2008) for Chinese NER. *Hashi_{sup}* and *Hashi_{uns}* did the named entity filtering of the same kind (footnote 3 of Hashimoto et al. (2011)), and thus we did not apply the filter to them any further.

and 0.85 for Chinese, all of which indicated reasonably good (Landis and Koch, 1977). We regarded a candidate phrase pair as a paraphrase if both annotators regarded it as a paraphrase.

Exp1 We compared the methods that take definition pairs as input, i.e. *Proposed_{Score}*, *Proposed_{local}*, *Hashi_{sup}*, *Hashi_{uns}*, and *SMT*. We randomly sampled 200 phrase pairs from the top 10,000 for each method for evaluation. The evaluation of each candidate phrase pair (p_1, p_2) was based on bidirectional checking of entailment relation, $p_1 \rightarrow p_2$ and $p_2 \rightarrow p_1$, with p_1 and p_2 embedded in contexts, as Hashimoto et al. (2011) did. Entailment relation of both directions hold if (p_1, p_2) is a paraphrase. We used definition pairs from which candidate phrase pairs were extracted as contexts.

Exp2 We compared *Proposed_{Score}* and *P&D*. Since *P&D* restricted its output to phrase pairs in which each phrase consists of two to four words, we restricted the output of *Proposed_{Score}* to 2-to-4-words phrase pairs, too. We randomly sampled 200 from the top 3,000 phrase pairs from each method for evaluation, and the annotators checked entailment relation of both directions between two phrases using Web sentence pairs that contained the two phrases as contexts.

3.2.2 Results

From *Exp1*, we obtained precision curves in the upper half of Figure 4. The curves were drawn from the 200 samples that were sorted in descending order by their score, and we plotted a dot for every 5 samples. *Proposed_{Score}* outperformed *Proposed_{local}* for the three languages, and thus *globalSim* was effective. *Proposed_{Score}* outperformed *Hashi_{sup}*. However, we observed that *Proposed_{Score}* acquired many candidate phrase pairs (p_1, p_2) for which p_1 and p_2 consisted of the same content words like “send a postcard to the author” and “send the author a postcard,” while the other methods tended to acquire more content word variations like “have a *chance*” and “have an *opportunity*.” Then we evaluated all the methods in terms of how many paraphrases with content word variations were extracted. We extracted from the evaluation samples only candidate phrase pairs whose *Diff* contained a content word (*content word variation pairs*), to see how many

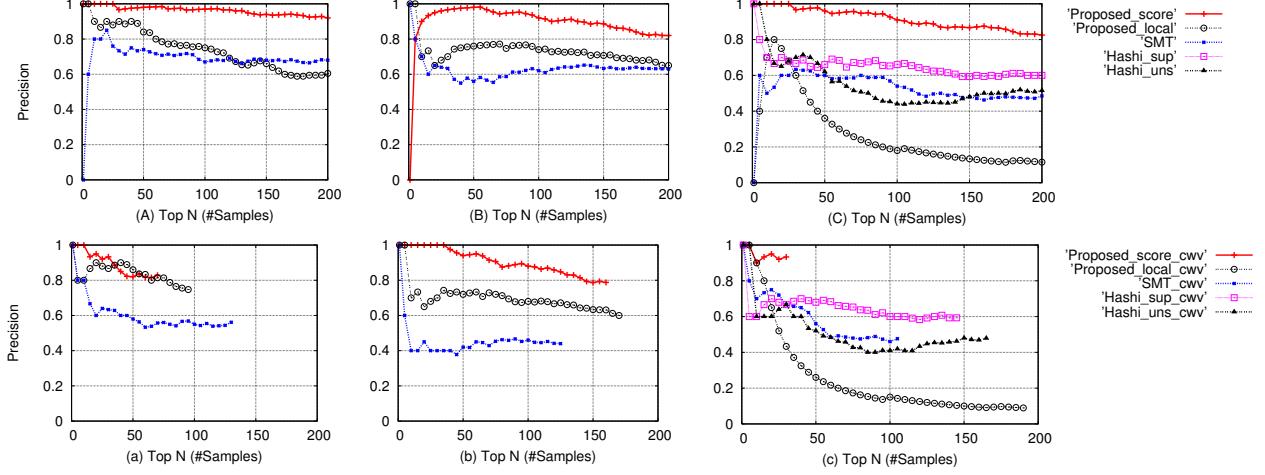

Figure 4: Precision curves of *Exp1*: English (A)(a), Chinese (B)(b), and Japanese (C)(c).

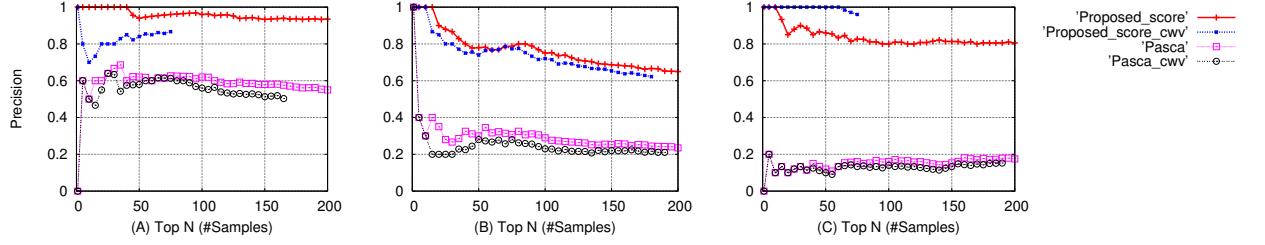

Figure 5: Precision curves of *Exp2*: English (A), Chinese (B), and Japanese (C).

of them were paraphrases. The lower half of Figure 4 shows the results (curves labeled with *_cwv*). The number of samples for *ProposedScore* reduced drastically compared to the others for English and Japanese, though precision was kept at a high level. It is due mainly to the *globalSim*; the *Diff* of the non-content word variation pairs appears frequently in paraphrase candidates, and thus their *globalSim* scores are high.

From *Exp2*, precision curves in Figure 5 were obtained. *P&D* acquired more content word variation pairs as the curves labeled by *_cwv* indicates. However, *ProposedScore*'s precision outperformed *P&D*'s by a large margin for the three languages.

From all of these results, we conclude (1) that our paraphrase extraction method outperforms unsupervised methods for the three languages, (2) that *globalSim* is effective, and (3) that our method is comparable to the state-of-the-art supervised method for Japanese, though our method tends to extract fewer content word variation pairs than the others.

Table 7 shows examples of English paraphrases extracted by *ProposedScore*.

is based in Halifax = is headquartered in Halifax
used for treating HIV = used to treat HIV
is a rare form = is an uncommon type
is a set = is an unordered collection
has an important role = plays a key role

Table 7: Examples of extracted English paraphrases.

4 Conclusion

We proposed a minimally supervised method for multilingual paraphrase extraction. Our experiments showed that our paraphrase extraction method outperforms unsupervised methods (Paşa and Dienes, 2005; Koehn et al., 2007; Hashimoto et al., 2011) for English, Japanese, and Chinese, and is comparable to the state-of-the-art language dependent supervised method for Japanese (Hashimoto et al., 2011).

Abstract

Traditional relation extraction predicts relations within some fixed and finite target schema. Machine learning approaches to this task require either manual annotation or, in the case of distant supervision, existing structured sources of the same schema. The need for existing datasets can be avoided by using a *universal schema*: the union of all involved schemas (surface form predicates as in OpenIE, and relations in the schemas of pre-existing databases). This schema has an almost unlimited set of relations (due to surface forms), and supports integration with existing structured data (through the relation types of existing databases). To populate a database of such schema we present matrix factorization models that learn latent feature vectors for entity tuples and relations. We show that such latent models achieve substantially higher accuracy than a traditional classification approach. More importantly, by operating simultaneously on relations observed in text and in pre-existing structured DBs such as Freebase, we are able to reason about unstructured and structured data in mutually-supporting ways. By doing so our approach outperforms state-of-the-art distant supervision.

1 Introduction

Most previous work in relation extraction uses a pre-defined, finite and fixed schema of relation types (such as *born-in* or *employed-by*). Usually some textual data is labeled according to this schema, and this labeling is then used in supervised training of an automated relation extractor, e.g. Culotta and Sorensen (2004). However, labeling textual rela-

tions is time-consuming and difficult, leading to significant recent interest in distantly-supervised learning. Here one aligns existing database records with the sentences in which these records have been “rendered”—effectively labeling the text—and from this labeling we can train a machine learning system as before (Craven and Kumlien, 1999; Mintz et al., 2009; Bunescu and Mooney, 2007; Riedel et al., 2010). However, this method relies on the availability of a large database that has the desired schema.

The need for pre-existing datasets can be avoided by using language itself as the source of the schema. This is the approach taken by OpenIE (Etzioni et al., 2008). Here surface patterns between mentions of concepts serve as relations. This approach requires no supervision and has tremendous flexibility, but lacks the ability to generalize. For example, OpenIE may find FERGUSON–historian-at–HARVARD but does not know FERGUSON–is-a-professor-at–HARVARD. OpenIE has traditionally relied on a large diversity of textual expressions to provide good coverage. But this diversity is not always available, and, in any case, the lack of generalization greatly inhibits the ability to support reasoning.

One way to gain generalization is to cluster textual surface forms that have similar meaning (Lin and Pantel, 2001; Pantel et al., 2007; Yates and Etzioni, 2009; Yao et al., 2011). While the clusters discovered by all these methods usually contain semantically related items, closer inspection invariably shows that they do not provide reliable implicature. For example, a typical representative cluster may include *historian-at*, *professor-at*, *scientist-at*, *worked-at*. Although these relation types are indeed semantically related, note that *scientist-at* does not necessarily imply *professor-at*, and *worked-at*

certainly does not imply *scientist-at*. In fact, we contend that any relational schema would inherently be brittle and ill-defined—having ambiguities, problematic boundary cases, and incompleteness.¹ For example, Freebase, in spite of its extensive effort towards high coverage, has no *critized* nor *scientist-at* relation.

In response to this problem, we present a new approach: implicature with *universal schemas*. Here we embrace the diversity and ambiguity of original inputs; we avoid forcing textual meaning into pre-defined boxes. This is accomplished by defining our schema to be the union of all source schemas: original input forms, e.g. variants of surface patterns similarly to OpenIE, as well as relations in the schemas of many available pre-existing structured databases. But then, unlike OpenIE, our focus lies on learning asymmetric implicature among relations. This allows us to probabilistically “fill in” inferred unobserved entity-entity relations in this union. For example, after observing FERGUSON–*historian-at*–HARVARD our system infers that FERGUSON–*professor-at*–HARVARD, but not vice versa.

At the heart of our approach is the hypothesis that we should concentrate on predicting source data—a relatively well defined task that can be evaluated and optimized—as opposed to modeling semantic equivalence, which we believe will always be illusive.

Note that by operating simultaneously on relations observed in text and in pre-existing structured databases such as Freebase, we are able to reason about unstructured and structured data in mutually-supporting ways. For example, we can predict surface pattern relations that effectively serve as additional features when predicting Freebase relations, hence improving generalization. Also notice that users of our system will not have to study and understand the complexities of a particular schema in order to issue queries; they can ask in whatever form naturally occurs to them, and our system will likely already have that relation in our universal schema.

Our technical approach is based on extensions to probabilistic models of matrix factorization and

¹ At NAACL 2012 Lucy Vanderwende asked “Where do the relation types come from?” There was no satisfying answer. At the same meeting, and in line with Brachman (1983), Ed Hovy stated “We don’t even know what is-a means.”

collaborative filtering (Collins et al., 2001; Koren, 2008; Rendle et al., 2009). We represent the probabilistic knowledge base as a matrix with entity-entity pairs in the rows and relations in the columns (see figure 1). The rows come from running cross-document entity resolution across pre-existing structured databases and textual corpora. The columns come from the union of surface forms and DB relations. We present a series of models that learn lower dimensional manifolds for tuples, relations and entities, and a set of weights that capture direct correlations between relations. Weights and lower dimensional representations act, through dot products, as the natural parameters of a single log-linear model to derive per-cell probabilities.

In experiments we show that our models can accurately predict surface patterns relationships which do not appear explicitly in text, and that learning latent representations of entities, tuples and relations substantially improves results over a traditional classifier approach. Moreover, we can improve accuracy by simultaneously operating on relations observed in the New York Times corpus and in Freebase. In particular, our model outperforms the current state-of-the-art distant supervision method (Surdeanu et al., 2012) by 10% points Mean Average Precision through joint implicature among surface patterns and Freebase relations.

2 Model

Before we present our approach in more detail, we briefly introduce some notation. We use \mathcal{R} to denote the set of relations we seek to predict (such as *works-written* in Freebase, or the X–*historian-at*–Y pattern), and \mathcal{T} to denote the set of input tuples. For simplicity we assume each relation to be binary, although our approach can be easily generalized to the n-ary case. Given a relation $r \in \mathcal{R}$ and a tuple $t \in \mathcal{T}$ the pair $\langle r, t \rangle$ is a *fact*, or relation instance. The input to our model is a set of observed facts \mathcal{O} , and the observed facts for a given tuple is denoted by $\mathcal{O}_t := \{\langle r, t \rangle \in \mathcal{O}\}$.

Our goal is a model that can estimate, for a given relation r (such as X–*historian-at*–Y) and a given tuple t (such as <FERGUSON,HARVARD>), the probability $p(y_{r,t} = 1)$ where $y_{r,t}$ is a binary random variable that is true iff t is in relation r . We

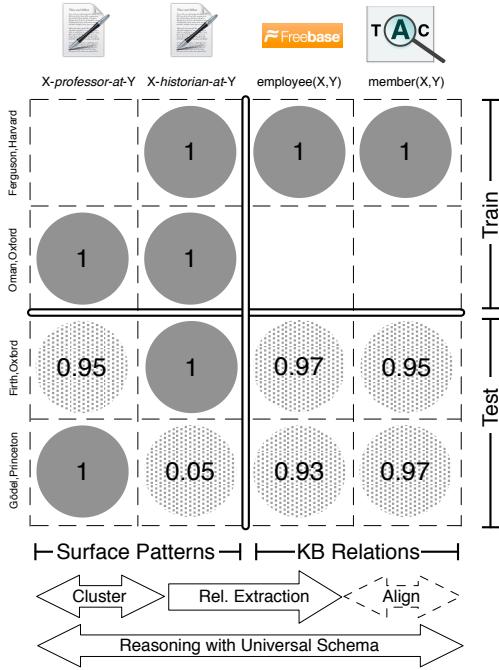

Figure 1: Filling up a database of universal schema. Dark circles are observed facts, shaded circles are inferred facts. Relation Extraction (RE) maps surface pattern relations (and other features) to structured relations. Surface form clustering models correlations between patterns, and can be fed into RE (Yao et al., 2011). Database alignment and integration models correlations between structured relations (not done in this work). Reasoning with the universal schema incorporates these tasks in a joint fashion.

introduce a series of exponential family models that estimate this probability using a *natural parameter* $\theta_{r,t}$ and the logistic function:

$$p(y_{r,t} = 1 | \theta_{r,t}) := \sigma(\theta_{r,t}) = \frac{1}{1 + \exp(-\theta_{r,t})}.$$

We will first describe our models through different definitions of the natural parameter $\theta_{r,t}$. In each case $\theta_{r,t}$ will be a function of r , t and a set of weights and/or latent feature vectors. In section 2.5 we will then show how these weights and vectors can be estimated based on the observed facts \mathcal{O} .

Notice that we can interpret $p(y_{r,t} = 1)$ as the probability that a customer t likes product r . This analogy allows us to draw from a large body of work in collaborative filtering, such as work in probabilistic matrix factorization and implicit feedback.

2.1 Latent Feature Model

One way to define $\theta_{r,t}$ is through a latent feature model F. Here we measure compatibility between relation r and tuple t as dot product of two latent feature representations of size K^F : \mathbf{a}_r for relation r , and \mathbf{v}_t for tuple t . This gives:

$$\theta_{r,t}^F := \sum_k a_{r,k} v_{t,k}.$$

This corresponds to generalized PCA (Collins et al., 2001), a model where the matrix $\Theta = (\theta_{r,t})$ of natural parameters is defined as the low rank factorization $\mathbf{A}\mathbf{V}$.

Notice that we intentionally omit any per-relation bias-terms. In section 4 we evaluate ranked answers to queries on a per-relation basis, and a per-relation bias term will have no effect on ranking facts of the same relation. Also consider that such latent feature models can capture asymmetry by assigning more peaked vectors to specific relations, and more uniform vectors to general relations.

2.2 Neighborhood Model

We can interpolate the confidence for a given tuple and relation based on the trueness of other similar relations for the same tuple. In collaborative filtering this is referred to as a *neighborhood-based* approach (Koren, 2008). In terms of our natural parameter, we implement a neighborhood model N via a set of weights $w_{r,r'}$, where each corresponds to a directed association strength between relations r and r' . For a given tuple t and relation r we then sum up the weights corresponding to all relations r' that have been observed for tuple t :

$$\theta_{r,t}^N := \sum_{(r',t) \in \mathcal{O} \setminus \{(r,t)\}} w_{r,r'}.$$

Notice that the neighborhood model amounts to a collection of local log-linear classifiers, one for each relation r with feature functions $f_{r,r'}(t) = \mathbb{I}[r' \neq r \wedge (r', t) \in \mathcal{O}]$ and weights \mathbf{w}_r . This means that in contrast to model F, this model cannot harness any synergies between textual and pre-existing DB relations.

2.3 Entity Model

Relations have selectional preferences: they allow only certain types in their argument slots. While knowledge bases such as Freebase or DBpedia have extensive ontologies of types of entities, these are often not sufficiently fine to allow relations to discriminate (Yao et al., 2012b). Hence, instead of using a predetermined set of entity types, in our *entity model* E we learn a latent entity representation from data. More concretely, for each entity e we introduce a latent feature vector \mathbf{t}_e of dimension K^E . In addition, for each relation r and argument slot i we introduce a feature vector \mathbf{d}_i of the same dimension. For example, binary relations have feature representations \mathbf{d}_1 for argument 1, and \mathbf{d}_2 for argument 2. Measuring compatibility of an entity tuple and relation amounts to measuring, and summing up, compatibility between each argument slot representation and the corresponding entity representation. This leads to:

$$\theta_{r,t}^E := \sum_{i=1}^{\text{arity}(r)} \sum_k d_{i,k} t_{t_i,k}.$$

Note that due to entity resolution, tuples may share entities, and hence parameters are shared across rows.

2.4 Combined Model

In practice all the above models can capture important aspects of the data. Hence we also use various combinations, such as:

$$\theta_{r,t}^{\text{NFE}} := \theta_{r,t}^N + \theta_{r,t}^F + \theta_{r,t}^E.$$

2.5 Parameter Estimation

Our models are parametrized through weights and latent component vectors. We could estimate these parameters by maximizing the loglikelihood of the observed data akin to Collins et al. (2001). However, as we do not have access to negative facts, the model would simply learn to predict all facts to be true. In our initial attempt to overcome this issue we sampled a set of unobserved facts as designated negative facts, as is done in related distant supervision approaches. However, we found that (a) our results were sensitive to the choice of negative data and (b) runtime was increased substantially because of a large number of required negative facts.

In collaborative filtering positive-only data is also known as *implicit feedback*. This type of feedback arises, for example, when users buy but not rate items. One successful approach to learning with implicit feedback is based on the observation that the actual task is not necessarily one of prediction (here: to predict a number between 0 and 1) but one of (generally simpler) ranking: to give true “user-item” cells higher scores than false ones. *Bayesian Personalized Ranking* (BPR) uses a variant of this ranking: giving observed true facts higher scores than unobserved (true or false) facts (Rendle et al., 2009). This relaxed constraint is to be contrasted with the log-likelihood setting that essentially requires (randomly sampled) negative facts to score below a globally defined threshold.

2.5.1 Objective

We first create a dataset of *ranked pairs*: for each relation r and each observed fact $f^+ := \langle r, t^+ \rangle \in \mathcal{O}$ we choose all tuples t^- such that $f^- := \langle r, t^- \rangle \notin \mathcal{O}$ —that is, tuples we have not observed to be in relation r . For each pair of facts f^+ and f^- we want $p(f^+) > p(f^-)$ and hence $\theta_{f^+} > \theta_{f^-}$. In BPR this is achieved by maximizing a sum terms of the form $\text{Obj}_{f^+, f^-} := \log(\sigma(\theta_{f^+} - \theta_{f^-}))$, one for each ranked pair:

$$\text{Obj} := \sum_{\langle r, t^+ \rangle \in \mathcal{O}} \sum_{\langle r, t^- \rangle \notin \mathcal{O}} \text{Obj}_{\langle r, t^+ \rangle, \langle r, t^- \rangle}. \quad (1)$$

Notice that this objective differs slightly from the one used by Rendle et al. (2009). Consider tuples as users and items as relations. We rank different users with respect to the same item, while BPR ranks items with respect to the same user. Also notice that the BPR objective is an approximation to the per-relation AUC (area under the ROC curve), and hence directly correlated to what we want to achieve: well-ranked tuples per relation.

Note that all parameters are regularized with quadratic penalty which we omit here for brevity.

2.5.2 Optimization

To maximize the objective² in equation 1 we follow Rendle et al. (2009) and employ Stochastic Gradient Descent (SGD). In particular, in each epoch

²This objective is non-convex for all models excluding the N model.

we sample $|\mathcal{O}|$ facts with replacement from \mathcal{O} . For each sampled fact $\langle r, t^+ \rangle$ we then sample a tuple $t^- \in \mathcal{T}$ such that $\langle r, t^- \rangle \notin \mathcal{O}$ is not an observed fact. This gives us $|\mathcal{O}|$ fact pairs $\langle f^+, f^- \rangle$, and for each pair we do an SGD update using the corresponding gradients of Obj_{f^+, f^-} . For the F model the gradients correspond to those presented by Rendle et al. (2009). The remaining gradients are easy to derive; we omit details for brevity.

3 Related Work

This work extends a previous workshop paper (Yao et al., 2012a) by introducing the neighborhood and entity model, by working with the BPR objective, and by more extensive experiments.

Relational Clustering There is a large body of work aiming to discover latent relations by clustering surface patterns (Hasegawa et al., 2004; Shinyama and Sekine, 2006; Kok and Domingos, 2008; Yao et al., 2011; Takamatsu et al., 2011), or by inducing synonymy relationships between patterns independently of the entities (Yates and Etzioni, 2009; Pantel et al., 2007; Lin and Pantel, 2001). Our approach has a fundamentally different objective: we are not (primarily) interested in clusters of patterns or their semantic representation, but in predicting patterns where they are not observed. Moreover, these related methods rely on a *symmetric* notion of synonymy in which clustered patterns are assumed to have the same meaning. Our approach rejects this assumption in favor of a model which learns that certain patterns, or combinations thereof, *entail* others in one direction, but not necessarily the other. This is similar in spirit to work on learning entailment rules (Szpektor et al., 2004; Zanzotto et al., 2006; Szpektor and Dagan, 2008). However, for us even entailment rules are just a by-product of our goal to improve prediction, and it is this goal we directly optimize for and evaluate.

Matrix Factorization Our approach is also related to work on factorizing YAGO to predict new links (Nickel et al., 2012). The primary differences are that we include surface patterns in our schema, use a ranking objective, and learn latent vectors for entities and tuples. Likewise, matrix factorization in various flavors has received significant attention in

the lexical semantics community, from LSA to recent work on non-negative sparse embeddings (Murphy et al., 2012). In our problem columns correspond to relations, and rows correspond to entity tuples. By contrast, there columns are words, and rows are contextual features such as “words in a local window.” Consequently, our objective is to *complete* the matrix, whereas their objective is to learn better latent embeddings of words (which by themselves again cannot capture any sense of asymmetry).

OpenIE Open IE (Etzioni et al., 2008) extracts facts mentioned in text, but does not predict potential facts not mentioned in text. Finding answers requires explicit mentions, and hence suffers from lower recall for not-so-frequently mentioned facts. Methods that learn rules between textual patterns in OpenIE aim at a similar goal as our proposed approach (Schoenmackers et al., 2008; Schoenmackers et al., 2010). However, their approach is substantially more complex, requires a categorization of entities into fine grained entity types, and needs inference in high tree-width Markov Networks. By contrast, our approach is based on a single unified model, requires no entity types, and for us inferring a fact amounts to not more than a few dot products. In addition, in our Universal Schema approach OpenIE surface patterns are just one kind of relations, and our aim is populate relations of all kinds. In the future we may even include relations between entities and continuous attributes (say, gene expression measurements).

Distant Supervision In Distant Supervision (DS) a set of facts from pre-existing structured sources is aligned with surface patterns mentioned in text (Bunescu and Mooney, 2007; Mintz et al., 2009; Riedel et al., 2010; Hoffmann et al., 2011; Surdeanu et al., 2012), and this alignment is then used to train a relation extractor. A core difference to our approach is the number of target relations: In DS it is the relatively small schema size of the knowledge base, while we also include surface patterns. This allows us to answer more expressive queries. Moreover, by learning from surface-pattern correlations, our latent models induce feature representations for patterns that do not appear in the DS training set. As we will see in section 4, this allows us to outperform state-of-the-art DS models.

Never-Ending Learning and Bootstrapping Our latent feature models are capable of never-ending learning (Carlson et al., 2010). That is, we can continue to train these models with incoming data, even if no structured annotation is available. In bootstrapping approaches the current model is used to predict new relations, and these hypothesized relations are used as new supervision targets (i.e. self-training). By contrast, our model only strengthens the correlations between incoming co-occurring observations. This has the advantage that wrong predictions are less likely be reinforced, hence reducing the risk of semantic drift.

4 Experiments

How accurately can we fill a database of Universal Schema, and does reasoning jointly across a universal schema help to improve over more isolated approaches? In the following we seek to answer this question empirically. To this end we train our models on observed facts in a newswire corpus and Freebase, and then manually evaluate ranked predictions: first for structured relations and then for surface form relations.

4.1 Data

Following previous work (Riedel et al., 2010), our documents are taken from the NYTimes corpus (Sandhaus, 2008). Articles after 2000 are used as training corpus, articles from 1990 to 1999 as test corpus. We also split Freebase facts 50/50 into train and test facts, and their corresponding tuples into train and test tuples. Then we align training tuples with the training corpus, and test tuples with the test corpus. This alignment relies on a preprocessing step that links NER mentions in text with entities in Freebase. In our case we use a simple string-match heuristic to find this linking. Now we align an entity tuple $\langle t_1, t_2 \rangle$ with a pair of mentions $\langle m_1, m_2 \rangle$ in the same sentence if m_1 is linked to t_1 and m_2 to t_2 . Based on this alignment we filter out all relations for which we find fewer than 10 tuples with mentions in text.

The above alignment and filtering process reduces the total number of tuples related according to Freebase to 16k: approximately 8k tuples with facts mentioned in the training set, and approximately 8k

such tuples for the test set. In addition we have a set of approximately 200k training tuples for which both arguments appear in the same sentence and both can be linked to Freebase entities, but for which no Freebase fact is recorded. This can either be because they are not related, or simply because Freebase does not contain the relationship yet. We also have about 200k such tuples in the test set. To simplify evaluation, we create a *subsampled test set* by randomly choosing 10k of the original test set tuples.

The above alignment allows us to determine, for each tuple t , the observed facts \mathcal{O}_t as follows. To find the surface pattern facts $\mathcal{O}_t^{\text{PAT}}$ for the tuple $t = \langle t_1, t_2 \rangle$ we extract, for each mention $m = \langle m_1, m_2 \rangle$ of t , the *lexicalized dependency path* p between m_1 and m_2 . Then we add $\langle p, t \rangle$ to $\mathcal{O}_t^{\text{PAT}}$. For example, we get “<-subj->head->obj->” for “M1 heads M2.” Filtering out patterns with fewer than 10 mentions in text yields approximately 4k patterns. For training tuples we add as Freebase facts $\mathcal{O}_t^{\text{FB}}$ all facts $\langle r, t \rangle$ that appear in Freebase, and for which r has not been filtered out beforehand. For the test set $\mathcal{O}_t^{\text{FB}}$ remains empty. The total set of observed facts \mathcal{O}_t is $\mathcal{O}_t^{\text{FB}} \cup \mathcal{O}_t^{\text{PAT}}$, and their union over all tuples forms the set of observed facts \mathcal{O} .

4.2 Evaluation

For evaluation we use collections of relations: surface patterns in one experiment and Freebase relations in the other. In either case we compare the competing systems with respect to their ranked results for each relation in the collection. Given this ranking task, our evaluation is inspired by the TREC competitions and work in information retrieval (Manning et al., 2008). That is, we treat each relation as query and receive the top 1000 (*run depth*) entity pairs from each system. Then we pool the top 100 (*pool depth*) answers from each system and manually judge their relevance or “truth.” This gives a set of relevant results that we can use to calculate recall and precision measures. In particular, we can use these annotations to measure an *average precision* across the precision-recall curve, and an aggregate *mean average precision* (MAP) across all relations. This metric has shown to be very robust and stable (Manning et al., 2008). In addition we also present a weighted version of MAP (weighted MAP) in which the average precision for each re-

Table 1: Average and (weighted) Mean Average Precisions for Freebase relations based on pooled results. The # column shows the number of true facts in the pool. NFE is statistically different to all but NF and F according to the sign test. Bold faced are winners per relation, italics indicate ties.

lation is weighted by the relation’s number of true facts.

Notice that we deviate from previous work in distant supervision that (a) combines the results from several relations in a single precision recall curve, and (b) uses held-out evaluation to measure how well the predictions match existing Freebase facts. This has several benefits. First, when aggregating across relations results are often dominated by a few very frequent relations, such as *containedby*, providing little information about how the models perform across the board. Second, evaluating with Freebase held-out data is biased. For example, we find that frequently mentioned entity pairs are more likely to have relations in Freebase. Systems that rank such tuples higher receives higher precision than those that do not have such bias, regardless of how correct their predictions are. Third, we can aggregate per-relation comparisons to establish statistical significance, for example via the sign test.

Also note that while we run our models on the complete training and test set, evaluation is restricted to the subsampled test set.

4.3 Predicting Freebase Relations

Table 1 shows our results for Freebase relations, omitting those for which none of the systems can find any relevant facts. Our first baseline is MI09, a distantly supervised classifier based on the work of Mintz et al. (2009). This classifier only learns from observed pattern-relation pairs in the training set (of which we only have about 8k). By contrast, our latent feature models can learn pattern-pattern correlations both on the unlabeled training and test set (comparable to bootstrapping). We hence also compare against YA11, a version of MI09 that uses preprocessed cluster features according to Yao et al. (2011). The third baseline is SU12, the state-of-the-art Multi-Instance Multi-Label system by Surdeanu et al. (2012).

The remaining systems are our neighborhood

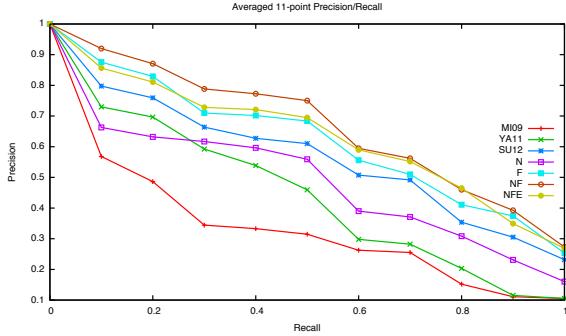

Figure 2: Averaged 11-point precision recall curve for Freebase relations in table 1.

model (N), the factorized model (F), their combination (NF) and the combined model with a latent entity representation (NFE). For all our models we use the same number of components when applicable ($K^F = K^E = 100$), 1000 epochs, and 0.01 as regularizer for component weights and 0.1 for neighborhood weights.

Table 1 shows that adding pattern cluster features (and hence incorporating more data) helps YA11 to improve over MI09. Likewise, we see that the factorized model F improves over N, again learning from unlabeled data. This improvement is bigger than the corresponding change between MI09 and YA11, possibly indicating that our latent representations are optimized directly towards improving prediction performance. The combination of N, F and E outperforms all other models in terms of weighted MAP, indicating the power of selectional preferences learned from data. Note that NFE is significantly different ($p \ll 0.05$ in sign test) to all but the NF and F models. In terms of MAP the NF model outperforms NFE, indicating that it does not do as well for frequent relations, but better for infrequent ones.

Figure 2 shows an averaged 11-point precision recall graph (Manning et al., 2008) for Freebase relations. We notice that our latent models outperform all remaining models across all recall levels, and that combining neighborhood and latent models is helpful. This finding is consistent with our MAP results. Figure 3 shows the recall-precision curve for the *works_written* relation with respect to our three baselines and the NFE model. Observe how preci-

Weighted MAP		0.28	0.56	0.50	0.46

Table 2: Average and (weighted) Mean Average Precisions for surface patterns.²

sion drops for both MI09 and SU12 at about 50% recall. At this point the remaining unretrieved facts have patterns that have not been seen together with *works_written* in the training set. By using cluster features, YA11 can overcome this problem partly, but not as dramatically as NFE—a pattern we observe for many relations.

All our models are fast to train. The slowest model trains in just 45 minutes. By contrast, training the topic model in YA11 alone takes 4 hours. Training SU12 takes two hours (on less data). Also notice that our models not only learn to predict Freebase relations, but also approximately 4k surface pattern relations.

4.4 Predicting Surface Patterns

Table 2 presents a comparison of our models with respect to 10 surface pattern relations. These relations

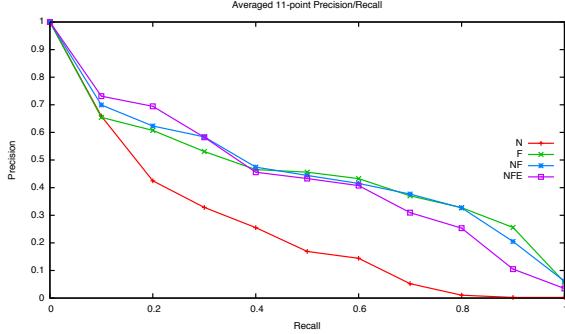

Figure 4: Averaged 11-point precision recall curve for surface pattern relations in table 2.

were chosen according to what we believe are interesting questions not currently captured in Freebase. We again see that learning a latent representation (F, NF and NFE) from additional data helps quite substantially over the N model. For in the weighted MAP metric we note that incorporating entity representations (in the NFE model) in fact hurts total performance.³ One reason may be the fact that Freebase relations are typed—they require very specific types of entities as arguments. By contrast, for a surface pattern like “X visits Y” X could be a person or organization, and Y could be a location, organization or person. However, in terms of MAP score this time there is no obvious winner among the latent models. This is also confirmed by the averaged 11-point precision recall curve in figure 4.

Notice that we can accurately predict the *X-scientist-at-Y* surface pattern relation in table 2, as well as the more general *person/company* (*employedBy*) relation in table 1. This indicates that our models can capture asymmetry—a symmetric model would either over-predict *X-scientist-at-Y* or under-predict *person/company*.

5 Conclusion

We present relation extraction into universal schemas. Such schemas contain surface patterns as relations, as well as relations from structured sources. By predicting missing tuples for surface pattern relations we can populate a database without any labelled data, and answer questions not sup-

³Due to the small set of relations only N is significantly different to F, NF and NFE ($p \ll 0.05$ in sign test).

ported by the structured schema alone. By predicting missing tuples in the structured schema we can expand a knowledge base of fixed schema, and only require a set of existing facts from this schema. Crucially, by predicting and modeling both surface patterns and structured relations *simultaneously* we can improve performance. We show this experimentally by contrasting a series of the popular weakly supervised models to our collaborative filtering models that learn latent feature representations across surface patterns and structured relations. Moreover, our models are computationally efficient, requiring less time than comparable methods, while learning more relations.

Reasoning with universal schemas is not merely a tool for information extraction. It can also serve as a framework for various data integration tasks. For example, we could integrate facts from one schema (say, Freebase) into another (say, the TAC KBP schema) by adding both sets of relations to the set of surface patterns. Reasoning with this schema will mean populating each database with facts from the other, and would leverage information in surface patterns to improve integration. In future work we also plan to integrate universal entity types and attributes into the model.

The source code of our system, its output, and all data annotations are available at <http://www.riedelcastro.org/uschema>.

Extracting the Native Language Signal for Second Language Acquisition

Abstract

We develop a method for effective extraction of linguistic patterns that are differentially expressed based on the native language of the author. This method uses multiple corpora to allow for the removal of data set specific patterns, and addresses both feature relevancy and redundancy. We evaluate different relevancy ranking metrics and show that common measures of relevancy can be inappropriate for data with many rare features. Our feature set is a broad class of syntactic patterns, and to better capture the signal we extend the Bayesian Tree Substitution Grammar induction algorithm to a supervised mixture of latent grammars. We show that this extension can be used to extract a larger set of relevant features.

1 Introduction

Native Language Identification (NLI) is a classification task in which a statistical signal is exploited to determine an author’s native language (L1) from their writing in a second language (L2). This academic exercise is often motivated not only by fraud detection or authorship attribution for which L1 can be an informative feature, but also by its potential to assist in Second Language Acquisition (SLA).

Our work focuses on the latter application and on the observation that the actual ability to automatically determine L1 from text is of limited utility in the SLA domain, where the native language of a student is either known or easily solicited. Instead, the likely role of NLP in the context of SLA is to provide a set of linguistic patterns that students with

certain L1 backgrounds use with a markedly unusual frequency. Experiments have shown that such L1 specific information can be incorporated into lesson plans that improve student performance (Laufer and Girsai, 2008; Horst et al, 2008).

This is essentially a feature selection task with the additional caveat that features should be individually discriminative between native languages in order to facilitate the construction of focused educational exercises. With this goal, we consider metrics for data set dependence, relevancy, and redundancy. We show that measures of relevancy based on mutual information can be inappropriate in problems such as ours where rare features are important.

While the majority of the methods that we consider generalize to any of the various feature sets employed in NLI, we focus on the use of Tree Substitution Grammar rules as features. Obtaining a compact feature set is possible with the well known Bayesian grammar induction algorithm (Cohn and Blunsom, 2010), but its rich get richer dynamics can make it difficult to find rare features. We extend the induction model to a supervised mixture of latent grammars and show how it can be used to incorporate linguistic knowledge and extract discriminative features more effectively.

The end result of this technique is a filtered list of patterns along with their usage statistics. This provides an enhanced resource for SLA research such as Jarvis and Crossley (2012) which tackles the manual connection of highly discriminative features with plausible linguistic transfer explanations. We output a compact list of language patterns that are empirically associated with native language labels, avoid-

ing redundancy and artifacts from the corpus creation process. We release this list for use by the linguistics and SLA research communities, and plan to expand it with upcoming releases of L1 labeled corpora¹.

2 Related Work

Our work is closely related to the recent surge of research in NLI. Beginning with Koppel et al (2005), several papers have proposed different feature sets to be used as predictors of L1 (Tsur and Rappaport, 2007; Wong and Dras, 2011a; Swanson and Charniak, 2012). However, due to the ubiquitous use of random subsamples, different data preparation methods, and severe topic and annotation biases of the data set employed, there is little consensus on which feature sets are ideal or sufficient, or if any reported accuracies reflect some generalizable truth of the problem’s difficulty. To combat the bias of a single data set, a new strain of work has emerged in which train and test documents come from different corpora (Brooke and Hirst, 2012; Tetreault et al, 2012; Bykh and Meurers, 2012). We follow this cross corpus approach, as it is crucial to any claims of feature relevance.

Feature selection itself is a well studied problem, and the most thorough systems address both relevancy and redundancy. While some work tackles these problems by optimizing a metric over both simultaneously (Peng et al, 2005), we decouple the notions of relevancy and redundancy to allow ad-hoc metrics for either, similar to the method of Yu and Liu (2004). The measurement of feature relevancy in NLI has to this point been handled primarily with Information Gain, and elimination of feature redundancy has not been considered.

Tree Substitution Grammars have recently been successfully applied in several domains using the induction algorithm presented by Cohn and Blunsom (2010). Our hierarchical treatment builds on this work by incorporating supervised mixtures over latent grammars into this induction process. Latent mixture techniques for NLI have been explored with other feature types (Wong and Dras, 2011b; Wong and Dras, 2012), but have not previously led to measurable empirical gains.

3 Corpus Description

We first make explicit our experimental setup in order to provide context for the discussion to follow. We perform analysis of English text from Chinese, German, Spanish, and Japanese L1 backgrounds drawn from four corpora. The first three consist of responses to essay prompts in educational settings, while the fourth is submitted by users in an internet forum.

The first corpus is the International Corpus of Learner English (ICLE) (Granger et al, 2002), a mainstay in NLI that has been shown to exhibit a large topic bias due to correlations between L1 and the essay prompts used (Brooke and Hirst, 2011). The second is the International Corpus of Crosslinguistic Interlanguage (ICCI) (Tono et al, 2012), which is annotated with sentence boundaries and has yet to be used in NLI. The third is the public sample of the Cambridge International Corpus (FCE), and consists of short prompted responses. One quirk of the FCE data is that several responses are written in the form of letters, leading to skewed distributions of the specialized syntax involved with use of the second person. The fourth is the Lang8 data set introduced by Brooke and Hirst (2011). This data set is free of format, with no prompts or constraints on writing aids. The samples are often very short and are qualitatively the most noisy of the four data sets.

One distinctive experimental decision is to treat each sentence as an individual datum. As document length can vary dramatically, especially across corpora, this gives increased regularity to the number of features per data item. More importantly, this creates a rough correspondence between feature co-occurrence and the expression of the same underlying linguistic phenomenon, which is desirable for automatic redundancy metrics.

We automatically detect sentence boundaries when they are not provided, and parse all corpora with the 6-split Berkeley Parser. As in previous NLI work, we then replace all word tokens that do not occur in a list of 614 common words with an unknown word symbol, UNK.

While these are standard data preprocessing steps, from our experience with this problem we propose additional practical considerations. First, we filter the parsed corpora, retaining only sentences that are

parsed to a Clause Level² tag. This is primarily due to the fact that automatic sentence boundary detectors must be used on the ICLE, Lang8, and FCE data sets, and false positives lead to sentence fragments that are parsed as NP, VP, FRAG, etc. The wild internet text found in the Lang8 data set also yields many non-Clause Level parses from non-English text or emotive punctuation. Sentence detection false negatives, on the other hand, lead to run-on sentences, and so we additionally remove sentences with more than 40 words.

We also impose a simple preprocessing step for better treatment of proper nouns. Due to the geographic distribution of languages, the proper nouns used in a writer’s text naturally present a strong L1 signal. The obvious remedy is to replace all proper nouns with UNK, but this is unfortunately insufficient as the structure of the proper noun itself can be a covert signal of these geographical trends. To fix this, we also remove all proper noun left sisters of proper nouns. We choose to retain the rightmost sister node in order to preserve the plurality of the noun phrase, as the rightmost noun is most likely the lexical head.

From these parsed, UNKed, and filtered corpora we draw 2500 sentences from each L1 background at random, for a total of 10000 sentences per corpus. The exception is the FCE corpus, from which we draw 1500 sentences per L1 due to its small size.

4 Tree Substitution Grammars

A Tree Substitution Grammar (TSG) is a model of parse tree derivations that begins with a single ROOT nonterminal node and iteratively rewrites nonterminal leaves until none remain. A TSG rewrite rule is a tree of any depth, as illustrated in Figure 1, and can be used as a binary feature of a parsed sentence that is triggered if the rule appears in any derivation of that sentence.

Related NLI work compares a plethora of suggested feature sets, ranging from character n-grams to latent topic activations to labeled dependency arcs, but TSG rules are best able to represent complex lexical and syntactic behavior in a homogeneous feature type. This property is summed up nicely by the desire for features that capture rather

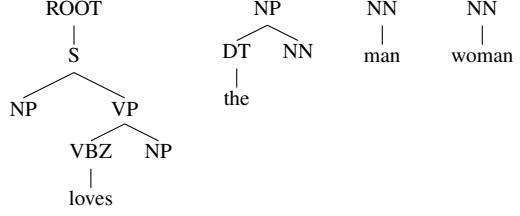

Figure 1: A Tree Substitution Grammar capable of describing the feelings of people of all sexual orientations.

than cover linguistic phenomena (Johnson, 2012); while features such as character n-grams, POS tag sequences, and CFG rules may provide a usable L1 signal, each feature is likely covering some component of a pattern instead of capturing it in full. TSG rules, on the other hand, offer remarkable flexibility in the patterns that they can represent, potentially capturing any contiguous parse tree structure.

As it is intractable to rank and filter the entire set of possible TSG rules given a corpus, we start with the large subset produced by Bayesian grammar induction. The most widely used algorithm for TSG induction uses a Dirichlet Process to choose a subset of frequently reoccurring rules by repeatedly sampling derivations for a corpus of parse trees (Cohn and Blunsom, 2010). The rich get richer dynamic of the DP leads to the use of a compact set of rules that is an effective feature set for NLI (Swanson and Charniak, 2012). However, this same property makes rare rules harder to find.

To address this weakness, we define a general model for TSG induction in labeled documents that combines a Hierarchical Dirichlet Process (Teh et al, 2005), with supervised labels in a manner similar to upstream supervised LDA (Mimno and McCallum, 2008). In the context of our work the document label η indicates both its authors native language L and data set D . Each η is associated with an observed Dirichlet prior ν_η , and a hidden multinomial θ_η over grammars is drawn from this prior. The traditional grammatical model of nonterminal expansion is augmented such that to rewrite a symbol we first choose a grammar from the document’s θ_η and then choose a rule from that grammar.

For those unfamiliar with these models, the basic idea is to jointly estimate a mixture distribution over grammars for each η , as well as the parameters of these grammars. The HDP is necessary as the size

²S, SINV, SQ, SBAR, or SBARQ

of each of these grammars is essentially infinite. We can express the generative model formally by defining the probability of a rule r expanding a symbol s in a sentence labeled η as

$$\begin{aligned}\theta_\eta &\sim Dir(\nu_\eta) \\ z_{i\eta} &\sim Mult(\theta_\eta) \\ H_s &\sim DP(\gamma, P_0(\bullet|s)) \\ G_{ks} &\sim DP(\alpha_s, H_s) \\ r_{i\eta s} &\sim G_{z_{i\eta}s}\end{aligned}$$

This is closely related to the application of the Hierarchical Pitman Yor Process used in (Blunsom and Cohn, 2010) and (Shindo et al, 2012), which interpolates between multiple coarse and fine mappings of the data items being clustered to deal with sparse data. While the underlying Chinese Restaurant Process sampling algorithm is quite similar, our approach differs in that it models several different distributions with the same support that share a common prior.

By careful choice of the number of grammars K , the Dirichlet priors ν , and the backoff concentration parameter γ , a variety of interesting models can easily be defined, as demonstrated in our experiments.

5 Feature Selection

5.1 Dataset Independence

The first step in our L1 signal extraction pipeline controls for patterns that occur too frequently in certain combinations of native language and data set. Such patterns arise primarily from the reuse of essay prompts in the creation of certain corpora, and we construct a hard filter to exclude features of this type.

A simple first choice would be to rank the rules in order of dependence on the corpus, as we expect an irregularly represented topic to be confined to a single data set. However, this misses the subtle but important point that corpora have different qualities such as register and author proficiency. Instead we treat the set of sentences containing an arbitrary feature X as a set of observations of a pair of categorical random variables L and D , representing native language and data set respectively.

To see why this treatment is superior, consider the outcomes for the two hypothetical features shown

	L_1	L_2		L_1	L_2
D_1	1000	500	D_1	1000	500
D_2	100	50	D_2	750	750

Figure 2: Two hypothetical feature profiles that illustrate the problems with filtering only on data set independence, which prefers the right profile over the left. Our method has the opposite preference.

in Figure 2. The left table has a high data set dependence but exhibits a clean twofold preference for L_1 in both data sets, making it a desirable feature to retain. Conversely, the right table shows a feature where the distribution is uniform over data sets, but has language preference in only one. This is a sign of either a large variance in usage or some data set specific tendency, and in either case we can not make confident claims as to this feature’s association with any native language.

The L-D dependence can be measured with Pearson’s χ^2 test, although the specifics of its use as a filter deserve some discussion. As we eliminate the features for which the null hypothesis of independence is rejected, our noisy data will cause us to overzealously reject. In order to prevent the unnecessary removal of interesting patterns, we use a very small p value as a cutoff point for rejection. In all of our experiments the χ^2 value corresponding to $p < .001$ is in the twenties; we use $\chi^2 > 100$ as our criteria for rejection.

Another possible source of error is the sparsity of some features in our data. To avoid making predictions of rules for which we have not observed a sufficient number of examples, we automatically exclude any rule with a count less than five for any L-D combination η . This also satisfies the common requirements for validity of the χ^2 test that require a minimum number of 5 expected counts for every outcome.

5.2 Relevancy

We next rank the features in terms of their ability to discriminate between L1 labels. We consider three relevancy ranking metrics: Information Gain (IG), Symmetric Uncertainty (SU), and χ^2 statistic.

	IG	SU	χ^2
r	.84	.72	.15

Figure 3: Sample Pearson correlation coefficients between different ranking functions and feature frequency over a large set of TSG features.

$$IG(L, X_i) = H(L) - H(L|X_i)$$

$$SU(L, X_i) = 2 \frac{IG(L, X_i)}{H(L) + H(X_i)}$$

$$\chi^2(X_i) = \sum_m \frac{(n_{im} - \frac{N_i}{M})^2}{\frac{N_i}{M}}$$

We define L as the Multinomial distributed L1 label taking values in $\{1, \dots, M\}$ and X_i as a Bernoulli distributed indicator of the presence or absence of the i th feature, which we represent with the events X_i^+ and X_i^- respectively. We use the Maximum Likelihood estimates of these distributions from the training data to compute the necessary entropies for IG and SU. For the χ^2 metric we use n_{im} , the count of sentences with L1 label m that contain feature X_i , and their sum over classes N_i .

While SU is often preferred over IG in feature selection for several reasons, their main difference in the context of selection of binary features is the addition of $H(X_i)$ in the denominator, leading to higher values for rare features under SU. This helps to counteract a subtle preference for common features that these metrics can exhibit in data such as ours, as shown in Figure 3. The source of this preference is the overwhelming contribution of $p(X_i^-)H(L|X_i^-)$ in $IG(L, X_i)$ for rare features, which will be essentially the maximum value of $\log(M)$. In most classification problems a frequent feature bias is a desirable trait, as a rare feature is naturally less likely to appear and contribute to decision making.

We note that binary features in sentences are sparsely observed, as the opportunity for use of the majority of patterns will not exist in any given sentence. This leads to a large number of rare features that are nevertheless indicative of their author’s L1. The χ^2 statistic we employ is better suited to retain

such features as it only deals with counts of sentences containing X_i .

The ranking behavior of these metrics is highlighted in Figure 4. We expect that features with profiles like X_a and X_b will be more useful than those like X_d , and only χ^2 ranks these features accordingly. Another view of the difference between the metrics is taken in Figure 5. As shown in the left plot, IG and SU are nearly identical for the most highly ranked features and significantly different from χ^2 .

	L_1	L_2	L_3	L_4	IG	SU	χ^2
X_a	20	5	5	5	.0008	.0012	19.29
X_b	40	20	20	20	.0005	.0008	12.0
X_c	2000	500	500	500	.0178	.0217	385.7
X_d	1700	1800	1700	1800	.0010	.0010	5.71

Figure 4: Four hypothetical features in a 4 label classification problem, with the number of training items from each class using the feature listed in the first four columns. The top three features under each ranking are shown in bold.

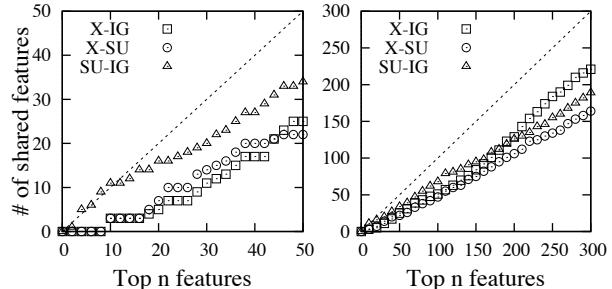

Figure 5: For all pairs of relevancy metrics, we show the number of features that appear in the top n of both. The result for low n is highlighted in the left plot, showing a high similarity between SU and IG.

5.3 Redundancy

The second component of thorough feature selection is the removal of redundant features. From an experimental point of view, it is inaccurate to compare feature selection systems under evaluation of the top n features or the number of features with ranking statistic at or beyond some threshold if redundancy has not been taken into account. Furthermore, as our stated goal is a list of discriminative patterns, multiple representations of the same pattern clearly

degrade the quality of our output. This is especially necessary when using TSG rules as features, as it is possible to define many slightly different rules that essentially represent the same linguistic act.

Redundancy detection must be able to both determine that a set of features are redundant and also select the feature to retain from such a set. We use a greedy method that allows us to investigate different relevancy metrics for selection of the representative feature for a redundant set (Yu and Liu, 2004). The algorithm begins with a list S containing the full list of features, sorted by an arbitrary metric of relevancy. While S is not empty, the most relevant feature X^* in S is selected for retention, and all features X_i are removed from S if $R(X^*, X_i) > \rho$ for some redundancy metric R and some threshold ρ .

We consider two probabilistic metrics for redundancy detection, the first being SU, as defined in the previous section. We contrast this metric with Normalized Pointwise Mutual Information (NPMI) which uses only the events $A = X_a^+$ and $B = X_b^+$ and has a range of [-1,1].

$$\text{NPMI}(X_a, X_b) = \frac{\log(P(A|B)) - \log(P(A))}{-\log(P(A, B))}$$

Another option that we explore is the structural redundancy between TSG rules themselves. We define a 0-1 redundancy metric such that $R(X_a, X_b)$ is one if there exists a fragment that contains both X_a and X_b with a total number of CFG rules less than the sum of the number of CFG rules in X_a and X_b . The latter constraint ensures that X_a and X_b overlap in the containing fragment. Note that this is not the same as a nonempty set intersection of CFG rules, as can be seen in Figure 6.

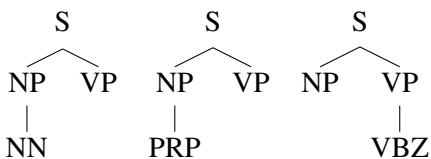

Figure 6: Three similar fragments that highlight the behavior of the structural redundancy metric; the first two fragments are not considered redundant, while the third is made redundant by either of the others.

6 Experiments

6.1 Relevancy Metrics

The traditional evaluation criterion for a feature selection system such as ours is classification accuracy or expected risk. However, as our desired output is not a set of features that capture a decision boundary as an ensemble, a per feature risk evaluation better quantifies the performance of a system for our purposes. We plot average risk against number of predicted features to view the rate of quality degradation under a relevancy measure to give a picture of each metric's utility.

The per feature risk for a feature X is an evaluation of the ML estimate of $P_X(L) = P(L|X^+)$ from the training data on T_X , the test sentences that contain the feature X . The decision to evaluate only sentences in which the feature occurs removes an implicit bias towards more common features.

We calculate the expected risk $\mathcal{R}(X)$ using a 0-1 loss function, averaging over T_X .

$$\mathcal{R}(X) = \frac{1}{|T_X|} \sum_{t \in T_X} P_X(L \neq L_t^*)$$

where L_t^* is the gold standard L1 label of test item t . This metric has two important properties. First, given any true distribution over class labels in T_X , the best possible $P_X(L)$ is the one that matches these proportions exactly, ensuring that preferred features make generalizable predictions. Second, it assigns less risk to rules with lower entropy, as long as their predictions remain generalizable. This corresponds to features that find larger differences in usage frequency across L1 labels.

The alternative metric of per feature classification accuracy creates a one to one mapping between features and native languages. This unnecessarily penalizes features that are associated with multiple native languages, as well as features that are selectively dispreferred by certain L1 speakers. Also, we wish to correctly quantify the distribution of a feature over all native languages, which goes beyond correct prediction of the most probable.

Using cross validation with each corpus as a fold, we plot the average $\mathcal{R}(X)$ for the best n features against n for each relevancy metric in Figure 7. This clearly shows that for highly ranked features χ^2 is

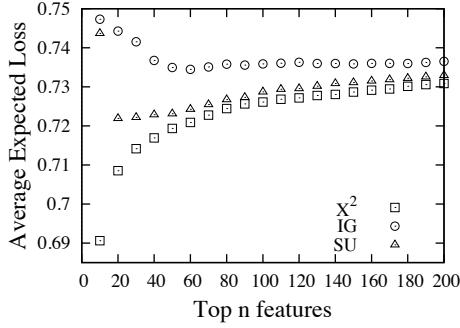

Figure 7: Per-feature Average Expected Loss plotted against top N features using χ^2 , IG , and SU as a relevancy metric

able to best single out the type of features we desire. Another point to be taken from the plot is that it is that the top ten features under SU are remarkably inferior. Inspection of these rules reveals that they are precisely the type of overly frequent but only slightly discriminative features that we predicted would corrupt feature selection using IG based measures.

6.2 Redundancy Metrics

We evaluate the redundancy metrics by using the top n features retained by redundancy filtering for ensemble classification. Under this evaluation, if redundancy is not being effectively eliminated performance should increase more slowly with n as the set of test items that can be correctly classified remains relatively constant. Additionally, if the metric is overzealous in its elimination of redundancy, useful patterns will be eliminated leading to diminished increase in performance. Figure 8 shows the tradeoff between Expected Loss on the test set and the number of features used with SU, NPMI, and the overlap based structural redundancy metric described above. We performed a coarse grid search to find the optimal values of ρ for SU and NPMI.

Both the structural overlap heuristic and SU perform similarly, and outperform NPMI. Analysis reveals that NPMI seems to overstate the similarity of large fragments with their small subcomponents. We choose to proceed with SU, as it is not only faster in our implementation but also can generalize to feature types beyond TSG rules.

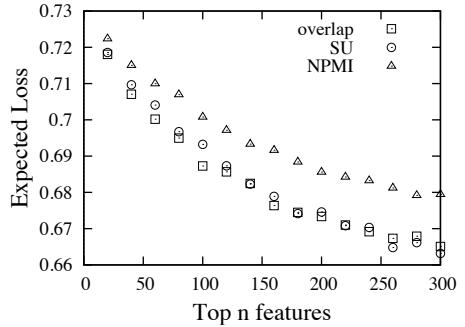

Figure 8: The effects of redundancy filtering on classification performance using different redundancy metrics. The cutoff values (ρ) used for SU and NPMI are .2 and .7 respectively.

6.3 TSG Induction

We demonstrate the flexibility and effectiveness of our general model of mixtures of TSGs for labeled data by example. The tunable parameters are the number of grammars K , the Dirichlet priors ν_η over grammar distributions for each label η , and the concentration parameter γ of the smoothing DP.

For a first baseline we set the number of grammars $K = 1$, making the Dirichlet priors ν irrelevant. With a large $\gamma = 10^{20}$, we essentially recover the basic block sampling algorithm of Cohn and Blunsom (2010). We refer to this model as M1. Our second baseline model, M2, sets K to the number of native language labels, and sets the ν variables such that each η is mapped to a single grammar by its L1 label, creating a naive Bayes model. For M2 and the subsequent models we use $\gamma = 1000$ to allow moderate smoothing.

We also construct a model (M3) in which we set $K = 9$ and ν_η is such that three grammars are likely for any single η ; one shared by all η with the same L1 label, one shared by all η with the same corpus label, and one shared by all η . We compare this with another $K = 9$ model (M4) where the ν are set to be uniform across all 9 grammars.

We evaluate these systems on the percent of their resulting grammar that rejects the hypothesis of language independence using a χ^2 test. Slight adjustments were made to α for these models to bring their output grammar size into the range of approximately 12000 rules. We average our results for each model over single states drawn from five indepen-

	$p < .1$	$p < .05$	$p < .01$	$p < .001$
M1	56.5(3.1)	54.5(3.0)	49.8(2.7)	45.1(2.5)
M2	55.3(3.7)	53.7(3.6)	49.1(3.3)	44.7(3.0)
M3	59.0(4.1)	57.2(4.1)	52.4(3.6)	48.4(3.3)
M4	58.9(3.8)	57.0(3.7)	51.9(3.4)	47.2(3.1)

Figure 9: The percentage of rules from each model that reject L1 independence at varying levels of statistical significance. The first number is with respect to the number rules that pass the L1/corpus independence and redundancy tests, and the second is in proportion to the full list returned by grammar induction.

dent Markov chains.

Our results in Figure 9 show that using a mixture of grammars allows the induction algorithm to find more patterns that fit arbitrary criteria for language dependence. The intuition supporting this is that in simpler models a given grammar must represent a larger amount of data that is better represented with more vague, general purpose rules. Dividing the responsibility among several grammars lets rare patterns form clusters more easily. The incorporation of informed structure in M3 further improves the performance of this latent mixture technique.

7 Discussion

Using these methods, we produce a list of L1 associated TSG rules that we release for public use. We perform grammar induction using model M3, apply our data dependence and redundancy filters, rank for relevancy using χ^2 and filter at the level of $p < .1$ statistical significance for relevancy. Each entry consists of a TSG rule and its matrix of counts with each η . We provide the total for each L1 label, which shows the overall prediction of the proportional use of that item. We also provide the χ^2 statistics for L1 dependence and the dependence of L1 and corpus.

It is speculative to assign causes to the discriminative rules we report, and we leave quantification of such statements to future work. However, the strength of the signal, as evidenced by actual counts in data, and the high level interpretation that can be easily assigned to the TSG rules is promising. As understanding the features requires basic knowledge

of Treebank symbols, we provide our interpretations for some of the more interesting rules and summarize their L1 distributions. Note that by describing a rule as being preferred by a certain set of L1 labels, our claim is relative to the other labels only; the true cause could also be a dispreference in the complement of this set.

One interesting comparison made easy by our method is the identification of similar structures that have complementary L1 usage. An example is the use of a prepositional phrase just before the first noun phrase in a sentence, which is preferred in German and Spanish, especially in the former. However, German speakers disprefer a prepositional phrase followed by a comma at the beginning of the sentence, and Chinese speakers use this pattern more frequently than the other L1s. Another contrastable pair is the use of the word “because” with upper or lower case, signifying sentence initial or medial use. The former is preferred in Chinese and Japanese text, while the latter is preferred in German and even more so in Spanish L1 data.

As these examples suggest, the data shows a strong division of preference between European and Asian languages, but many patterns exist that are uniquely preferred in single languages as well. Japanese speakers are seen to frequently use a personal pronoun as the subject of the sentence, while Spanish speakers use the phrase “the X of Y”, the verb “go”, and the determiner “this” with markedly higher frequency. Germans tend to begin sentences with adverbs, and various modal verb constructions are popular with Chinese speakers. We suspect these patterns to be evidence of preference in the specified language, rather than dispreference in the other three.

Our strategy in regard to the hard filters for L1-corpus dependence and redundancy has been to prefer recall to precision, as false positives can be easily ignored through subsequent inspection of the data we supply. This makes the list suitable for human qualitative analysis, but further work is required for its use in downstream automatic systems.

8 Conclusion

This work contributes to the goal of leveraging NLI data in SLA applications. We provide evidence for

our hypothesis that relevancy metrics based on mutual information are ill-suited for this task, and recommend the use of the χ^2 statistic for rejecting the hypothesis of language independence. Explicit controls for dependence between L1 and corpus are proposed, and redundancy between features are addressed as well. We argue for the use of TSG rules as features, and develop an induction algorithm that is a supervised mixture of hierarchical grammars. This generalizable formalism is used to capture linguistic assumptions about the data and increase the amount of relevant features extracted at several thresholds.

This project motivates continued incorporation of more data and induction of TSGs over these larger data sets. This will improve the quality and scope of the resulting list of discriminative syntax, allowing broader use in linguistics and SLA research. The prospect of high precision and recall in the extraction of such patterns suggests several interesting avenues for future work, such as determination of the actual language transfer phenomena evidenced by an arbitrary count profile. To achieve the goal of automatic detection of plausible transfer the native languages themselves must be considered, as well as a way to distinguish between preference and dispreference based on usage statistics. Another exciting application of such a refined list of patterns is the automatic integration of its features in L1 targeted SLA software.

An Analysis of Frequency- and Memory-Based Processing Costs

Marten van Schijndel

schuler@ling.osu.edu

Abstract

The frequency of words and syntactic constructions has been observed to have a substantial effect on language processing. This begs the question of what causes certain constructions to be more or less frequent. A theory of grounding (Phillips, 2010) would suggest that cognitive limitations might cause languages to develop frequent constructions in such a way as to avoid processing costs. This paper studies how current theories of working memory fit into theories of language processing and what influence memory limitations may have over reading times. Measures of such limitations are evaluated on eye-tracking data and the results are compared with predictions made by different theories of processing.

1 Introduction

Frequency effects in language have been isolated and observed in many studies (Trueswell, 1996; Jurafsky, 1996; Hale, 2001; Demberg and Keller, 2008). These effects are important because they illuminate the ontogeny of language (how individual speakers have acquired language), but they do not answer questions about the phylogeny of language (how the language came to its current form).

Phillips (2010) has hypothesized that grammar rule probabilities may be grounded in memory limitations. Increased delays in processing center-embedded sentences as the number of embeddings increases, for example, are often explained in terms of a complexity cost associated with maintaining incomplete dependencies in working memory (Gibson, 2000; Lewis and Vasishth, 2005). Other studies have shown a link between processing delays

and the low frequency of center-embedded constructions like object relatives (Hale, 2001), but they have not explored the source of this low frequency. A grounding hypothesis would claim that the low probability of generating such a structure may arise from an associated memory load. In this account, while these complexity costs may involve language-specific concepts such as referent or argument linking, the underlying explanation would be one of memory limitations (Gibson, 2000) or neural activation (Lewis and Vasishth, 2005).

This paper seeks to explore the different predictions made by these theories on a broad-coverage corpus of eye-tracking data (Kennedy et al., 2003). In addition, the current experiment seeks to isolate memory effects from frequency effects in the same task. The results show that memory load measures are a significant factor even when frequency measures are residualized out.

The remainder of this paper is organized as follows: Sections 2 and 3 describe several frequency and memory measures. Section 4 describes a probabilistic hierachic sequence model that allows all of these measures to be directly computed. Section 5 describes how these measures were used to predict reading time durations on the Dundee eye-tracking corpus. Sections 6 and 7 present results and discuss.

2 Frequency Measures

2.1 Surprisal

One of the strongest predictors of processing complexity is surprisal (Hale, 2001). It has been shown in numerous studies to have a strong correlation with reading time durations in eye-tracking and self-paced reading studies when calculated with a variety

of models (Levy, 2008; Roark et al., 2009; Wu et al., 2010).

Surprisal predicts the integration difficulty that a word x_t at time step t presents given the preceding context and is calculated as follows:

$$\text{surprisal}(x_t) = -\log_2 \left(\frac{\sum_{s \in S(x_1 \dots x_t)} P(s)}{\sum_{s \in S(x_1 \dots x_{t-1})} P(s)} \right) \quad (1)$$

where $S(x_1 \dots x_t)$ is the set of syntactic trees whose leaves have $x_1 \dots x_t$ as a prefix.¹

In essence, surprisal measures how unexpected constructions are in a given context. What it does not provide is an explanation for why certain constructions would be less common and thus more surprising.

2.2 Entropy Reduction

Processing difficulty can also be measured in terms of entropy (Shannon, 1948). A larger entropy over a random variable corresponds to greater uncertainty over the observed value it will take. The entropy of a syntactic derivation over the sequence $x_1 \dots x_t$ is calculated as:²

$$H(x_1 \dots x_t) = \sum_{s \in S(x_1 \dots x_t)} -P(s) \cdot \log_2 P(s) \quad (2)$$

Reduction in entropy has been found to predict processing complexity (Hale, 2003; Hale, 2006; Roark et al., 2009; Wu et al., 2010; Hale, 2011):

$$\Delta H(x_1 \dots x_t) = \max(0, H(x_1 \dots x_{t-1}) - H(x_1 \dots x_t)) \quad (3)$$

This measures the change in uncertainty about the discourse as each new word is processed.

3 Memory Measures

3.1 Dependency Locality

In Dependency Locality Theory (DLT) (Gibson, 2000), complexity arises from intervening referents introduced between a predicate and its argument. Under the original formulation of DLT, there is a

¹The parser in this study uses a beam. However, given high parser accuracy, Roark (2001) showed that calculating complexity metrics over a beam should obtain similar results to the full complexity calculation.

²The incremental formulation used here was first proposed in Wu et al. (2010).

storage cost for each new referent introduced and an *integration* cost for each referent intervening in a dependency projection. This is a simplification made for ease of computation, and subsequent work has found DLT to be more accurate cross-linguistically if the intervening elements are structurally defined rather than defined in terms of referents (Kwon et al., 2010). That is, simply having a particular referent intervene in a dependency projection may not have as great an effect on processing complexity as the syntactic construction the referent appears in. Therefore, this work reinterprets the costs of dependency locality to be related to the events of beginning a center embedding (storage) and completing a center embedding (integration). Note that anti-locality effects (where longer dependencies are easier to process) have also been observed in some languages, and DLT is unable to account for these phenomena (Vasishth and Lewis, 2006).

3.2 ACT-R

Processing complexity has also been attributed to confusability (Lewis and Vasishth, 2005) as defined in domain-general cognitive models like ACT-R (Anderson et al., 2004).

ACT-R is based on theories of neural activation. Each new word is *encoded* and stored in working memory until it is *retrieved* at a later point for modification before being re-encoded into the parse. A newly observed sign (word) associatively activates any appropriate arguments from working memory, so multiple similarly appropriate arguments would slow processing as the parser must choose between the highly activated hypotheses. Any intervening signs (words or phrases) that modify a previously encoded sign re-activate it and raise its resting activation potential. This can ease later retrieval of that sign in what is termed an *anti-locality* effect, contra predictions of DLT. In this way, returning out of an embedded clause can actually speed processing by having primed the retrieved sign before it was needed. ACT-R attributes locality phenomena to frequency effects (e.g. unusual constructions) overriding such priming and to activation decay if embedded signs do not prime the target sign through modification (as in parentheticals). Finally, ACT-R predicts something like DLT's storage cost due to the need to differentiate each newly encoded sign from

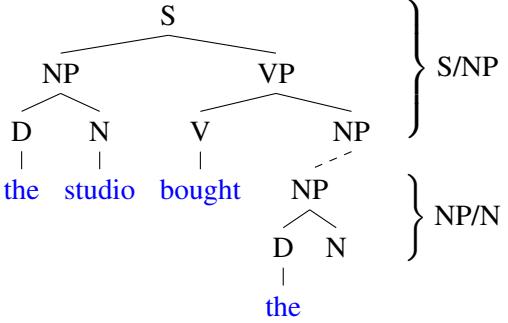

Figure 1: Two disjoint connected components of a phrase structure tree for the sentence *The studio bought the publisher's rights*, shown immediately prior to the word *publisher*.

those previously encoded (similarity-based encoding interference) (Lewis et al., 2006).

3.3 Hierarchic Sequential Prediction

Current models of working memory in structured tasks are defined in terms of hierarchies of sequential processes, in which superordinate sequences can be interrupted by subordinate sequences and resume when the subordinate sequences have concluded (Botvinick, 2007). These models rely on *temporal* cueing as well as content-based cueing to explain how an interrupted sequence may be recalled for continuation.

Temporal cueing is based on a context of temporal features for the current state (Howard and Kahana, 2002). The temporal context in which the subordinate sequence concludes must be similar enough to the temporal context in which it was initiated to recall where in the superordinate sequence the subordinate sequence occurred. For example, the act of making breakfast may be interrupted by a phone call. Once the call is complete, the temporal context is sufficiently similar to when the call began that one is able to continue preparing breakfast. The association between the current temporal context and the temporal context prior to the interruption is strong enough to cue the next action.

Temporal cueing is complemented by *sequential* (content-based) cueing (Botvinick, 2007) in which the content of an individual element is associated with, and thus cues, the following element. For example, recalling the 20th note of a song is difficult, but when playing the song, each note cues the fol-

lowing note, leading one to play the 20th note without difficulty.

Hierarchic sequential prediction may be directly applicable to processing syntactic center embeddings (van Schijndel et al., in press). An ongoing parse may be viewed graph-theoretically as one or more connected components of incomplete phrase structure trees (see Figure 1). Beginning a new subordinate sequence (a center embedding) introduces a new connected component, disjoint from that of the superordinate sequence. As the subordinate sequence proceeds, the new component gains associated discourse referents, each sequentially cued from the last, until finally it merges with the superordinate connected component at the end of the embedded clause, forming a single connected component representing the parse up to that point. Since it is not connected to the subordinate connected component prior to merging, the superordinate connected component must be recalled through temporal cueing.

McElree (2001; 2006) has found that retrieval of any non-focused (or in this case, unconnected) element from memory leads to slower processing. Therefore, integrating two disjoint connected components should be expected to incur a processing cost due to the need to recall the current state of the superordinate sequence to continue the parse. Such a cost would corroborate a DLT-like theory where integration slows processing.

3.4 Dynamic Recruitment of Additional Processing Resources

Language processing is typically centered in the left hemisphere of the brain (for right-handed individuals). Just and Varma (2007) provide fMRI results suggesting readers dynamically recruit additional processing resources such as the right-side homologues of the language processing areas of the brain when processing center-embedded constructions. Once an embedded construction terminates, the reader may still have temporary access to these extra processing resources, which may briefly speed processing.

This hypothesis would, therefore, predict an *encoding* cost when a center embedding is initiated. The resulting inhibition would trigger recruitment of additional processing resources, which would then

allow the rest of the embedded structure to be processed at the usual speed. Upon completing an embedding, the difficulty arising from memory retrieval (McElree, 2001) would be ameliorated by these extra processing resources, and the reduced processing complexity arising from reduced memory load would yield a temporary *facilitation* in processing. No longer requiring the additional resources to cope with the increased embedding, the processor would release them, returning the processor to its usual speed. Unlike anti-locality, where processing is facilitated in longer passages due to accumulating probabilistic evidence, a model of dynamic recruitment of additional processing resources would predict universal facilitation after a center embedding of any length, modulo frequency effects.

3.5 Embedding Difference

Wu et al. (2010) propose an explicit measure of the difficulty associated with processing center-embedded constructions, which is similar to the predictions of dynamic recruitment and is defined in terms of changes in memory load. They calculate a probabilistically-weighted average embedding depth as follows:

$$\mu_{emb}(x_1 \dots x_t) = \sum_{s \in S(x_1 \dots x_t)} d(s) \cdot P(s) \quad (4)$$

where $d(s)$ returns the embedding depth of the derivation s at x_t in a variant of a left-corner parsing process.³ Embedding difference may then be derived as:

$$EmbDiff(x_1 \dots x_t) = \mu_{emb}(x_1 \dots x_t) - \mu_{emb}(x_1 \dots x_{t-1}) \quad (5)$$

This is hypothesized to correlate positively with processing load: increasing the embedding depth increases processing load and decreasing it reduces processing load. Note that embedding difference makes the opposite prediction from DLT in that integrating an embedded clause is predicted to speed processing. In fact, the predictions of embedding

³As pointed out by Wu et al. (2010), in practice this can be computed over a beam of potential parses in which case it must be normalized by the total probability of the beam.

difference are such that it may be viewed as an implementation of the predictions of a hierarchic sequential processing model with dynamic recruitment of additional resources.

4 Model

This paper uses a hierarchic sequence model implementation of a left-corner parser variant (van Schijndel et al., in press), which represents connected components of phrase structure trees in hierarchies of hidden random variables. This requires, at each time step t :

- a hierarchically-organized set of N connected component states q_t^n , each consisting of an active sign of category $a_{q_t^n}$, and an awaited sign of category $b_{q_t^n}$, separated by a slash ‘/’; and

- an observed word x_t .

Each connected component state in this model then represents a contiguous portion of a phrase structure tree (see Figure 1 on preceding page).

The operations of this parser can be defined as a deductive system (Shieber et al., 1995) with an input sequence consisting of a top-level connected component state \top/\top , corresponding to an existing discourse context, followed by a sequence of observed words x_1, x_2, \dots .⁴ If an observation x_t can attach as the awaited sign of the most recent (most subordinate) connected component a/b , it is hypothesized to do so, turning this incomplete sign into a complete sign a (F-, below); or if the observation can serve as a lower descendant of this awaited sign, it is hypothesized to form the first complete sign a' in a newly initiated connected component (F+):

$$\frac{a/b \quad x_t}{a} b \rightarrow x_t \quad (\text{F-})$$

$$\frac{a/b \quad x_t}{a/b \quad a'} b \stackrel{+}{\rightarrow} a' \dots ; \quad a' \rightarrow x_t \quad (\text{F+})$$

Then, if either of these complete signs (a or a' above, matched to a'' below) can attach as an initial

⁴A deductive system consists of inferences or productions of the form: $\frac{P}{Q} R$, meaning premise P entails conclusion Q according to rule R .

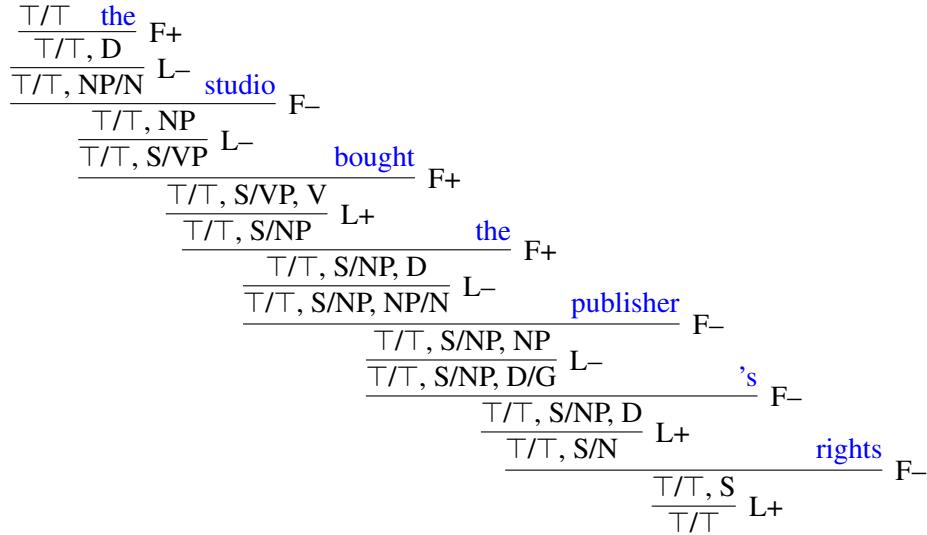

Figure 2: Example parse (in the form of a deductive proof) of the sentence *The studio bought the publisher's rights*, using F+, F-, L+, and L- productions. Each pair of deductions combines a context of one or more connected component states with a sign (word) observed in that context. By applying the F and L rules to the observed sign and context, the parser is able to generate a consequent context. Initially, the context corresponds to a connected pre-sentential dialogue state T/T. When *the* is observed, the parser applies F+ to begin a new connected component state D. By applying L-, the parser determines that this new connected component is unfinished and generates an appropriate incomplete connected component state NP/N, encoding the superordinate state T/T for later retrieval. Further on, the parser observes *'s* and uses F- to avoid generating a new connected component, which completes the sign D. The parser follows this up with L+ to recall the superordinate connected component state S/NP and integrate it into the most deeply embedded connected component, which results in a less deeply embedded structure.

child of the awaited sign of the immediately superordinate connected component state a/b , it is hypothesized to do so and terminate the subordinate connected component state, with x_t as the last observation of the terminated connected component (L+); or if the observation can serve as a lower descendant of this awaited sign, it is hypothesized to remain disjoint and form its own connected component (L-):

$$\frac{a/b \quad a''}{a/b''} b \rightarrow a'' b'' \quad (\text{L+})$$

$$\frac{a/b \quad a''}{a/b \quad a'/b''} b \stackrel{+}{\rightarrow} a' \dots ; \quad a' \rightarrow a'' b'' \quad (\text{L-})$$

These operations can be made probabilistic. The probability σ of a transition at time step t is defined in terms of (i) a probability ϕ of initiating a new connected component state with x_t as its first observation, multiplied by (ii) the probability λ of terminating a connected component state with x_t as its last observation, multiplied by (iii) the probabilities α and β of generating categories for active and awaited signs $a_{q_t^n}$ and $b_{q_t^n}$ in the resulting most subordinate

connected component state q_t^n . This kind of model can be defined directly on PCFG probabilities and trained to produce state-of-the-art accuracy by using the latent variable annotation of Petrov et al. (2006) (van Schijndel et al., in press).⁵

An example parse is shown in Figure 2. Since two binary structural decisions (F and L) must be made in order to generate each word, there are four possible structures that may be generated (see Table 1). The F+L- transition initiates a new level of embedding at word x_t and so requires the superordinate state to be encoded for later retrieval (e.g. on observing *the* in Figure 2). The F-L+ transition completes the deepest level of embedding and therefore requires the recall of the current superordinate connected component state with which the

⁵The model has been shown to achieve an F-score of 87.8, within .2 points of the Petrov and Klein (2007) parser, which obtains an F-score of 88.0 on the same task. Because the sequence model is defined over binary-branching phrase structure, both parsers were evaluated on binary-branching phrase structure trees to provide a fair comparison.

F-L-	Cue Active Sign
F+L-	Initiate/Encode
F-L+	Terminate/Integrate
F+L+	Cue Awaited Sign

Table 1: The hierarchical structure decisions and the operations they represent. F+L– initiates a new connected component, F-L+ integrates two disjoint connected components into a single connected component, and F-L– and F+L+ sequentially cue, respectively, a new active sign (along with an associated awaited sign) and a new awaited sign from the most recent connected component.

subordinate connected component state will be integrated. For example, in Figure 2, upon observing ‘s, the parser must use temporal cueing to recall that it is in the middle of processing an NP (to complete an S), which sequentially cues a prediction of N. F-L– transitions complete the awaited sign of the most subordinate state and so sequentially cue a following connected component state at the same tier of the hierarchy. For example, in Figure 2, after observing *studio*, the parser uses the completed NP to sequentially cue the prediction that it has finished the left child of an S. F+L+ transitions locally expand the awaited sign of the most subordinate state and so should also not require any recall or encoding. For example, in Figure 2, observing *bought* while awaiting a VP sequentially cues a prediction of NP.

F+L–, then, loosely corresponds to a *storage* action under DLT as more hierachic levels must now be maintained at each future step of the parse. As stated before, it differs from DLT in that it is sensitive to the depth of embedding rather than a particular subset of syntactic categories. Wu et al. (2010) found that increasing the embedding depth led to longer reading times in a self-paced reading experiment. In ACT-R terms, F+L– corresponds to an *encoding* action, potentially causing processing difficulty resulting from the similarity of the current sign to previously encoded signs.

F-L+, by contrast, is similar to DLT’s *integration* action since a subordinate connected component is integrated into the rest of the parse structure. This represents a temporal cueing event in which the awaited category of the superordinate connected

Theory	F+L–	F-L+
DLT	positive	positive
ACT-R	positive	positive
Hier. Sequential Prediction		positive
Dynamic Recruitment	positive	negative
Embedding Difference	positive	negative

Table 2: Each theory’s prediction of the direction of the correlation between each hierachical structure predictor and reading times. Hierachic sequential prediction is agnostic about the processing speed of F+L– operations, and none of the theories make any predictions as to the sign associated with the within-embedding measures F-L– and F+L+.

component is recalled. In contrast to DLT, embedding difference and dynamic recruitment would predict a *shorter* reading time in the F-L+ case because of the reduction in memory load. In an ACT-R framework, reading time durations can increase at the retrieval site because the retrieval causes competition among similarly encoded signs in the context set. While it is possible for reading times to decrease when completing a center embedding in ACT-R (Vasisht and Lewis, 2006), this would be expressed as a frequency effect due to certain argument types commonly foreshadowing their predicates (Jaeger et al., 2008). Since frequency effects are factored separately from memory effects in this study, ACT-R would predict longer residual (memory-based) reading times when completing an embedding.

Predicted correlations to reading times for the F and L transitions are summarized in Table 2.

5 Eye-tracking

Eye-tracking and reading time data are often used to test complexity measures (Gibson, 2000; Demberg and Keller, 2008; Roark et al., 2009) under the assumption that readers slow down when reading more complex passages. Readers saccade over portions of text and regress back to preceding text in complex patterns, but studies have correlated certain measures with certain processing constraints (see Clifton et al. 2007 for a review). For example, the initial length of time fixated on a single word is correlated with word identification time; whereas regression durations after a word is fixated (but prior to a fixation in a new region) are hypothesized to correlate

with integration difficulty.

Since this work focuses on incremental processing, all processing that occurs up to a given point in the sentence is of interest. Therefore, in this study, predictions will be compared to *go-past durations*. Go-past durations are calculated by summing all fixations in a region of text, including regressions, until a new region is fixated, which accounts for additional processing that may take place after initial lexical access, but before the next region is processed. For example, if one region ends at word 5 in a sentence, and the next fixation lands on word 8, then the *go-past region* consists of words 6-8 and the *go-past duration* sums all fixations until a fixation occurs after word 8.

6 Evaluation

The measures presented in this paper were evaluated on the Dundee eye-tracking corpus (Kennedy et al., 2003). The corpus consists of 2388 sentences of naturally occurring news text written in standard British English. The corpus also includes eye-tracking data from 10 native English speakers, which provides a test corpus of 260,124 subject-duration pairs of reading time data. Of this, any fixated words appearing fewer than 5 times in the training data were considered unknown and were filtered out to obtain accurate predictions. Fixations on the first or last words of a line were also filtered out to avoid any ‘wrap-up’ effects resulting from preparing to saccade to the beginning of the next line or resulting from orienting to a new line. Additionally, following Demberg and Keller (2008), any fixations that skip more than 4 words were attributed to track loss by the eyetracker or lack of attention of the reader and so were excluded from the analysis. This left the final evaluation corpus with 151,331 subject-duration pairs.

The evaluation consisted of fitting a linear mixed-effects model (Baayen et al., 2008) to reading time durations using the *lmer* function of the *lme4* R package (Bates et al., 2011; R Development Core Team, 2010). This allowed by-subject and by-item variation to be included in the initial regression as random intercepts in addition to several baseline predictors.⁶ Before fitting, the durations extracted from

⁶Each fixed effect was centered to reduce collinearity.

the corpus were log-transformed, producing more normally distributed data to obey the assumptions of linear mixed effects models.⁷

Included among the fixed effects were the position in the sentence that initiated the go-past region (SENTPOS) and the number of characters in the initiating word (NRCHAR). The difficulty of integrating a word may be seen in whether the immediately following word was fixated (NEXTISFIX), and similarly if the immediately previous word was fixated (PREVISFIX) the current word probably need not be fixated for as long. Finally, unigram (LOGPROB) and bigram probabilities are included. The bigram probabilities are those of the current word given the previous word (LOGFWPROB) and the current word given the following word (LOGBWPROB). Fossum and Levy (2012) showed that for n-gram probabilities to be effective predictors on the Dundee corpus, they must be calculated from a wide variety of texts, so following them, this study used the Brown corpus (Francis and Kucera, 1979), the WSJ Sections 02-21 (Marcus et al., 1993), the written text portion of the British National Corpus (BNC Consortium, 2007), and the Dundee corpus (Kennedy et al., 2003). This amounted to an n-gram training corpus of roughly 87 million words. These statistics were smoothed using the SRILM (Stolcke, 2002) implementation of modified Kneser-Ney smoothing (Chen and Goodman, 1998). Finally, total surprisal (SURP) was included to account for frequency effects in the baseline.

The preceding measures are commonly used in baseline models to fit reading time data (Demberg and Keller, 2008; Frank and Bod, 2011; Fossum and Levy, 2012) and were calculated from the final word of each go-past region. The following measures create a more sophisticated baseline by accumulating over the entire go-past region to capture what must be integrated into the discourse to continue the parse. One factor (CWDELTA) simply counts the number of words in each go-past region. Cumula-

⁷In particular, these models assume the noise in the data is normally distributed. Initial exploratory trials showed that the residuals of fitting any sensible baseline also become more normally distributed if the response variable is log-transformed. Finally, the directions of the effects remain the same whether or not the reading times are log-transformed, though significance cannot be ascertained without the transform.

tive total surprisal (CUMUSURP) and cumulative entropy reduction (ENTRED) give the surprisal (Hale, 2001) and entropy reduction (Hale, 2003) summed over the go-past region. To avoid convergence issues, each of the cumulative measures is residualized from the next simpler model in the following order: CWDELTA from the standard baseline, CUMUSURP from the baseline with CWDELTA, and ENTRED from the baseline with all other effects.

Residualization was accomplished by using the simpler mixed-effects model to fit the measure of interest. The residuals from that model fit were then used in place of the factor of interest. All joint interactions were included in the baseline model as well. Finally, to account for spillover effects (Just et al., 1982) where processing from a previous region contributes to the following duration, the above baseline predictors from the previous go-past region were included as factors for the current region.

Having SURP as a predictor with CUMUSURP may seem redundant, but initial analyses showed SURP was a significant predictor over CUMUSURP when CWDELTA was a separate factor in the baseline (current: $p = 2.2 \cdot 10^{-16}$ spillover: $p = 2 \cdot 10^{-15}$) and vice versa (current: $p = 2.2 \cdot 10^{-16}$ spillover: $p = 6 \cdot 10^{-5}$). One reason for this could be that go-past durations conflate complexity experienced when initially fixating on a region with the difficulty experienced during regressions. By including both versions of surprisal, the model is able to account for frequency effects occurring in both conditions.

This study is only interested in how well the proposed memory-based measures fit the data over the baseline, so to avoid fitting to the test data or weakening the baseline by overfitting to training data, the full baseline was used in the final evaluation.

Each measure proposed in this paper was summed over go-past regions to make it cumulative and was residualized from all non-spillover factors before being included on top of the full baseline as a main effect. Likewise, the spillover version of each proposed measure was residualized from the other spillover factors before being included as a main effect. Only a single proposed measure (or its spillover corollary) was included in each model. The results shown in Table 3 reflect the probability of the full model fit being obtained by the model lacking each factor of interest. This was found via posterior sam-

Factor	Operation	t-score	p-value
F-L-	Cue Active	0.60	0.55
F+L-	Initiate	7.10	$2.22 \cdot 10^{-14}$
F-L+	Integrate	-5.44	$5.23 \cdot 10^{-8}$
F+L+	Cue Awaited	-1.55	0.12

Table 3: Significance of each of the structure generation outcomes at predicting log-transformed durations when added to the baseline as a main effect after being residualized from it. The sign of the t-score indicates the direction of the correlation between the residualized factor and go-past durations. Note that these factors are all based on the current go-past region; the spillover corollaries of these were not significant predictors of reading times.

pling of each factor using the Markov chain Monte Carlo implementation of the *languageR* R package (Baayen, 2008).

The results indicate that the F+L- and F-L+ measures were both significant predictors of duration as expected. Further, F-L- and F+L+, which both simply reflect sequential cueing, were not significant predictors of go-past duration, also as expected.

7 Discussion and Conclusion

The fact that F+L- was strongly predictive over the baseline is encouraging as it suggests that memory limitations could provide at least a partial explanation of *why* certain constructions are less frequent in corpora and thus yield a high surprisal. Moreover, it indicates that the model corroborates the shared prediction of most of the memory-based models that initiating a new connected component slows processing.

The fact that F-L+ is predictive but has a negative coefficient could be evidence of anti-locality, or it could be an indication of some sort of processing momentum due to dynamic recruitment of additional processing resources (Just and Varma, 2007). Since anti-locality is an expectation-based frequency effect, and since this study controlled for frequency effects with n-grams, surprisal, and entropy reduction, an anti-locality explanation would rely on either (i) more precise variants of the metrics used in this study or (ii) other frequency metrics altogether. Future work could investigate the possibility of anti-locality by looking at the distance between an encoding operation and its corresponding

integration action to see if the integration facilitation observed in this study is driven by longer embeddings or if there is simply a general facilitation effect when completing embeddings.

The finding of a negative integration cost was previously observed by Wu et al. (2010) as well as Demberg and Keller (2008), although Demberg and Keller calculated it using the original referent-based definitions of Gibson (1998; 2000) and varied which parts of speech counted for calculating integration cost. Ultimately, Demberg and Keller (2008) concluded that the negative coefficient was evidence that integration cost was not a good broad-coverage predictor of reading times; however, this study has replicated the effect and showed it to be a very strong predictor of reading times, albeit one that is correlated with facilitation rather than inhibition.

It is interesting that many studies have found negative integration cost using naturalistic stimuli while others have consistently found positive integration cost when using constructed stimuli with multiple center embeddings presented without context (Gibson, 2000; Chen et al., 2005; Kwon et al., 2010). It may be the case that any dynamic recruitment is overwhelmed by the memory demands of multiply center-embedded stimuli. Alternatively, it may be that the difficulty of processing multiply center-embedded sentences containing ambiguities produces anxiety in subjects, which slows processing at implicit prosodic boundaries (Fodor, 2002; Mitchell et al., 2008). In any case, the source of this discrepancy presents an attractive target for future research.

In general, sequential prediction does not seem to present people with any special ease or difficulty as evidenced by the lack of significance of F-L- and F+L+ predictions when frequency effects are factored out. This supports a theory of sequential, content-based cueing (Botvinick, 2007) that predicts that certain states would directly cue other states and thus avoid recall difficulty. An example of this may be seen in the case of a transitive verb triggering the prediction of a direct object. This kind of cueing would show up as a frequency effect predicted by surprisal rather than as a memory-based cost, due to frequent occurrences becoming ingrained as a learned skill. Future work could use these sequential cueing operations to investigate further claims

of the dynamic recruitment hypothesis. One of the implications of the hypothesis is that recruitment of resources alleviates the initial encoding cost, which allows the parser to continue on as before the embedding. DLT, on the other hand, predicts that there is a storage cost for maintaining unresolved dependencies during a parse (Gibson, 2000). By weighting each of the sequential cueing operations with the embedding depth at which it occurs, an experiment may be able to test these two predictions.

This study has shown that measures based on working memory operations have strong predictivity over other previously proposed measures including those associated with frequency effects. This suggests that memory limitations may provide a partial explanation of what gives rise to frequency effects. Lastly, this paper provides evidence that there is a robust facilitation effect in English that arises from completing center embeddings.

The hierachic sequence model, all evaluation scripts, and regression results for all baseline predictors used in this paper are freely available at <http://sourceforge.net/projects/modelblocks/>.

Abstract

We propose a new approach to identifying semantically similar words across languages. The approach is based on an idea that two words in different languages are similar if they are likely to generate similar words (which includes both source and target language words) as their top semantic word responses. Semantic word responding is a concept from cognitive science which addresses detecting most likely words that humans output as free word associations given some cue word. The method consists of two main steps: (1) it utilizes a probabilistic multilingual topic model trained on comparable data to learn and quantify the semantic word responses, (2) it provides ranked lists of similar words according to the similarity of their semantic word response vectors. We evaluate our approach in the task of bilingual lexicon extraction (BLE) for a variety of language pairs. We show that in the cross-lingual settings without any language pair dependent knowledge the response-based method of similarity is more robust and outperforms current state-of-the art methods that directly operate in the semantic space of latent cross-lingual concepts/topics.

1 Introduction

Cross-lingual semantic word similarity addresses the task of detecting words that refer to similar semantic concepts and convey similar meanings across languages. It ultimately boils down to the automatic identification of translation pairs, that is, bilingual lexicon extraction (BLE). Such lexicons and semantically similar words serve as important resources

in cross-lingual knowledge induction (e.g., Zhao et al. (2009)), statistical machine translation (Och and Ney, 2003) and cross-lingual information retrieval (Ballesteros and Croft, 1997; Levow et al., 2005).

From parallel corpora, semantically similar words and bilingual lexicons are induced on the basis of word alignment models (Brown et al., 1993; Och and Ney, 2003). However, due to a relative scarcity of parallel texts for many language pairs and domains, there has been a recent growing interest in mining semantically similar words across languages on the basis of comparable data readily available on the Web (e.g., Wikipedia, news stories) (Haghghi et al., 2008; Hassan and Mihalcea, 2009; Vulic et al., 2011; Prochasson and Fung, 2011).

Approaches to detecting semantic word similarity from comparable corpora are most commonly based on an idea known as the *distributional hypothesis* (Harris, 1954), which states that words with similar meanings are likely to appear in similar contexts. Each word is typically represented by a high-dimensional vector in a feature vector space or a so-called *semantic space*, where the dimensions of the vector are its *context features*. The semantic similarity of two words, w_1^S given in the source language L_S with vocabulary V^S and w_2^T in the target language L_T with vocabulary V^T is then:

$$\text{Sim}(w_1^S, w_2^T) = SF(cv(w_1^S), cv(w_2^T)) \quad (1)$$

$cv(w_1^S) = [sc_1^S(c_1), \dots, sc_1^S(c_N)]$ denotes a context vector for w_1^S with N context features c_k , where $sc_1^S(c_k)$ denotes the score for w_1^S associated with context feature c_k (similar for w_2^T). SF is a similarity function (e.g., cosine, the Kullback-Leibler

divergence, the Jaccard index) operating on the context vectors (Lee, 1999; Cha, 2007).

In order to compute cross-lingual semantic word similarity, one needs to design the context features of words given in two different languages that span a shared cross-lingual semantic space. Such cross-lingual semantic spaces are typically spanned by: (1) bilingual lexicon entries (Rapp, 1999; Gaussier et al., 2004; Laroche and Langlais, 2010; Tamura et al., 2012), or (2) latent language-independent semantic concepts/axes (e.g., latent cross-lingual topics) induced by an algebraic model (Dumais et al., 1996), or more recently by a generative probabilistic model (Haghghi et al., 2008; Daumé III and Jagarlamudi, 2011; Vulic et al., 2011). Context vectors $cv(w_1^S)$ and $cv(w_2^T)$ for both source and target words are then compared in the semantic space independently of their respective languages.

In this work, we propose a new approach to constructing the shared cross-lingual semantic space that relies on a paradigm of *semantic word responding* or *free word association*. We borrow that concept from the psychology/cognitive science literature. Semantic word responding addresses a task that requires participants to produce first words that come to their mind that are related to a presented cue word (Nelson et al., 2000; Steyvers et al., 2004).

The new cross-lingual semantic space is spanned by *all vocabulary words in the source and the target language*. Each axis in the space denotes a semantic word response. The similarity between two words is then computed as the similarity between the vectors comprising their semantic word responses using any of existing *SF*-s. Two words are considered semantically similar if they are likely to generate similar semantic word responses and assign similar importance to them.

We utilize a shared semantic space of latent cross-lingual topics learned by a multilingual probabilistic topic model to obtain semantic word responses and quantify the strength of association between any cue word and its responses monolingually and across languages, and, consequently, to build *semantic response vectors*. That effectively translates the task of word similarity from the semantic space spanned by latent cross-lingual topics to the semantic space spanned by all vocabulary words in both languages.

The main contributions of this article are:

- We propose a new approach to modeling cross-lingual semantic similarity of words based on the similarity of their semantic word responses.
- We present how to estimate and quantify semantic word responses by means of a multilingual probabilistic topic model.
- We demonstrate how to employ our novel paradigm that relies on semantic word responding in the task of bilingual lexicon extraction (BLE) from comparable data.
- We show that the response-based model of similarity is more robust and obtains better results for BLE than the models that operate in the semantic space spanned by latent semantic concepts, i.e., cross-lingual topics directly.

The following sections first review relevant prior work and provide a very short introduction to multilingual probabilistic topic modeling, then describe our response-based approach to modeling cross-lingual semantic word similarity, and finally present our evaluation and results on the BLE task for a variety of language pairs.

2 Related Work

When dealing with the cross-lingual semantic word similarity, the focus of the researchers is typically on BLE, since usually the most similar words across languages are direct translations of each other. Numerous approaches emerged over the years that try to induce bilingual word lexicons on the basis of distributional information. Especially challenging is the task of mining semantically similar words from comparable data without any external knowledge source such as machine-readable seed bilingual lexicons used in (Fung and Yee, 1998; Rapp, 1999; Fung and Cheung, 2004; Gaussier et al., 2004; Morin et al., 2007; Andrade et al., 2010; Tamura et al., 2012), predefined explicit ontology or category knowledge used in (Déjean et al., 2002; Hassan and Mihalcea, 2009; Agirre et al., 2009), or orthographic clues as used in (Koehn and Knight, 2002; Haghghi et al., 2008; Daumé III and Jagarlamudi, 2011). This work addresses that particularly difficult setting which does not assume any language pair dependent background knowledge. It makes methods

developed in such a setting applicable even on distant language pairs with scarce resources.

Recently, Griffiths et al. (2007), and Steyvers and Griffiths (2007) proposed models of free word association and semantic word similarity in the monolingual settings based on per-topic word distributions from probabilistic topic models such as pLSA (Hofmann, 1999) and LDA (Blei et al., 2003). Additionally, Vulić et al. (2011) constructed several models that utilize a shared cross-lingual topical space obtained by a multilingual topic model (Mimno et al., 2009; De Smet and Moens, 2009; Boyd-Graber and Blei, 2009; Ni et al., 2009; Jagarlamudi and Daumé III, 2010; Zhang et al., 2010) to identify potential translation candidates in the cross-lingual settings without any background knowledge. In this paper, we show that a transition from their semantic space spanned by cross-lingual topics to a semantic space spanned by all vocabulary words yields more robust models of cross-lingual semantic word similarity.

3 Modeling Word Similarity as the Similarity of Semantic Word Responses

This section contains a detailed description of our semantic word similarity method that relies on semantic word responses. Since the method utilizes the concept of multilingual probabilistic topic modeling, we first provide a very short overview of that concept, then present the intuition behind the approach, and finally describe our method in detail.

3.1 Multilingual Probabilistic Topic Modeling

Assume that we are given a *multilingual corpus* \mathcal{C} of l languages, and \mathcal{C} is a set of text collections $\{\mathcal{C}_1, \dots, \mathcal{C}_l\}$ in those languages. A *multilingual probabilistic topic model* (Mimno et al., 2009; De Smet and Moens, 2009; Boyd-Graber and Blei, 2009; Ni et al., 2009; Jagarlamudi and Daumé III, 2010; Zhang et al., 2010) of a multilingual corpus \mathcal{C} is defined as a set of semantically coherent multinomial distributions of words with values $P_j(w_i^j|z_k)$, $j = 1, \dots, l$, for each vocabulary $V^1, \dots, V^j, \dots, V^l$ associated with text collections $\mathcal{C}_1, \dots, \mathcal{C}_j, \dots, \mathcal{C}_l \in \mathcal{C}$ given in languages $L_1, \dots, L_j, \dots, L_l$. $P_j(w_i^j|z_k)$ is calculated for each $w_i^j \in V^j$. The probability scores $P_j(w_i^j|z_k)$ build *per-topic word distributions*, and they consti-

tute a language-specific representation (e.g., a probability value is assigned only for words from V^j) of a language-independent cross-lingual latent concept, that is, latent cross-lingual topic $z_k \in \mathcal{Z}$. $\mathcal{Z} = \{z_1, \dots, z_K\}$ represents the set of all K latent cross-lingual topics present in the multilingual corpus. Each document in the multilingual corpus is thus considered a mixture of K cross-lingual topics from the set \mathcal{Z} . That mixture for some document $d_i^j \in \mathcal{C}_j$ is modeled by the probability scores $P_j(z_k|d_i^j)$ that altogether build *per-document topic distributions*.

Each cross-lingual topic from the set \mathcal{Z} can be observed as a latent language-independent concept present in the multilingual corpus, but each language in the corpus uses only words from its own vocabulary to describe the content of that concept. For instance, having a multilingual collection in English, Spanish and Dutch and discovering a topic on *Soccer*, that cross-lingual topic would be represented by words (actually probabilities over words) $\{player, goal, coach, \dots\}$ in English, $\{balón (ball), futbolista (soccer player), goleador (scorer), \dots\}$ in Spanish, and $\{wedstrijd (match), elftal (soccer team), doelpunt (goal), \dots\}$ in Dutch. We have $\sum_{w_i^j \in V^j} P_j(w_i^j|z_k) = 1$, for each vocabulary V^j representing language L_j , and for each topic $z_k \in \mathcal{Z}$. Therefore, the latent cross-lingual topics also span a shared cross-lingual semantic space.

3.2 The Intuition Behind the Approach

Imagine the following thought experiment. A group of human subjects who have been raised bilingually and thus are native speakers of two languages L_S and L_T , is playing a game of word associations. The game consists of possibly an infinite number of iterations, and each iteration consists of 4 rounds. In the first round (the *S-S round*), given a word in the language L_S , the subject has to generate a list of words in the same language L_S that first occur to her/him as semantic word responses to the given word. The list is in descending order, with more prominent word responses occurring higher in the list. In the second round (the *S-T round*), the subject repeats the procedure, and generates the list of word responses to the same word from L_S , but now in the other language L_T . The third (the *T-T round*)

and the fourth round (the *T-S round*) are similar to the first and the second round, but now a list of word responses in both L_S and L_T has to be generated for some cue word from L_T . The process of generating the lists of semantic responses then continues with other cue words and other human subjects.

As the final result, for each word in the source language L_S , and each word in the target language L_T , we obtain a single list of semantic word responses comprising words in both languages. All lists are sorted in descending order, based on some association score that takes into account both the number of times a word has occurred as an associative response, as well as the position in the list in each round. We can now measure the similarity of any two words, regardless of their corresponding languages, according to the similarity of their corresponding lists that contain their word responses. Words that are equally likely to trigger the same associative responses in the human brain, and moreover assign equal importance to those responses, as provided in the lists of associative responses, are very likely to be closely semantically similar. Additionally, for a given word w_1^S in the source language L_S , some word w_2^T in L_T that has the highest similarity score among all words in L_T should be a direct word-to-word translation of w_1^S .

3.3 Modeling Semantic Word Responses via Cross-Lingual Topics

Cross-lingual topics provide a sound framework to construct a probabilistic model of the aforementioned experiment. To model semantic word responses via the shared space of cross-lingual topics, we have to set a probabilistic mass that quantifies the degree of association. Given two words $w_1, w_2 \in V^S \cup V^T$, a natural way of expressing the *asymmetric semantic association* is by modeling the probability $P(w_2|w_1)$ (Griffiths et al., 2007), that is, the probability to generate word w_2 as a response given word w_1 . After the training of a multilingual topic model on a multilingual corpus, we obtain per-topic word distributions with scores $P_S(w_i^S|z_k)$ and $P_T(w_i^T|z_k)$ (see Sect. 3.1).¹ The probability

$P(w_2|w_1)$ is then decomposed as follows:

$$Resp(w_1, w_2) = P(w_2|w_1) = \sum_{k=1}^K P(w_2|z_k)P(z_k|w_1) \quad (2)$$

The probability scores $P(w_2|z_k)$ select words that are highly descriptive for each particular topic. The probability scores $P(z_k|w_1)$ ensure that topics z_k that are semantically relevant to the given word w_1 dominate the sum, so the overall high score $Resp(w_1, w_2)$ of the semantic word response is assigned only to highly descriptive words of the semantically related topics. Using the shared space of cross-lingual topics, semantic response scores can be derived for any two words $w_1, w_2 \in V^S \cup V^T$.¹

The generative model closely resembles the actual process in the human brain - when we generate semantic word responses, we first tend to associate that word with a related semantic/cognitive concept, in this case a cross-lingual topic (the factor $P(z_k|w_1)$), and then, after establishing the concept, we output a list of words that we consider the most prominent/descriptive for that concept (words with high scores in the factor $P(w_2|z_k)$) (Nelson et al., 2000; Steyvers et al., 2004). Due to such modeling properties, this model of semantic word responding tends to assign higher association scores for *high frequency words*. It eventually leads to *asymmetric associations/responses*. We have detected that phenomenon both monolingually and across languages. For instance, the first response to Spanish word *mutación* (*mutation*) is English word *gene*. Other examples include *caldera* (*boiler*)-steam, *deportista* (*sportsman*)-sport, *horario* (*schedule*)-hour or *pescador* (*fisherman*)-fish. In the other association direction, we have detected top responses such as *merchant-comercio* (*trade*) or *neologism-palabra* (*word*). In the monolingual setting, we acquire English pairs such as *songwriter-music*, *discipline-sport*, or Spanish pairs *gripe* (*flu*)-*enfermedad* (*disease*), *cuenca* (*basin*)-*río* (*river*), etc.

3.4 Response-Based Model of Similarity

Eq. (2) provides a way to measure the strength of semantic word responses. In order to establish the

¹A remark on notation throughout the paper: Since the shared space of cross-lingual topics allows us to construct a uniform representation for all words regardless of a vocabulary they belong to, due to simplicity and to stress the uniformity, we sometimes use notation $P(w_i|z_k)$ and $P(z_k|w_i)$ instead of $P_S(w_i|z_k)$ or $P_S(z_k|w_i)$ (similar for subscript T). However, the reader must be aware that, for instance, $P(w_i|z_k)$ actually means $P_S(w_i|z_k)$ if $w_i \in V^S$, and $P_T(w_i|z_k)$ if $w_i \in V^T$.

Semantic responses				Response-based similarity	
dramaturgo (playwright)		play	playwright	dramaturgo

contribution	.025	teatro (theatre)	.019	drama	.026

Table 1: An example of top 10 semantic word responses and the final response-based similarity for some Spanish and English words. The responses are estimated from Spanish-English Wikipedia data by bilingual LDA. We can observe several interesting phenomena: (1) High-frequency words tend to appear higher in the lists of semantic responses (e.g., *play* and *obra* for all 3 words), (2) Due to the modeling properties that give preference to high-frequency words (Sect. 3.3), a word might not generate itself as the top semantic response (e.g., *playwright-play*), (3) Both source and target language words occur as the top responses in the lists, (4) Although *play* is the top semantic response in English for both *dramaturgo* and *playwright*, its list of top semantic responses is less similar to the lists of those two words, (5) Although the English word *playwright* does not appear in the top 10 semantic responses to *dramaturgo*, and *dramaturgo* does not appear in the top 10 responses to *playwright*, the more robust response-based similarity method detects that the two words are actually very similar based on their lists of responses, (6) *dramaturgo* and *playwright* have very similar lists of semantic responses which ultimately leads to detecting that *playwright* is the most semantically similar word to *dramaturgo* across the two languages (the last column), i.e., they are direct one-to-one translations of each other, (7) Another English word *dramatist* very similar to Spanish *dramaturgo* is also pushed higher in the final list, although it is not found in the list of top semantic responses to *dramaturgo*.

final similarity between two words, we have to compare their *semantic response vectors*, that is, their semantic response scores over all words in both vocabularies. The final model of word similarity closely mimics our thought experiment. First, for each word $w_i^S \in V^S$, we generate probability scores $P(w_j^S|w_i^S)$ for all words $w_j^S \in V^S$ (the S-S rounds). Note that $P(w_i^S|w_i^S)$ is also defined by Eq. (2). Following that, for each word $w_i^S \in V^S$, we generate probability scores $P(w_j^T|w_i^S)$, for all words $w_j^T \in V^T$ (the S-T rounds). Similarly, we calculate probability scores $P(w_j^T|w_i^T)$ and $P(w_j^S|w_i^T)$, for each $w_i^T, w_j^T \in V^T$, and for each $w_j^S \in V^S$ (the T-T and T-S rounds).

Now, each word $w_i \in V^S \cup V^T$ may be represented by a $(|V^S| + |V^T|)$ -dimensional context vector $cv(w_i)$ as follows:² $[P(w_1^S|w_i), \dots, P(w_{|V^S|}^S|w_i), \dots, P(w_{|V^T|}^T|w_i)]$. We have created a language-independent cross-

lingual semantic space spanned by all vocabulary words in both languages. Each feature corresponds to one word from vocabularies V^S and V^T , while the exact score for each feature in the context vector $cv(w_i)$ is precisely the probability that this word/feature will be generated as a word response given word w_i . The degree of similarity between two words is then computed on the basis of similarity between their feature vectors using some of the standard similarity functions (Cha, 2007).

The novel response-based approach of similarity removes the effect of high-frequency words that tend to appear higher in the lists of semantic word responses. Therefore, the real synonyms and translations should occur as top candidates in the lists of similar words obtained by the response-based method. That property may be exploited to identify one-to-one translations across languages and build a bilingual lexicon (see Table 1).

4 Experimental Setup

4.1 Data Collections

We work with the following corpora:

²We assume that the two sets V^S and V^T are disjunct. It means that, for instance, Spanish word *pie* (*foot*) from V^S and English word *pie* from V^T are treated as two different word types. In that case, it holds $|V^S \cup V^T| = |V^S| + |V^T|$.

- IT-EN-W: A collection of 18,898 Italian-English Wikipedia article pairs previously used by Vulić et al. (2011).
- ES-EN-W: A collection of 13,696 Spanish-English Wikipedia article pairs.
- NL-EN-W: A collection of 7,612 Dutch-English Wikipedia article pairs.
- NL-EN-W+EP: The NL-EN-W corpus augmented with 6,206 Dutch-English document pairs from Europarl (Koehn, 2005). Although Europarl is a parallel corpus, no explicit use is made of sentence-level alignments.

All corpora are theme-aligned, that is, the aligned document pairs discuss similar subjects, but are in general not direct translations (except the Europarl document pairs). NL-EN-W+EP serves to test whether better semantic responses could be learned from data of higher quality, and to measure how it affects the response-based similarity method and the quality of induced lexicons. Following (Koehn and Knight, 2002; Haghghi et al., 2008; Prochasson and Fung, 2011), we consider only noun word types. We retain only nouns that occur at least 5 times in the corpus. We record the lemmatized form when available, and the original form otherwise. Again following their setup, we use TreeTagger (Schmid, 1994) for POS tagging and lemmatization.

4.2 Multilingual Topic Model

The multilingual probabilistic topic model we use is a straightforward multilingual extension of the standard Blei et al.’s LDA model (Blei et al., 2003) called bilingual LDA (Mimno et al., 2009; Ni et al., 2009; De Smet and Moens, 2009). For the details regarding the modeling assumptions, generative story, training and inference procedure of the bilingual LDA model, we refer the interested reader to the aforementioned relevant literature. The potential of the model in the task of bilingual lexicon extraction was investigated before (Mimno et al., 2009; Vulić et al., 2011), and it was also utilized in other cross-lingual tasks (e.g., Platt et al. (2010); Ni et al. (2011)). We use Gibbs sampling for training. In a typical setting for mining semantically similar words using latent topic models in both monolingual

(Griffiths et al., 2007; Dinu and Lapata, 2010) and cross-lingual setting (Vulić et al., 2011), the best results are obtained with the number of topics set to a few thousands (≈ 2000). Therefore, our bilingual LDA model on all corpora is trained with the number of topics $K = 2000$. Other parameters of the model are set to the standard values according to Steyvers and Griffiths (2007): $\alpha = 50/K$ and $\beta = 0.01$. We are aware that different hyper-parameter settings (Asuncion et al., 2009; Lu et al., 2011), might have influence on the quality of learned cross-lingual topics, but that analysis is out of the scope of this paper.

4.3 Compared Methods

We evaluate and compare the following word similarity approaches in all our experiments:

- 1) The method that regards the lists of semantic word responses across languages obtained by Eq. (2) directly as the lists of semantically similar words (**Direct-SWR**).
- 2) The state-of-the-art method that employs a similarity function (SF) on the K -dimensional word vectors $cv(w_i)$ in the semantic space of latent cross-lingual topics. The dimensions of the vectors are conditional topic distribution scores $P(z_k|w_i)$ that are obtained by the multilingual topic model directly (Steyvers and Griffiths, 2007; Vulić et al., 2011). We have tested different SF-s (e.g., the Kullback-Leibler and the Jensen-Shannon divergence, the cosine measure), and have detected that in general the best scores are obtained when using the Bhattacharyya coefficient (BC) (Bhattacharyya, 1943; Kazama et al., 2010) (**Topic-BC**).
- 3) The best scoring similarity method from Vulić et al. (2011) named **TI+Cue**. This state-of-the-art method also operates in the semantic space of latent cross-lingual concepts/topics.
- 4) The response-based similarity described in Sect. 3. As for **Topic-BC**, we again use BC as the similarity function, but now on $|V^S \cup V^T|$ -dimensional context vectors in the semantic space spanned by all words in both vocabularies that represent semantic word responses (**Response-BC**). Given two N -dimensional word vectors $cv(w_1^S)$ and $cv(w_2^T)$, the BC or the *fidelity* measure (Cha, 2007) is defined as:

$$BC(cv(w_1^S), cv(w_2^T)) = \sum_{n=1}^N \sqrt{sc_1^S(c_n) \cdot sc_2^T(c_n)} \quad (3)$$

Corpus:	IT-EN-W			ES-EN-W			NL-EN-W			NL-EN-W+EP		
Method	Acc ₁	MRR	Acc ₁₀	Acc ₁	MRR	Acc ₁₀	Acc ₁	MRR	Acc ₁₀	Acc ₁	MRR	Acc ₁₀
Direct-SWR	.501	.576	.740	.332	.437	.675	.186	.254	.423	.344	.450	.652
Topic-BC	.578	.667	.834	.433	.576	.843	.237	.314	.489	.534	.630	.836

Table 2: BLE performance of all the methods for Italian-English, Spanish-English and Dutch-English (with 2 different corpora utilized for the training of bilingual LDA and the estimation of semantic word responses for Dutch-English).

For the *Topic-BC* method $N = K$, while $N = |V^S \cup V^T|$ for *Response-BC*. Additionally, since $P(z_k|w_i) > 0$ and $P(w_k|w_i) > 0$ for each $z_k \in \mathcal{Z}$ and each $w_k \in V^S \cup V^T$, a lot of probability mass is assigned to topics and semantic responses that are completely irrelevant to the given word. Reducing the dimensionality of the semantic representation a posteriori to only a smaller number of most important semantic axes in the semantic spaces should decrease the effects of that statistical noise, and even more firmly emphasize the latent correlation among words. The utility of such *semantic space truncating* or *feature pruning* in monolingual settings (Reisinger and Mooney, 2010) was also detected previously for LSA and LDA-based models (Landauer and Dumais, 1997; Griffiths et al., 2007). Therefore, unless noted otherwise, we perform all our calculations over the best scoring 200 cross-lingual topics and the best scoring 2000 semantic word responses.³

4.4 Evaluation

Ground truth translation pairs.⁴ Since our task is bilingual lexicon extraction, we designed a set of ground truth one-to-one translation pairs for all 3 language pairs as follows. For Dutch-English and Spanish-English, we randomly sampled a set of Dutch (Spanish) nouns from our Wikipedia corpora. Following that, we used the *Google Translate* tool plus an additional annotator to translate those words to English. The annotator manually revised the lists and retained only words that have

³The values are set empirically. Calculating similarity $Sim(w_1^S, w_2^T)$ may be interpreted as: “Given word w_1^S detect how similar word w_2^T is to the word w_1^S .” Therefore, when calculating $Sim(w_1^S, w_2^T)$, even when dealing with symmetric similarity functions such as BC, we always consider only the scores $P(\cdot|w_1^S)$ for truncating.

⁴Available online: <http://people.cs.kuleuven.be/~ivan.vulic/software/>

their corresponding translation in the English vocabulary. Additionally, only one possible translation was annotated as correct. When more than 1 translation is possible, the annotator marked as correct the translation that occurs more frequently in the English Wikipedia data. Finally, we built a set of 1000 one-to-one translation pairs for Dutch-English and Spanish-English. The same procedure was followed for Italian-English, but there we obtained the ground truth one-to-one translation pairs for 1000 most frequent Italian nouns in order to test the effect of word frequency on the quality of semantic word responses and the overall lexicon quality.

Evaluation metrics. All the methods under consideration actually retrieve ranked lists of semantically similar words that could be observed as potential translation candidates. We measure the performance on BLE as *Top M* accuracy (Acc_M). It denotes the number of source words from ground truth translation pairs whose top M semantically similar words contain the correct translation according to our ground truth over the total number of ground truth translation pairs (=1000) (Tamura et al., 2012). Additionally, we compute the *mean reciprocal rank* (MRR) scores (Voorhees, 1999).

5 Results and Discussion

Table 2 displays the performance of each compared method on the BLE task. It shows the difference in results for different language pairs and different corpora used to extract latent cross-lingual topics and estimate the lists of semantic word responses. Example lists of semantically similar words over all 3 language pairs are shown in Table 3. Based on these results, we are able to derive several conclusions: (i) *Response-BC* performs consistently better than the other 3 methods over all corpora and all language pairs. It is more robust and is able to find some cross-lingual similarities omitted by the other meth-

Italian-English (IT-EN)			Spanish-English (ES-EN)			Dutch-English (NL-EN)

Table 4: Example translations found by the *Response-BC* method, but missed by the other 3 methods.

ods (see Table 4). The overall quality of the cross-lingual word similarities and lexicons extracted by the method is dependent on the quality of estimated semantic response vectors. The quality of these vectors is of course further dependent on the quality of multilingual training data. For instance, for Dutch-English, we may observe a rather spectacular increase in overall scores (the tests are performed over the same set of 1000 words) when we augment Wikipedia data with Europarl data (compare the scores for NL-EN-W and NL-EN-W+EP).

(ii) A transition from a semantic space spanned by cross-lingual topics (*Topic-BC*) to a semantic space spanned by vocabulary words (*Response-BC*) leads to better results over all corpora and language pairs. The difference is less visible when using training data of lesser quality (the scores for NL-EN-W). Moreover, since the shared space of cross-lingual topics is used to obtain and quantify semantic word responses, the quality of learned cross-lingual topics influences the quality of semantic word responses. If the semantic coherence of the cross-lingual topical space is unsatisfying, the method is unable to generate good semantic response vectors, and ul-

timately unable to correctly identify semantically similar words across languages.

(iii) Due to its modeling properties that assign more importance to high-frequency words, *Direct-SWR* produces reasonable results in the BLE task only for high-frequency words (see results for IT-EN-W). Although Eq. (2) models the concept of semantic word responding in a sound way (Griffiths et al., 2007), using the semantic word responses directly is not suitable for the actual BLE task.

(iv) The effect of word frequency is clearly visible when comparing the results obtained on IT-EN-W with the results obtained on the other Wikipedia corpora. High-frequency words produce more redundancies in training data that are captured by statistical models such as latent topic models. High-frequency words then obtain better estimates of their semantic response vectors which consequently leads to better overall scores. The effect of word frequency on statistical methods in the BLE task was investigated before (Pekar et al., 2006; Prochasson and Fung, 2011; Tamura et al., 2012), and we also confirm their findings.

(v) Unlike (Koehn and Knight, 2002; Haghghi et al., 2008), our response-based method does not rely on any orthographic features such as cognates or words shared across languages. It is a pure statistical method that only relies on word distributions over a multilingual corpus. Based on these distributions, it performs the initial shallow semantic analysis of the corpus by means of a multilingual probabilistic model. The method then builds, via the concept of semantic word responding, a language-

independent semantic space spanned by all vocabulary words/responses in both languages. That makes the method portable to distant language pairs. However, for similar languages, including more evidence such as orthographic clues might lead to further increase in scores, but we leave that for future work.

6 Conclusion

We have proposed a new statistical approach to identifying semantically similar words across languages that relies on the paradigm of semantic word responding previously defined in cognitive science. The proposed approach is robust and does not make any additional language-pair dependent assumptions (e.g., it does not rely on a seed lexicon, orthographic clues or predefined concept categories). That effectively makes it applicable to any language pair. Our experiments on the task of bilingual lexicon extraction for a variety of language pairs have proved that the response-based approach is more robust and outperforms the methods that operate in the semantic space of latent concepts (e.g., cross-lingual topics) directly.

Acknowledgments

We would like to thank Steven Bethard and the anonymous reviewers for their useful suggestions. This research has been carried out in the framework of the TermWise Knowledge Platform (IOF-KP/09/001) funded by the Industrial Research Fund, KU Leuven, Belgium.

Combining multiple information types in Bayesian word segmentation

Gabriel Doyle and Roger Levy

Department of Linguistics

University of California, San Diego

{gdoyle, rlevy}@ucsd.edu

Abstract

Humans identify word boundaries in continuous speech by combining multiple cues; existing state-of-the-art models, though, look at a single cue. We extend the generative model of Goldwater et al (2006) to segment using syllable stress as well as phonemic form. Our new model treats identification of word boundaries and prevalent stress patterns in the language as a joint inference task. We show that this model improves segmentation accuracy over purely segmental input representations, and recovers the dominant stress pattern of the data. Additionally, our model retains high performance even without single-word utterances. We also demonstrate a discrepancy in the performance of our model and human infants on an artificial-language task in which stress cues and transition-probability information are pitted against one another. We argue that this discrepancy indicates a bound on rationality in the mechanisms of human segmentation.

1 Introduction

For an adult speaker of a language, word segmentation from fluid speech may seem so easy that it barely needed to be learned. However, pauses in speech and word boundaries are not well correlated (Cole & Jakimik, 1980), word boundaries are marked by a conspiracy of partially-informative cues (Johnson & Jusczyk, 2001), and different languages mark their boundaries differently (Cutler & Carter, 1987). This makes the problem of unsupervised word segmentation acquisition, whether by a computational model or an infant, a daunting task.

Effective segmentation relies on the flexible integration of multiple types of segmentation cues, among them statistical regularities in phonemes and prosody, coarticulation, and allophonic variation. Infants begin using multiple segmentation cues within their first year of life (Johnson & Jusczyk, 2001). Despite this, many state-of-the-art models look at only one type of information: phonemes.

In this study, we expand an existing model to incorporate multiple cues, leading to an improvement in segmentation performance and opening new ways of investigating human segmentation acquisition. On the latter point, we show that rational learners can learn to segment without encountering words in isolation, and that human learners deviate from rationality in certain segmentation tasks.

2 Previous work

The prevailing unsupervised word segmentation systems (e.g., Brent, 1999; Goldwater, Griffiths, & Johnson, 2006; Blanchard & Heinz, 2008) use only phonemic information to segment speech. However, human segmenters use additional information types, notably stress information, in their segmentation. We present an overview of these phonemic models here before discussing the prosodic model expansion. A more complete review is available in Goldwater (2007).

2.1 Goldwater et al (2006)

The Goldwater et al model is related to Brent (1999)'s model, both of which use strictly phonemic information to segment. The model assumes that the corpus is generated by a Dirichlet process over

word bigrams.¹ We present a basic overview here, based on Sect. 5.5 of Goldwater, 2007. To generate the word w_i given the preceding word w_{i-1} :

1. Decide if bigram $b_i = \langle w_{i-1}, w_i \rangle$ is novel
2. If b_i non-novel, draw b_i from bigram lexicon
3. If b_i novel, decide whether w_i is novel
 - a. If w_i non-novel, draw w_i from word lexicon
 - b. If w_i novel, draw w_i from word-generating distribution P_0 .

The Dirichlet process first decides whether to draw a non-novel (“nn”) bigram, with probability proportional to the number of times the previous word has appeared in the corpus:

$$p(\langle w_{i-1}, w_i \rangle \text{ nn} | w_{i-1}) = \frac{n_{\langle w_{i-1}, \cdot \rangle}}{n_{\langle w_{i-1}, \cdot \rangle} + \alpha_1}, \quad (1)$$

where $n_{\langle x, y \rangle}$ is the token count for bigram $\langle x, y \rangle$. If the bigram is non-novel, word w_i is drawn in proportion to the number of times it has appeared after w_{i-1} in the corpus:

$$p(w_i = x | \langle w_{i-1}, w_i \rangle \text{ nn}) = \frac{n_{\langle w_{i-1}, x \rangle}}{n_{\langle w_{i-1}, \cdot \rangle}} \quad (2)$$

If the bigram is novel, this could either be due to w_i being a novel word or due to w_i being an existing word that had not appeared with w_{i-1} before. The probability of w_i being a non-novel word x is

$$p(w_i = x, w_i \text{ nn} | \begin{array}{c} \langle w_{i-1}, w_i \rangle \\ \text{novel} \end{array}) = \frac{b_{\langle \cdot, w_i \rangle}}{(b_{\langle \cdot, \cdot \rangle} + \alpha_0)}, \quad (3)$$

where $b_{\langle \cdot, \cdot \rangle}$ is the count of word bigram types. Finally, if w_i is a new word, its phonemic form is generated from a distribution P_0 . In the Goldwater et al model, this distribution is simply the product of the unigram probabilities of the phonemes, $P(\sigma_j)$, times the probability of a word boundary, $p_{\#}$, to end the word:

$$p(w_i = \sigma_1 \cdots \sigma_M | \begin{array}{c} w_i \\ \text{novel} \end{array}) = p_{\#}(1 - p_{\#})^{M-1} \prod P(\sigma_j) \quad (4)$$

¹We will only discuss the bigram model here because it is more appropriate from both a cognitive perspective (it posits latent hierarchical structure) and engineering perspective (it segments more accurately) than the unigram model.

To segment an observed corpus, the model Gibbs samples over the possible word boundaries (utterance boundaries are assumed to be word boundaries).² The exchangability of draws from a Dirichlet process allows for Gibbs sampling of each possible boundary given all the others.

2.2 A cognitively-plausible variant

Phillips and Pearl (2012) make these Bayesian segmentation models more cognitively plausible in two ways. The first is to move from phonemes to syllables as the base representational unit from which words are constructed, as infants learn to categorize syllables before phonemes (Eimas, 1999). The second is to add memory and processing constraints on the learner. They find that syllable-based segmentation is better than phoneme-based segmentation in the bigram model (though worse in the unigram model), and that, counter-intuitively, the constrained learner outperforms the unconstrained learner. This improvement appears to be driven by better performance in segmenting more common words. In this work, we adopt the syllabified representation but retain the unconstrained rational learner assumption.

2.3 Other multiple-cue models

Some previous models have incorporated multiple cues, specifically the phonemic and stress information that our model will use. Two prominent examples are Christiansen, Allen, and Seidenberg (1998)’s connectionist model and Gambell and Yang (2006)’s algebraic model. The connectionist model places word boundaries where the combination of phonemic and stress information predict likely utterance boundaries, but does not include an explicit sense of “word”, and performs only modestly on the segmentation task (boundary F-scores of .40-.45). The algebraic model also underperforms the Bayesian model (Phillips & Pearl, 2012) unless it includes the heuristic that there is a word boundary between any two stressed syllables. Our model presents a more general and completely unsupervised approach to segmentation with multiple cue-types.

²The model assumes that utterance boundaries are generated just like other words, and includes an adjustable parameter $p_{\$}$ to account for their frequency.

In general, joint inference is becoming more common in language acquisition problems and has been shown to improve performance over single-feature inference. Examples include joint inference of a lexicon and phonetic categories (Feldman, Griffiths, & Morgan, 2009), joint inference of syntactic word order and word reference (Maurits, Perfors, & Navarro, 2009), and joint inference of word meanings and speaker intentions in child-directed speech (Frank, Goodman, & Tenenbaum, 2009).

3 Model design

Our model changes P_0 from a single-cue distribution, generating only phonemes, to a multiple-cue distribution that generates a stress form as well. This can improve segmentation performance and allows the investigation of rational segmentation behavior in a multiple-cue world.

In the original model, $P_0(w_i = \sigma_1 \cdots \sigma_M) \propto \prod_j P(\sigma_j)$, where $P(\sigma_j)$ is the frequency of the phoneme σ_j . In the multiple-cue model, we first generate a phonemic form w_i , then assign a stress pattern s_i to it.

$$\begin{aligned} P_0(w_i, s_i) &= P_W(w_i) P_S(s_i|M) \\ &= p_{\#}(1 - p_{\#})^{M-1} \prod_j^M P(\sigma_j) P_S(s_i|M) \end{aligned} \quad (5)$$

The phonemic form w_i has the same product-of-segments probability as the Goldwater et al model, but σ_j are now syllables instead of phonemes. We discuss the rationale behind this change in the next section.

The phonemic form is generated first, and the stress form is then drawn as a multinomial over all possible stress patterns with the same number of syllables as w_i . The stress distribution P_S is a multinomial distribution over word-length stress templates. P_S can be learned by the model based on a Dirichlet prior, but for simplicity in the present implementation, we estimate P_S as the plus-one-smoothed frequency of the stress patterns in the current segmentation. There are two stress levels (stressed or unstressed), and 2^M possible stress templates for a word of length M .³

³We do not assume that each word has one and only one

Unlike phonemic forms, stress patterns are drawn as a whole word. This allows the model to capture a wide range of stress biases, although it prevents the model from generalizing biases across different word lengths. A potential future change to P_S that would allow for better generalization is discussed in Section 6.

3.1 On syllabification and stress

We change from segmenting on phonemes to segmenting on syllables in order to more easily implement stress information, which is a supersegmental feature most appropriately located on syllables. Syllabified data has been used in some previous models of segmentation, especially those using stress information or syllable-level transition probabilities (Christiansen et al., 1998; Swingley, 2005; Gambell & Yang, 2006; Phillips & Pearl, 2012).

For studying human word segmentation, Phillips and Pearl argue syllabified speech may be a more cognitively plausible testing ground. 3-month-old infants appear to have categorical representations of syllables (Eimas, 1999), three months before word segmentation appears (Borfeld, Morgan, Golinkoff, & Rathbun, 2005), and seven months before phoneme categorization (Werker & Tees, 1984). In addition, syllabification is assumed in much work on human word segmentation, especially in artificial-language studies (e.g., Thiessen & Safran, 2003), which calculate statistical cues at the syllable level.

The assumption that syllable boundaries are known affects the baseline performance of the model, as it reduces the number of possible word boundary locations (since a word boundary is necessarily a syllable boundary). As such performance over syllabified data cannot be directly compared to performance on non-syllabified data.

It may seem that syllabification is so closely tied to word segmentation that including the former in a model of the latter leaves little to the model. However, the determinants of syllable boundaries are not the same as those for word boundaries. The prob-

stressed syllable, which would reduce the number of possible stress templates to M , for two reasons. First, in the current corpus, some words have citation forms with multiple stressed syllables. Second, in actual speech this assumption will not hold (e.g., many function words go unstressed).

lem of assigning syllable boundaries is a question of deciding where a boundary goes between two syllable nuclei, with the assumption that there must be a boundary there. The problem of assigning word boundaries is a question of deciding whether there is a boundary between two syllable nuclei, and if so, where it is. Knowing the syllable boundaries reduces the set of possible word boundaries, but does not directly address the question of how likely a boundary is. The difference in these tasks is supported by the three-month gap between syllable and word identification in infants.

4 Data

We use the Korman (1984) training corpus, as compiled by Christiansen et al. (1998), in this study. This is a 24493-word corpus of English spoken by adults to infants aged 6–16 weeks.⁴ Phonemes, stresses, and syllable boundaries are the same as those used by Christiansen et al., which were based on citation forms in the MRC Psycholinguistic Database. All monosyllabic words were coded as stressed. Only utterances for which all words had citation forms were included.

This corpus is largely monosyllabic (87.3% of all word tokens), and heavily biased toward initial stress (89.2% of all multisyllable word tokens). No word is longer than three syllables, and most words have only one stressed syllable. A breakdown of the corpus by stress pattern is given in Table 1. This monosyllabic bias is an inherent property of English, not idiosyncratic to this corpus. The Bernstein-Ratner child-directed corpus is also over 80% monosyllabic. We expect that the results of segmentation on child-directed data will extend to adult speech, as the adult-directed corpus used by Gambell and Yang (2006) has an average word length of 1.17 syllables.

5 Experiments

We test the model on three problems. First, we show that the addition of stress information improves segmentation performance compared to a stress-less model. Next, we apply the model to a question in human segmentation acquisition. Finally, we look at

⁴Approximately 150 word tokens from the original corpus were omitted in our version of the corpus due to a disparity between recorded number of syllables and number of stresses.

Types		Tokens	
Stress pattern	Count	Stress pattern	Count

Other	5	Other	2

Table 1: Corpus stress patterns by types and tokens, showing an initial-stress bias in all lengths.

a task where the rational model deviates from human performance.

5.1 Parameter setting

The model has four free parameters: α_0 and α_1 , which affect the likelihood of new words and bigrams, respectively, and $p_{\#}$ and $p_{\$}$, which affect the expected likelihood of word and utterance boundaries. Following Goldwater, Griffiths, and Johnson (2009), we set $\alpha_0 = 20$, $\alpha_1 = 100$, $p_{\#} = 0.8$ and $p_{\$} = 0.5$ in all experiments.⁵

In all cases, the model performed five independent runs of 20000 iterations of Gibbs sampling the boundaries for the full corpus. Simulated annealing was performed during the burn-in period to improve convergence. All performance measures are reported as the mean of these five runs.

Performance is measured as word, boundary, and lexicon precision, recall, and F-scores. A word is matched iff both of its true boundaries are marked as boundaries and no internal boundaries are marked as word boundaries. Boundary counts omit utterance boundaries, which are assumed to be word boundaries. Lexical counts are based on word type counts.

5.2 Stress improves performance

We begin by showing that including a second cue type improves segmentation performance. We compare segmentation on a corpus with the attested stress patterns to that of a corpus without stress. With stress information included in the model, word/boundary/lexicon F-scores are

⁵Performance was similar for a range of settings between 1 and 100 for α_0 and between 10 and 200 for α_1 .

	With stress			Without stress		
	Word	Bnd	Lex	Word	Bnd	Lex
Prec	.76	.99	.75	.76	.99	.72
Rec	.61	.70	.87	.60	.69	.84
F	.68	.82	.80	.67	.82	.77

Table 2: Precision, recall, and F-score over corpora with and without stress information available. Stress information especially improves lexical performance.

.68/.82/.80. Without stress, performance drops to .67/.82/.77.⁶ Full results are given in Table 2.

Stress information primarily improves lexicon performance, along with a small improvement in token segmentation. Accounting for stress reduces both false positives and negatives in the lexicon; the fact that the lexical improvement is greater than that for words or boundaries suggests that much of the improvement rests on rare words.

These effects are small but significant. For word token performance, we performed a paired *t*-test on utterance token F-scores between the with- and without-stress models. This difference was significant ($t = 11.28, df = 8125, p < .001$). We performed a similar utterance-by-utterance test on boundaries; again a small significant improvement was found ($t = 8.92, df = 6084, p < .001$). To assess lexicon performance, we calculated for each word type in the gold-standard lexicon the proportion of the five trials in which that word appeared in the learned lexicon for the two models. We then examined the words where the proportions differed between the models. 89 true words appeared more often in the with-stress lexicons; 40 appeared more often in the without-stress lexicons. (683 appeared equally often in both.) By a sign test, this is significant at $p < .001$. We also tested lexicon performance with a binomial test on the two models' lexicon accuracy; this result was marginal ($p = .06$).

The explicit tracking of stress information also improves the model's acquisition of the stress bias of the language. Acquisition of the stress bias is potentially useful for generalization; stress patterns can be used for an initial segmentation if few or none of the words are familiar. In practice, we see children use

⁶Recall that due to the syllabified data, these results are not directly comparable to unsyllabified results in previous work.

their stress biases to segment new words from English speech (Jusczyk, Houston, & Newsome, 1999) as well as artificial languages (Thiessen & Saffran, 2003).

We assess the learned stress bias by dividing up the corpus as the model has segmented it, and count the number of tokens with SW versus WS stress patterns.⁷ With stress representation, the learned stress bias is 6.77:1, and without stress representation, the stress bias is lower, at 6.33:1. Although these are both underestimates of the corpus's true stress bias (7.86:1), the stressed model is stronger and a better estimate of the true value.

The model's performance can be compared to various baselines, but perhaps the strongest is one with every syllable boundary being a word boundary. This baseline represents a shift from boundary *precision* being at ceiling (as in the model) to boundary *recall* being at ceiling. In fact, due to the preponderance of monosyllabic words in English child-directed speech, this baseline outperforms the model on word and boundary F-scores (.68 and .82 in the model, .82 and .91 in the baseline). However, the baseline's lexicon is much worse than the model's (F=.80 in the with-stress model, F=.64 in the baseline), and the baseline fails to learn anything about the language's stress biases. In addition, the baseline oversegments, whereas both the model and infant segmenters undersegment (Peters, 1983). This raises an important question about what the model should seek to optimize: though the baseline is more accurate by token, no structure is learned; type performance is more important if we want to learn the underlying structure.

5.3 Are isolated words necessary?

We next use this model to test the necessity of isolated words in rational word segmentation. It is not immediately obvious how human learners begin to segment words from fluid speech. Stress biases and other phonological cues are dominant in all but the earliest of infant word segmentation (Johnson & Jusczyk, 2001). This raises a chicken-and-egg problem; if the cues infants favor to segment words, such as stress biases, are dependent on the words of the

⁷Note this defines a stress bias for the stressless model as well.

language, how do they learn enough words to determine the cues' biases?

One existing proposal is that human learners develop their stress biases based on words frequently heard in isolation (Jusczyk et al., 1999). In English, these include names and common diminutives (e.g., *mommy*, *kitty*) that generally have initial stress. These single-word utterances could offer the segmenter an initial guess of the stress bias, by supposing that short utterances are single words and recording their stress patterns. The most common stress patterns in short utterances could then be used as an initial guess at the stress bias to bootstrap other words and thereby improve the learned stress bias.

We test the rational learner's need for such explicit bootstrapping by learning to segment a corpus with all single-word utterances removed. The corpus is produced by excising all single-word utterances from the Korman corpus. This results in a 22081-word corpus, 10% fewer tokens than in the original. However, it does not substantially change the lexicon; the number of distinct word types only drops from 811 to 806.

We compare performance only on ambiguous boundaries and lexicon, as these are comparable between the corpora, and find that the model performs almost equally well. Without single-word utterances, boundary and lexical F-scores are .81 and .80, compared to .82 and .80 with single-word utterances. This shows that rational learners are able to segment even without the possibility of bootstrapping stress patterns from single-word utterances.

5.4 Bounded rationality in human segmentation

Lastly, we use this model to examine rational performance in a multiple-cue segmentation task. We show that humans' segmentation does not adhere to these predictions, suggesting a bound on human rationality in word segmentation.

We consider an artificial language study by Thiessen and Saffran (2003). In this study, infants are exposed to an artificial language consisting of four bisyllabic word types uttered repeatedly without pauses. Each syllable appears in only one word type, so within-word transition probabilities are always 1, while across-word transition probabilities are less than 0.5. Segmentation strategies that hy-

Table 3: Examples of segmenting an artificial language according to transition probabilities (top) or stress bias (bottom), when the true words have weak-strong stress. Vertical lines represent word boundaries. The top segmentation produces a smaller lexicon, but the bottom segmentation produces primarily words with the preferred stress pattern.

pothesize word boundaries at low transition probabilities or that seek to minimize the lexicon size will segment out the four word types as expected.

Segmentation in the experiment is complicated by the presence of stress in the artificial language. Depending on the condition, the words are either all strong-weak or all weak-strong. In the first condition, segmenting according to transition probabilities, lexicon size, or English stress bias favors the same segmentation. In the second condition, though, segmenting by the English stress bias to yield a lexicon of strong-weak words requires boundaries in the middle of the words. The segmenter must decide whether transition probabilities or preferred stress patterns are more important in segmentation. This situation is illustrated in Table 3, with a corpus consisting of two word types, *AB* and *CD*, each with weak-strong stress.

Thiessen and Saffran found that seven-month-old English-learning infants consistently segmented according to the transition probabilities, regardless of stress. However, nine-month-olds segmented according to the English stress bias, even if this meant going against the transition probabilities.

Intuitively, this could be rational behavior according to our model. A child's increasing age means more exposure to data, potentially leading the child to develop more confidence in the stress bias. As confidence in the stress bias increases, the cost of segmenting against it increases as well. A sufficiently strong stress preference could lead the segmenter to accept a large lexicon, all of whose words have the preferred stress pattern, over a small lexicon.

con, all of whose words have the dispreferred stress pattern.

To judge by the Korman corpus, English has a stress bias of approximately 7:1 in favor of SW bisyllabic stress over WS.⁸ If human segmentation behavior follows the rational model, the model should predict segmentation to favor strong-weak words over the transition probabilities when the stress bias is approximately this strong.

We test this rationality hypothesis with a smaller version of the Thiessen and Saffran artificial language, consisting of 48 tokens.⁹ In one version, all tokens have the preferred SW pattern, and in the other all tokens have the dispreferred WS pattern. We then adjust the P_S distribution such that $P_S(SW|M = 2) = b * P_S(WS|M = 2)$, where b is the bias ratio. We run the model otherwise the same as in the previous experiments, except with 10 runs instead of 5.

Contrary to this hypothesis, the model's segmentation with $b = 7$ was the same whether the true words were strong-weak or weak-strong. In all ten runs, transition probabilities dictated the segmentation. To switch to stress-based segmentation, the bias must be orders of magnitude greater than the English bias. Figure 1 shows the proportions of runs in the weak-strong condition that show segmentation according to the stress bias, as the bias increases by factors of 10. When $b = 10000$, three of the ten runs segmented according to the stress bias; below that, the stress bias did not affect the rational model's segmentation.

Why is this? In the Bayesian model, the stress bias of a language affects only the $P_S(s_i|M)$ term in the P_0 distribution, so non-novel words are not penalized for their stress pattern. The model pays only once to create a word; once the word is generated, no matter how a priori implausible the word was, it may be cheaply drawn again as a non-novel word. This effect can be illustrated with a brief calculation.

Consider a corpus built from four bisyllabic word types (AB, CD, EF, GH), each appearing N times. If

⁸The specific bias varies from corpus to corpus, but this appears to be a representative value.

⁹The 48 tokens come from four word types, with two types appearing 16 times and the other two appearing 8 times, mimicking the relative frequencies of Thiessen and Saffran's languages. Their test language had 270 tokens.

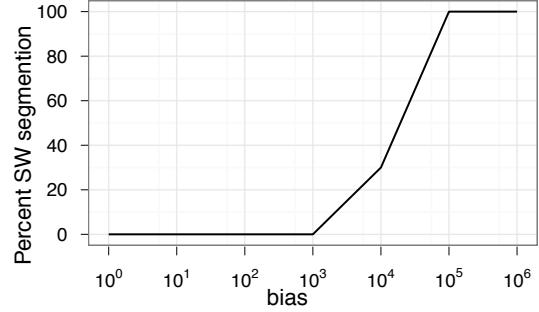

Figure 1: Percentage of runs segmented with the stress bias, against transition probabilities, as bias varies. At English-level biases, the rational model still overrules the stress bias when segmenting.

the corpus is segmented against the transition probabilities, the resulting lexicon will have 16 bisyllabic word types (BA, BC, BE, BG, DA, etc.), each occurring approximately $\frac{N}{4}$ times.

The probability of the against-bias corpus (C_{WS}) is proportional to the probability of generating the four word types, and then drawing them non-novelly from the lexicon.¹⁰ (To simplify the calculations, we use the unigram version of the Goldwater et al model.)

$$p(C_{WS}) \propto P_W^4 P_S(WS)^4 (N!)^4 \frac{1}{4N!} \quad (6)$$

The first two terms are the probability of generating the four word types (Eqn. 5);¹¹ the second two terms are the Dirichlet process draws from the existing lexicon N times each (Eqn. 2). By comparison, the probability of the with-bias corpus C_{SW} depends on generating the 16 word types, and drawing each non-novelly $\frac{N}{4}$ times.

$$p(C_{SW}) \propto P_W^{16} P_S(SW)^{16} \left(\frac{N}{4}!\right)^{16} \frac{1}{4N!} \quad (7)$$

Given an SW bias b and a uniform distribution over syllables (so $P_W = \frac{1}{64}$), we find:

$$\frac{p(C_{WS})}{p(C_{SW})} = 64^{12} \frac{(b+1)^{12}}{b^{16}} \frac{(N!)^4}{\left(\frac{N}{4}!\right)^{16}} \quad (8)$$

¹⁰It is also possible to generate this corpus by re-drawing the words novelly, but this is much less likely than non-novel draws.

¹¹Because all syllables have equal unigram probabilities, the probability of all words' phonemic forms are equal, and will be written as P_W .

This equation shows that the rational model is heavily biased toward the segmentation that fits the transition probabilities. Increasing the stress bias b or decreasing the number of observed word tokens makes the rational model more likely to segment with the stress bias (against transition probabilities), but as we see in the experimental results, the stress bias must be very strong to overcome the efficient lexicon that the transition probability segmentation provides.

Since humans do not show this same inherent bias (or quickly lose it as they acquire the stress bias), we can ask how humans deviate from rationality. One possibility is that humans simply do not segment in this Bayesian manner. However, previous work (Frank, Goldwater, Griffiths, & Tenenbaum, 2010) has shown that human word segmentation shows similar behavior to a resource-limited Bayesian model. Equation 8 suggests that human segmentation could deviate from rationality by having an effectively stronger bias than English would suggest (reducing the first fraction)¹² or, as with Phillips and Pearl's constrained learners, by having effectively less input than the model assumes (reducing the second fraction).

6 Future work

Introducing stress into the Bayesian segmentation model suggests a few additional expansions. One possibility is to add other cues into the generative model via P_0 . Any cue that is based on the word itself can be added in this way, with little change to the general model structure. Phonotactics can be added using an n-gram distribution for P_0 (Blanchard & Heinz, 2008). Coarticulation between adjacent phonemes is also used in human segmentation (Johnson & Jusczyk, 2001), so the P_0 distribution could predict higher within-word coarticulation. Integrating additional cues used by human segmenters extends the investigation of the bounds on rationality in human segmentation and in balancing multiple conflicting cues.

¹²A potential source of an inflated bias is infants' preference for strong-weak patterns. Jusczyk, Cutler, and Redanz (1993) found English-hearing infants listened longer to strong-weak patterns than weak-strong. This could lead to overestimation of the stress bias by making possible strong-weak segmentations more prominent in the segmenter's mind.

A more complex view of the stress system of a language may also be useful. One possibility is to place a Dirichlet prior over the stress templates and allow P_S to be learned as a latent variable in the model. Another possibility is to treat the stress templates more generally; in the present implementation, knowledge of the preferred stress patterns for word of one length tells the segmenter nothing about preferred stress patterns in another length. Cross-linguistically common stress rules (e.g., those that place stress a certain number of syllables from the left or right edge of a word) can be coded into P_S to improve generalization. Each rule dictates a specific stress pattern for each word length. When a word is generated in the Dirichlet process, the generative model would decide whether to assign stress according to one of these rules or to assign lexical stress from a default multinomial distribution. (This "default" distribution would handle idiosyncratic stress assignments, as one might see with names or morphologically complex words, like Spanish reflexive verbs.) A sparse prior over these rules, asymmetrically weighted against the default category, will encourage the model to explain as much of the observed stress patterns as possible with a few dominant rules, improving the phonological structure that the segmenter learns.

Improving the realism of the data is also important. The corpora used in much of segmentation research are idealized representations of the true data, and the dictionary-based phoneme and stress patterns used in this study are no exception. This ideal setting may paint a skewed picture of the segmentation problem, by providing a more consistent and learnable data source than humans actually receive. Elsner, Goldwater, and Eisenstein (2012)'s model unifying lexical and phonetic acquisition takes a significant step in showing that a rational segmenter can handle noisy input by recognizing phonetic variants of a base form. In terms of stress representations, dictionary-based stress has been standard in previous work (Christiansen et al., 1998; Gambell & Yang, 2006; Rytting, Brew, & Fosler-Lussier, 2010), but it is important to confirm such results against a (currently nonexistent) corpus with stresses based on the actual utterances. Effective use of stress in a less idealized setting may require a more complex representation of stress in the model.

7 Conclusion

Effective word segmentation combines multiple factors to make predictions about word boundaries. We extended an existing Bayesian segmentation model to account for two factors, phonemes and stress, when segmenting. This improves segmentation performance and opens up new possibilities for comparing rational segmentation and human segmentation.

Training Parsers on Incompatible Treebanks

Richard Johansson

richard.johansson@gu.se

Abstract

We consider the problem of training a statistical parser in the situation when there are multiple treebanks available, and these treebanks are annotated according to different linguistic conventions. To address this problem, we present two simple adaptation methods: the first method is based on the idea of using a shared feature representation when parsing multiple treebanks, and the second method on guided parsing where the output of one parser provides features for a second one.

To evaluate and analyze the adaptation methods, we train parsers on treebank pairs in four languages: German, Swedish, Italian, and English. We see significant improvements for all eight treebanks when training on the full training sets. However, the clearest benefits are seen when we consider smaller training sets. Our experiments were carried out with unlabeled dependency parsers, but the methods can easily be generalized to other feature-based parsers.

1 Introduction

When developing a data-driven syntactic parser, we need to fit the parameters of its statistical model on a collection of syntactically annotated sentences – a *treebank*. Generally speaking, a larger collection of examples in the training treebank will give a higher quality of the resulting parser, but the cost in time and effort of annotating training sentences is fairly high. Most existing treebanks are in the range of a few thousand sentences.

However, there is an abundance of theoretical models of syntax and there is no consensus on how treebanks should be annotated. For some languages, there exist multiple treebanks annotated according

to different syntactic theories. Apart from German, Swedish, and Italian, which will be considered in this paper, there are important examples among the world’s major languages, such as Arabic and Chinese.

To exemplify how syntactic annotation conventions may differ in even such a simple case as unlabeled dependency annotation, consider the Italian sentence fragment *la sospensione o l’interruzione* (‘the suspension or the interruption’) in Figure 1. As we will see in detail in §3.1.3, there are two Italian treebanks: the ISST and TUT. If annotating as in the ISST treebank (drawn above the sentence) determiners (*la*, *l'*) are annotated as dependents of the following nouns (*sospensione*, *interruzione*); in TUT (drawn below the sentence), we have the reverse situation. There are also differences in how coordinate structures are represented: in ISST, the two conjuncts are directly conjoined and the conjunction attached to the first of them, while in TUT the conjunction acts as a link between the conjuncts.

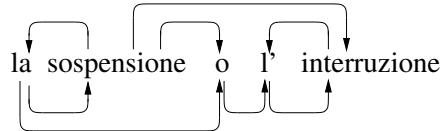

Figure 1: Differences in dependency annotation styles.

Given the high cost of treebank annotation and the importance of a proper amount of data for parser development, this situation is frustrating. How could we then make use of multiple treebanks when training a parser? A naïve way would be simply to concatenate them, but as we will see this results in a parser that performs badly on all the treebanks.

In this paper, we investigate two simple adaptation methods to bridge the gap between differing

syntactic annotation styles, allowing us to use more data for parser training. The first approach treats the problem of parsing with multiple syntactic annotation styles as a multiview learning problem and addresses it by using feature representation that is partly shared between the views. In the second one we use a parser trained on one treebank to guide a new parser trained on another treebank. We evaluate these methods as well as their combination on four languages: German, Swedish, Italian, and English. In all four languages, we see a similar picture: the shared features approach is generally better when one of the treebanks is very small, while the guided parsing approach is better when the treebanks are more similar in size. However, for most training set sizes the combination of the two methods achieves a higher performance than either of them individually.

2 Methods for Training Parsers on Multiple Treebanks

We now describe the two adaptation methods to leverage multiple treebanks for parser training. For clarity of presentation, we assume that there are two treebanks, although we can easily generalize to more. We use a common graph-based parsing technique (Carreras, 2007); the approaches described here could be used in transition-based parsing as well.

In a graph-based parser, for a given sentence x the task of finding the top-scoring parse \hat{y} is stated as an optimization problem of maximizing a linear objective function:

$$\hat{y} = \arg \max_y w \cdot f(x, y).$$

Here w is a weight vector produced by some learning algorithm and $f(x, y)$ a *feature representation* that maps the sentence x with a parse tree y to a high-dimensional vector; the adaptation methods presented in this work is implemented as modifications of the feature representation function f . Since the search space is too large to be enumerated, the maximization must be handled carefully, and how this is done determines the expressivity of the feature representation f . In the parser by Carreras (2007) the maximization is carried out by a dynamic

programming procedure relying on crucial independence assumptions to break down the search space into tractable parts. The factorization used in this approach allows f to express features extracted not only from single edges, as McDonald et al. (2005), but also from sibling and grandchild edges.

To understand the machine learning problem of training parsers on incompatible treebanks, we compare it to the related problem of domain adaptation: training a system for a target domain, using a large collection of training data from a source domain combined with a small labeled or large unlabeled set from the target domain. Some algorithms for domain adaptation rely on the assumption that the differences between source and target distributions P_s and P_t can be explained in terms of a *covariate shift*: $P_s(y|x) = P_t(y|x)$ for all x, y , but $P_s(x) \neq P_t(x)$ for some x . In our case, we have the reverse situation: the input distribution is at least in theory unchanged between the two treebanks, while the input–output relation (i.e. the treebank annotation style) is different. However, domain adaptation and cross-treebank training can be seen as instances of the more general problem of *multitask learning* (Caruana, 1997). Indeed, one of the simplest and most well-known approaches to domain adaptation (Daumé III, 2007), which will also be considered in this paper, should more correctly be seen as a trick to handle multitask learning with any machine learning algorithm. On the other hand, there is no point in trying to use domain adaptation methods assuming a covariate shift, e.g. instance weighting, or any method in which the target data is unlabeled (Blitzer et al., 2007; Ben-David et al., 2010).

2.1 Sharing Feature Representations

Our first adaptation method relies on the intuition that some properties of two treebanks are shared, while others are unique to each of them. For instance, as we have seen in Figure 1 the two Italian treebanks annotate coordination differently; on the other hand, these treebanks also annotate several other linguistic phenomena in the same way. This observation can then be used to devise a model where we train two parsers at the same time and use a feature representation that is partly shared between the two models, allowing the machine learning algorithm to automatically determine which properties

of the two datasets are common and which are different. The idea of using features that are shared between the source and target training sets is a slight generalization of a well-known method for supervised domain adaptation (Daumé III, 2007).

In practice, this is implemented as follows. Assume that originally a sentence x with a parse tree y was represented as $f_1(x, y)$ if it came from the first treebank, and $f_2(x, y)$ if from the second treebank. We then add a *shared feature representation* f_s to f_1 and f_2 , and embed them into a single feature space. The resulting feature vectors then become

$$f_1(x, y) \oplus \mathbf{0}_2 \oplus f_s(x, y) \quad (1)$$

for a sentence from the first treebank, and

$$\mathbf{0}_1 \oplus f_2(x, y) \oplus f_s(x, y) \quad (2)$$

for the second treebank. Here, $\mathbf{0}_1$ means an all-zero vector with the dimensionality of the feature space of f_1 , and \oplus is vector concatenation. Using this new representation, the two datasets are combined and a single model trained. The hope is then that the learning algorithm will store the information about the respective particularities in the weights for f_1 and f_2 , and about the commonalities in the weights for f_s . The result of this process is a symmetric parser that can handle both treebank formats: when we parse a sentence at test time, we just use the representation (1) if we want an output according to the first treebank and (2) for the second treebank.

In this work, f_1 , f_2 , and f_s are identical: all of them correspond to the feature set described by Carreras (2007). However, it is certainly imaginable that f_s could consist of specially tailored features that make generalization easier. In particular, using a generalized f_s would allow us to use this approach in more complex cases than considered here, for instance if the dependencies would be labeled with two different sets of grammatical function labels, or if one of the treebanks would use constituents rather than dependencies.

2.2 Using One Parser to Guide Another

The second method is inspired by work in parser combination, an idea that has been applied successfully several times and relies on the fact that different parsing methods have different strengths and

weaknesses (McDonald and Nivre, 2007), so that combining them may result in a better overall parsing accuracy. There are several ways to combine parsers; one of the simplest and most successful methods of parsing combination uses one parser as a *guide* for a second parser. This is normally implemented as a pipeline where the second parser extracts features based on the output of the first parser. Nivre and McDonald (2008) used this approach for combining a graph-based and a transition-based parser and achieved excellent results on test sets for several languages, and similar ideas were proposed by Martins et al. (2008).

We added guide features to the parser feature representation. However, the features by Nivre and McDonald (2008) are slightly too simple since they only describe whether two words are directly connected or not. That makes sense if the two parsers are trying to predict the same type of representation, but will not help us if there are systematic annotation differences between the two treebanks, for instance in whether to annotate a function word or a lexical word as the head. Instead, following work in semantic role labeling and similar areas, we use a generalized notion of syntactic relationship that we encode by determining a *path* between two nodes in a syntactic tree. We defined the function $\text{Path}(x, y)$ as a representation describing the steps required to traverse the parse tree from x to y , first the steps up from x to the common ancestor a and then down from a to y . Since we are working with unlabeled trees, the path can be represented as just two integers; to generalize to labeled dependency parsing, we could have used a full path representation as commonly used in dependency-based semantic role labeling (Johansson and Nugues, 2008).

We added the following path-based feature templates, assuming we have a potential head h with dependent d , a sibling dependent s and grandchild (dependent-of-dependent) g :

- $\text{POS}(h) + \text{POS}(d) + \text{Path}(h, d)$
- $\text{POS}(h) + \text{POS}(s) + \text{Path}(h, s)$
- $\text{POS}(h) + \text{POS}(d) + \text{POS}(s) + \text{Path}(h, s)$
- $\text{POS}(h) + \text{POS}(g) + \text{Path}(h, g)$
- $\text{POS}(h) + \text{POS}(d) + \text{POS}(g) + \text{Path}(h, g)$

To exemplify, consider again the example *la sospensione o l'interruzione* shown in Figure 1. As-

sume that we are parsing according to the ISST representation (drawn above the sentence) and we consider adding an edge with *sospensione* as head and *la* as dependent, and another parser following the TUT representation (below the sentence) has created an edge in the opposite direction. The first feature template above would then result in a feature NOUN+DET+(1,0), where (1,0) represents the path relationship between the two words in the TUT tree (one step up, no step down). Similarly, when the ISST parser adds the coordination edge between *sospensione* and *interruzione*, it can make use of the information that these two nouns are *indirectly* connected in the output by the TUT parser; this is represented as a path (1,3). This is an example of a situation where we have a systematic correspondence where a single edge in one representation corresponds to several edges in the other.

Like the multiview approach described above, this method is trivially adaptable to more complex situations such as labeled dependency parsers with differing label sets, or dependency/constituent parsing.

2.3 Combining Methods

The two adaptation methods are orthogonal and can easily be combined. When trying to improve the performance of a parser trained on the primary treebank T_1 by leveraging a supporting treebank T_2 , we then use T_2 in two different ways: first by training a guide parser, and secondly by concatenating it to T_1 using a shared feature representation.

3 Experiments

We carried out experiments to evaluate the cross-framework adaptation methods. The evaluations were carried out using the official CoNLL-X evaluation script using the default parameters. Since our parsers do not predict edge labels, we report unlabeled attachment scores in all tables and plots.

3.1 Treebanks Used in the Experiments

In our experiments, we used four languages: German, Swedish, Italian, and English. For each language, we had two treebanks. Our approaches currently require that the treebanks use the same tokenization conventions, so for Italian and Swedish we automatically retokenized the treebanks. We also made sure that the two treebanks for one language

used the same part-of-speech tag sets, by applying an automatic tagger when necessary.

3.1.1 German: Tiger and TüBa-D/Z

For German, there are two treebanks available: Tiger (Brants et al., 2002) and TüBa-D/Z (Telljohann et al., 2004). These treebanks are constituent treebanks, but dependency versions are available: TüBa-D/Z (version 7.0) includes the dependency version in the distribution, while for Tiger we used the version from CoNLL-X (Buchholz and Marsi, 2006). The constituent annotation styles in the two treebanks are radically different: Tiger uses a very flat structure with a minimal amount of intermediate nodes, while TüBa-D/Z uses a more elaborate structure including topological field information. However, the dependency versions are actually quite similar, at least with respect to attachment. The most common systematic difference we observed is in the annotation of coordination.

Both treebanks are large: for Tiger, the training set was 31,243 sentences and the test set 7,973 sentences, and for TüBa-D/Z 40,000 and 11,428 sentences respectively. We did not use the Tiger test set from the CoNLL-X shared task since it is very small. We applied the TreeTagger POS tagger (Schmid, 1994) to both treebanks, using the pre-trained German model.

3.1.2 Swedish: Talbanken05 and Syntag

As previously noted by Nivre (2002) *inter alia*, Swedish has a venerable tradition in treebanking: there are not only one but two treebanks which must be counted among the earliest efforts of that kind. The oldest one is the Talbanken or MAMBA treebank (Einarsson, 1976), which has later been reprocessed for modern use (Nilsson et al., 2005). The original annotation is a function-tagged constituent syntax without phrase labels, but the reprocessed release includes a version converted to dependency syntax. The dependency treebank was used in the CoNLL-X Shared Task (Buchholz and Marsi, 2006), and we used that version in this work.

The second treebank is called Syntag (Järborg, 1986). Similar to Talbanken, its representation uses function-tagged constituents but no phrase labels. We developed a conversion to dependency trees, which was straightforward since many constituents

have explicitly defined heads (Johansson, 2013).

The two treebank annotation styles have significant differences. Most prominently, the Syntag annotation is fairly semantically oriented in its treatment of function words such as prepositions and subordinating conjunctions: in Talbanken, a preposition is the head of a prepositional phrase, while in Syntag the head is the prepositional complement. There are also some domain differences: Talbanken consists of student essays and public information, while Syntag consists of news text.

To make the two treebanks compatible on the token level, we retokenized Syntag – which handles punctuation in an idiosyncratic way – and applied a POS tagger trained on the Stockholm–Umeå Corpus (Gustafson-Capkova and Hartmann, 2006) to both treebanks. For Talbanken, we used 7,362 sentences for training and set aside a new test set of 3,680 sentences since the CoNLL-X test set is too small for serious experimental purposes – only 389 sentences. For Syntag, we split the treebank into 3,524 sentences for training and 1,763 sentences for testing.

3.1.3 Italian: ISST and TUT

There are two Italian treebanks. The first is the Italian Syntactic–Semantic Treebank or ISST (Montemagni et al., 2003). Here, we used the version that was prepared (Montemagni and Simi, 2007) for the CoNLL-2007 Shared Task (Nivre et al., 2007).

The TUT treebank¹ is a more recent effort. This treebank is available in multiple constituent and dependency formats, and we have used the CoNLL-formatted dependency version in this work. The representation used in TUT is inspired by the Word Grammar theory (Hudson, 1984) and tends to be more surface-oriented than that of ISST. For instance, as pointed out above in the discussion of Figure 1, TUT differs from ISST in its treatment of determiner–noun constructions and coordination. It has been noted (Bosco and Lavelli, 2010; Bosco et al., 2010) that the TUT representation is easier to parse than the ISST representation.

We simplified the tokenization of both treebanks. In ISST, we split multiwords into separate tokens and reattached clitics to nonfinite verb forms. For instance, a single token *a-causa-di* was converted into

¹<http://www.di.unito.it/~tutreeb/>

three tokens *a*, *causa*, *di*, and the three tokens *trovarse-lo* into a single token *trovarselo*. In TUT, we applied the same conversions and also recomposed preposition–article and multiple-clitic contractions that had been split by the annotators, e.g. *della*, *glielo* etc.² After changing the tokenization, we applied the TreeTagger POS tagger (Schmid, 1994) to both treebanks, using the pre-trained Italian model with the Baroni tagset³.

After preprocessing the data, we created training and test sets. For ISST, the training set was 2,239 and the test set 1,120 sentences, while for TUT the training set was 1,906 and the test set 954 sentences.

3.1.4 English: Two Different Conversions of the Penn Treebank

For English, there is no significant dependency treebank so we followed most previous work in using dependency trees automatically derived from constituent trees in the large Penn Treebank WSJ corpus (Marcus et al., 1993). Due to the fact that there is a highly parametrizable constituent-to-dependency conversion tool available (Johansson and Nugues, 2007), we could create two dependency treebanks with very different annotation styles.

The first training set was created from sections 02–12 of the WSJ corpus. By default, the conversion tool outputs a treebank using the annotation style of the CoNLL-2008 Shared Task (Surdeanu et al., 2008); however we wanted to create a more surface-oriented style for this treebank, so we turned on options to make *wh*-words heads of relative clauses, and possessive markers heads of noun phrases. This corpus had 20,706 sentences, and will be referred to as WSJ Part 1 in the experimental section.

The second training treebank was built from sections 13–22. For this treebank, we inverted the value of most options in order to get a more semantically oriented treebank where content words are connected directly. In this treebank, we also used “Prague-style” annotation of coordination: the conjuncts are annotated as dependents of the conjunction. This set contained 20,826 sentences, and will

²It should be noted that these conversions also make sense from a practical NLP point of view, since a number of contractions are homonymic with other words.

³<http://sslmit.unibo.it/~baroni/collocazioni/itwac.tagset.txt>

be called WSJ Part 2.

We finally applied both conversion methods to sections 24 and 23 to create development and test sets. The development set contained 1,346 and the test set 2,416 sentences. We did not change the tokenization or part-of-speech tags of the WSJ corpora. Here, we should note that we have a slightly more synthetic and controlled experimental setting than for Swedish and German: the parsers are evaluated on the same test set, so we know that there is no difference in test set difficulty. We also know *a priori* that performance differences are not due to any significant differences in genre, since all texts come from the same source (the Wall Street Journal) and tend to focus on business-oriented news.

3.2 Baseline Parsing Performance

As a starting point, we trained parsers on all treebanks. In addition, we created a parser using a naïve adaptation method by combining the training sets for each language, and training parsers on those three sets. We then applied all three parsers for every language on both test sets for that language. The results for German, Swedish, Italian, and English are presented in Table 1.

Every parser performed well on the test set annotated in the same annotation style as its training set. As has been observed previously, surface-oriented styles are easier to parse than semantically oriented styles: The Talbanken and WSJ Part 1 parsers all achieve much higher performance on their respective test sets than the Syntag and WSJ Part 2 parsers. The better performance of the Talbanken parser is also partly explainable by the fact that its training set is more than twice as large as the Syntag training set. Similarly for German, we see slightly higher performance for TüBa-D/Z than for Tiger.

However, as can be expected every parser performed very poorly when applied to the test set using the annotation style it was not trained on. For Swedish and English, the accuracy figures are in the range of 50-60, while the figure are a bit less poor for German since the two treebanks are more similar. We also see, again unsurprisingly, that the naïve combination baseline performs poorly in all situations: we just get a “worst-of-both-worlds” parser that performs badly on both test sets.

	GERMAN	Acc. on Tiger	Acc. on TBDZ
Tiger	87.8	72.0	
TüBa-D/Z	71.8	89.4	
Tiger+TBDZ	77.7	87.7	
	SWEDISH	Acc. on ST	Acc. on TB
Syntag	81.4	52.6	
Talbanken	50.3	88.2	
Syntag+Talbanken	61.8	82.7	
	ITALIAN	Acc. on ISST	Acc. on TUT
ISST	81.1	57.4	
TUT	55.9	84.0	
ISST+TUT	73.9	71.6	
	ENGLISH	Acc. on WSJ 1	Acc. on WSJ 2
WSJ part 1	92.6	57.4	
WSJ part 2	57.4	89.5	
WSJ parts 1+2	75.3	72.1	

Table 1: Baseline performance figures.

3.3 Evaluation on the Full Training Sets

We trained new parsers using the shared features and guided parsing adaptation methods described in §2. Additionally, we trained parsers using both methods at the same time; we refer to these parsers as *combined*. Including the baseline parsers, this gave us 24 parsers to evaluate on their respective test sets.

The results for German are given in Table 2. Here, we see that all three adaptation methods give statistically significant⁴ improvements over the baseline when parsing the Tiger treebank. In particular, the combined method gives a strong 0.7-point improvement, a 6% error reduction. For TüBa-D/Z, the improvements are smaller, although still significant except for the guided parsing method.

Method	Acc. on Tiger	Acc. on TüBa-D/Z
Baseline	87.8	89.4
Shared	88.1	89.6
Guided	88.4	89.5
Combined	88.5	89.6

Table 2: Performance figures for the German adapted parsers. Results that are significantly different from the baseline performances are written in boldface.

⁴At the 95% level. The significance levels of differences were computed using permutation tests.

Method	Acc. on ST	Acc. on TB
Baseline	81.4	88.2
Shared	81.3	88.3
Guided	82.5	88.4
Combined	82.5	88.5

Table 3: Performance of the Swedish adapted parsers.

For Swedish, we have a similar story: we see stronger improvements in the weak parser. Since the Talbanken treebank is twice as large as the Syntag treebank and has a surface-oriented representation that is easier to parse, this parser is useful as a guide for the Syntag parser: the improvements of the guided and combined Syntag parsers are statistically significant. However, it is harder to improve the Talbanken parser, for which the baseline is much stronger. 3 shows the results for the Swedish parsers.

Method	Acc. on ISST	Acc. on TUT
Baseline	81.1	84.0
Shared	81.5	84.4
Guided	81.7	84.3
Combined	81.8	84.7

Table 4: Performance of the Italian adapted parsers.

When we turn to the English corpora, the adaptation methods again gave us a number of very large improvements. The results are shown in Table 5. The shared features and combined methods gave statistically significant improvements for the WSJ Part 1 parser, and the guided parsing method an improvement that is nearly significant. However the most dramatic change is the 1.2-point improvement of the WSJ Part 2 parser, given by the guided parsing and combined methods. It is possible that this result partly can be explained by the fact that this experiment is a bit cleaner: in particular, as outlined in §3.1.4, there are no domain differences.

Method	Acc. on WSJ 1	Acc. on WSJ 2
Baseline	92.6	89.5
Shared	92.8	89.5
Guided	92.8	90.7
Combined	92.9	90.7

Table 5: Performance of the English adapted parsers.

For WSJ Part 2, we analyzed the differences between the baseline and the best adapted parser.

While there were improvements for all POS tags, the most notable one was in the attachment of conjunctions, where we got an increase from 69% to 75% in attachment accuracy, an 18% relative error reduction. Here we saw a very clear benefit of guided parsing: since this treebank uses “Prague-style” coordination annotation (i.e. the conjunction governs the conjuncts), it is hard for the parser to handle valencies and selectional preferences when there is a conjunction involved. It has been noted (Nilsson et al., 2007) that this style of annotating coordination is hard to parse. Since the WSJ Part 1 parser uses a coordination style that is easier to parse, the WSJ Part 2 parser can rely on its judgment.

Although conclusions must be very tentative since we are testing on just four languages, we can make a few general observations.

- The largest improvements (absolute and relative) all happen in treebanks that are harder to parse. In particular, Syntag and WSJ Part 2 are harder to parse due to their representation, and to some extent this may be true for Tiger as well – its learning curve rises more slowly than for TüBa-D/Z. Of course, in some cases (in particular Syntag, but also Tiger) this may partly be explained by the training set being smaller, but not for WSJ Part 2. In these cases, the guided parsing method seems to be more effective.
- The languages where the shared features method gives significant improvement for both treebanks are German and Italian, where we do not have the situation that one treebank is much larger or much easier to parse.
- The combination of the two methods gave significant improvements in all eight cases, and had the highest performance in six cases.

3.4 The Effect of the Training Set Size

In order to better understand the differences between the adaptation methods, we analyzed the impact of training set size on the improvement given by the respective methods. Let us refer to the training treebank annotated according to the same style as the test set as the *primary treebank*, and the other one as the *supporting treebank*. We carried out the experiments in this section by varying the number of

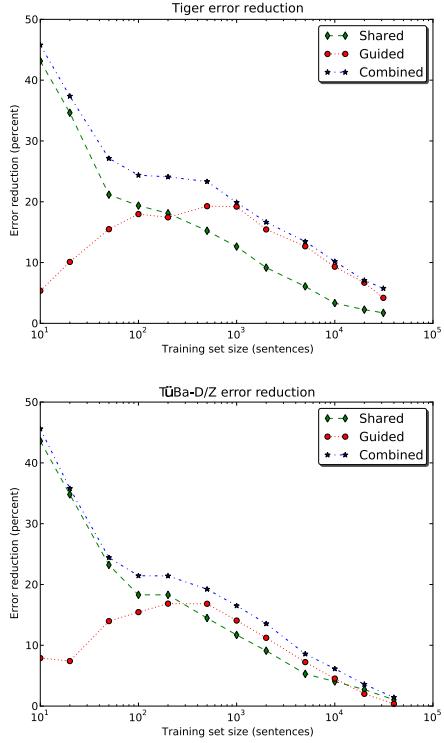

Figure 2: Error reduction by training set size, German.

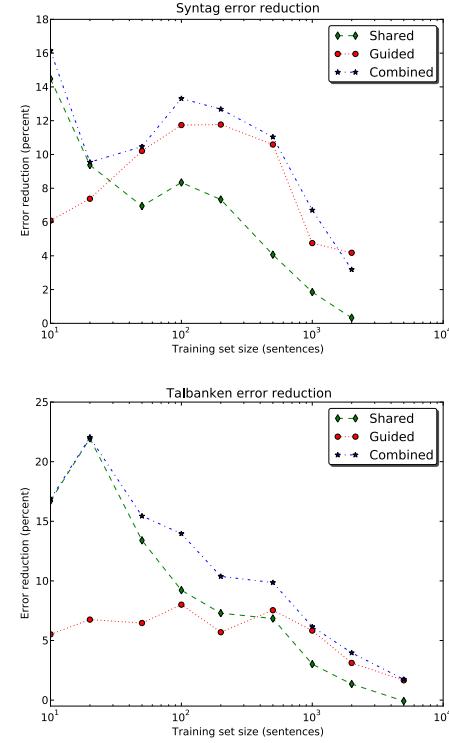

Figure 3: Error reduction by training set size, Swedish.

training sentences in the primary treebank and keeping the size of the supporting treebank constant.

In order to highlight the differences between the three adaptation methods, we show error reduction plots in Figures 2, 3, 4, and 5 for German, Swedish, Italian, and English respectively. For each training set size on the x axis, the plot shows the reduction in relative error with respect to the baseline.

We note that *every single one* of the 24 adapted parsers learns faster than the corresponding baseline parser. While we saw a number of significant improvements in §3.3 when using the full training sets, the relative improvements are much stronger when the training sets are small- and medium-sized.

These plots illustrate the different properties of the two methods. Using a shared feature representation tends to be very effective when the primary treebank is small: the error reductions are over 40 percent for German and over 25 percent for English. Guided parsing works best for mid-sized sets, and the relative effectiveness of both methods decreases as the size of the primary treebank increases. Again, we see that guided parsing is less effective if the guide uses an annotation style that is hard to parse.

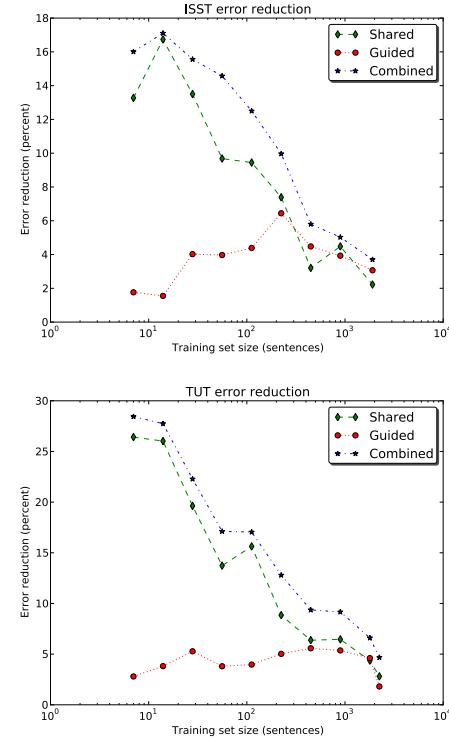

Figure 4: Error reduction by training set size, Italian.

In particular, for Swedish the Syntag parser never gives a very large improvement when guiding the Talbanken parser, and this is also true of both Italian parsers. To a smaller extent, this also holds for English and German: the WSJ Part 2 and Tiger parsers are less useful as guides than their counterparts.

The combination method generally performs very well: in all eight experiments, it outperforms the other two for almost every training set size. Its performance is very close to that of the guided parsing method for larger training sets, when the effect of the shared features method is less pronounced.

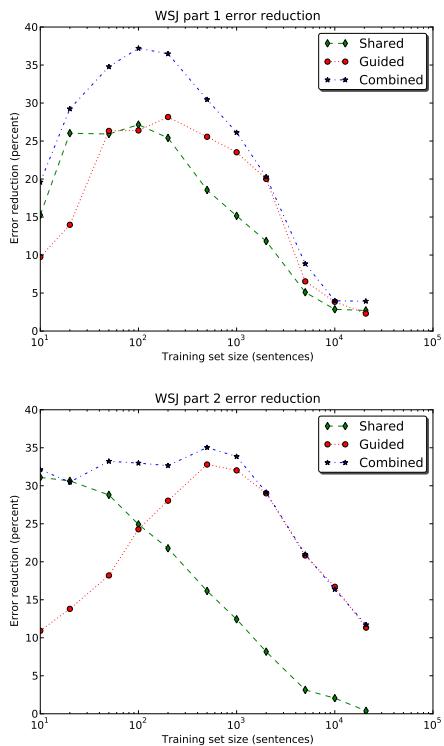

Figure 5: Error reduction by training set size, English.

4 Conclusion

We have considered the problem of training a dependency parser on incompatible treebanks, and we studied two very simple methods for addressing this problem, the shared features and guided parsing methods. These methods allow us to use more than one treebank when training dependency parsers. We evaluated the methods on eight treebanks in four languages, and had statistically significant improvements in all eight cases. In particular, for English

we saw a strong 1.2-point absolute improvement (an 11% relative error reduction) in the performance of a semantically oriented parser when trained on the full training set. For German, we also had very strong results for the Tiger treebank: a 6% error reduction. For Swedish, the parser trained on the small Syntag treebank got a boost from a guide parser trained on the larger Talbanken. In general, it seems to be easier to improve parsers that use representations that are harder to parse.

For all eight treebanks, both methods achieved large improvements for small training set sizes, while the effect gradually diminished as the training set size increased. The shared features method was the most effective for very small training sets, while guided parsing surpassed it when training sets got larger. The combination of the two methods was also effective, in most cases outperforming both methods on their own. In particular, when using the full training sets, this was the only method that had statistically significant improvements for all treebanks.

While this work used an unlabeled graph-based dependency parser, our methods generalize naturally to other parsing approaches, including transition-based dependency parsing. Labeled parsing with incompatible label sets is easy to implement in the shared features framework by removing the label information from the shared feature representation f_s , and similar modifications of f_s could be carried out to handle more complex situations such as combined constituent and dependency parsing. Furthermore, the paths used by the feature extractor in the guided parser can be extended without much effort as well. The models presented here are very simple, and in future work we would like to explore more complex approaches such as quasi-synchronous grammars (Smith and Eisner, 2009; Li et al., 2012) or automatic treebank transformation (Niu et al., 2009).

Abstract

Most work on weakly-supervised learning for part-of-speech taggers has been based on unrealistic assumptions about the amount and quality of training data. For this paper, we attempt to create true low-resource scenarios by allowing a linguist just two hours to annotate data and evaluating on the languages Kinyarwanda and Malagasy. Given these severely limited amounts of either type supervision (tag dictionaries) or token supervision (labeled sentences), we are able to dramatically improve the learning of a hidden Markov model through our method of automatically generalizing the annotations, reducing noise, and inducing word-tag frequency information.

1 Introduction

The high performance achieved by part-of-speech (POS) taggers trained on plentiful amounts of labeled word tokens is a success story of computational linguistics (Manning, 2011). However, research on learning taggers using type supervision (e.g. tag dictionaries or morphological transducers) has had a more checkered history. The setting is a seductive one: by labeling the possible parts-of-speech for high frequency words, one might learn accurate taggers by incorporating the type information as constraints to a semi-supervised generative learning model like a hidden Markov model (HMM). Early work showed much promise for this strategy (Kupiec, 1992; Merialdo, 1994), but successive efforts in recent years have continued to peel away and address layers of unrealistic assumptions about the

size, coverage, and quality of the tag dictionaries that had been used (Toutanova and Johnson, 2008; Ravi and Knight, 2009; Hasan and Ng, 2009; Garrette and Baldridge, 2012). This paper attempts to strip away further layers so we can build better intuitions about the effectiveness of type-supervised and token-supervised strategies in a realistic setting of POS-tagging for low-resource languages.

In most previous work, tag dictionaries are extracted from a corpus of annotated tokens. To explore the type-supervised scenario, these have been used as a proxy for dictionaries produced by linguists. However, this overstates their effectiveness. Researchers have often manually *pruned* tag dictionaries by removing low-frequency word/tag pairs; this violates the assumption that frequency information is not available. Others have also created tag dictionaries by extracting every word/tag pair in a large, labeled corpus, *including the test data*—even though actual applications would never have such complete lexical knowledge. Dictionaries extracted from corpora are also biased towards including only the most likely tag for each word type, resulting in a cleaner dictionary than one would find in real scenario. Finally, tag dictionaries extracted from annotated tokens benefit from the annotation process of labeling *and* review *and* refinement over an extended collaboration period. Such high quality annotations are simply not available for most low-resource languages.

This paper describes an approach to learning a POS-tagger that can be applied in a truly low-resource scenario. Specifically, we discuss techniques that allow us to learn a tagger given only

the amount of labeled data that a human annotator could provide in *two hours*. Here, we evaluate on the languages Malagasy and Kinyarwanda, as well as English as a control language. Furthermore, we are interested in whether type-supervision or token-supervision is more effective, given the strict time constraint; accordingly, we had annotators produce both a tag dictionary and a set of labeled sentences.

The data produced under our conditions differs in several ways from the labeled data used in previous work. Most obviously, there is less of it. Instead of using hundreds of thousands of labeled tokens to construct a tag dictionary (and hundreds of thousands more as unlabeled (raw) data for training), we only use the 1k-2k labeled tokens or types provided by our annotators within the timeframe. Our training data is also much noisier than the data from a typical corpus: the annotations were produced by a single non-native-speaker working alone for two hours. Therefore, dealing with the size and quality of training data were core challenges to our task.

To learn a POS-tagger from so little labeled data, we developed an approach that starts by generalizing the initial annotations to the entire raw corpus. Our approach uses label propagation (LP) (Talukdar and Crammer, 2009) to infer tag distributions on unlabeled tokens. We then apply a novel *weighted* variant of the model minimization procedure originally developed by Ravi and Knight (2009) to estimate sequence and word-tag frequency information from an unlabeled corpus by approximating the minimal set of tag bigrams needed to explain the data. This combination of techniques turns a tiny, unweighted, initial tag dictionary into a weighted tag dictionary that covers the entire corpus’s vocabulary. This weighted information limits the potential damage of tag dictionary noise and bootstraps frequency information to approximate a good starting point for the learning of an HMM using expectation-maximization (EM), and far outperforms just using EM on the raw annotations themselves.

2 Data

Our experiments use Kinyarwanda (KIN), Malagasy (MLG), and English (ENG). KIN is a Niger-Congo language spoken in Rwanda. MLG is an Austronesian language spoken in Madagascar. Both KIN and

MLG are low-resource and KIN is morphologically-rich. For each language, the word tokens are divided into four sets: training data to be labeled by annotators, raw training data, development data, and test data. For consistency, we use 100k raw tokens for each language.

Data sources For ENG, we used the Penn Treebank (PTB) (Marcus et al., 1993). Sections 00-04 were used as raw data, 05-14 as a dev set, and 15-24 (473K tokens) as a test set. The PTB uses 45 distinct POS tags. The KIN texts are transcripts of testimonies by survivors of the Rwandan genocide provided by the Kigali Genocide Memorial Center. The MLG texts are articles from the websites¹ *Lakroa* and *La Gazette* and Malagasy Global Voices,² a citizen journalism site.³ Texts in both KIN and MLG were tokenized and labeled with POS tags by two linguistics graduate students, each of which was studying one of the languages. The KIN and MLG data have 14 and 24 distinct POS tags, respectively, and were developed by the annotators.

Time-bounded annotation One of our main goals is to evaluate POS-tagging for low-resource languages in experiments that correspond better to a real-world scenario than previous work. As such, we collected two forms of annotation, each constrained by a two-hour time limit. The annotations were done by the same linguists who had annotated the KIN and MLG data mentioned above. Our experiments are thus relevant to the reasonable context in which one has access to a linguist who is familiar with the target language and a given set of POS tags.

The first annotation task was to directly produce a dictionary of words to their possible POS tags—i.e., collecting an actual tag dictionary of the form that is typically *simulated* in POS-tagging experiments. For each language, we compiled a list of word types, ordered starting with most frequent, and presented it to the annotator with a list of admissible POS tags. The annotator had two hours to specify POS tags for as many words as possible. The word types and frequencies used for this task were taken from the raw training data and did not include the test sets. This

¹www.lakroa.mg and www.lagazette-dgi.com

²mg.globalvoicesonline.org/

³The public-domain data is available at github.com/dhgarrette/low-resource-pos-tagging-2013

data is used for what will call *type-supervised* training. The second task was annotating full sentences with POS tags, again for two hours. We refer to this as *token-supervised* training.

Having both sets of annotations allows us to investigate the relative value of each with respect to training taggers. Token-supervision provides valuable frequency and tag context information, but type-supervision produces larger dictionaries. This can be seen in Table 1, where the dictionary size column in the table gives the number of unique word/tag pairs derived from the data.

We also wanted to directly compare the two annotators to see how the differences in their relative annotation speeds and quality would affect the overall ability to learn an accurate tagger. We thus had them complete the same two tasks for English. As can be seen in Table 1, there are clear differences between the two annotators. Most notably, annotator B was faster at annotating full sentences while annotator A was faster at annotating word types.

3 Approach

Our approach to learning POS-tagger is based on Garrette and Baldridge (2012), which properly separated test data from learning data, unlike much previous work. The input to our system is a raw corpus and either a human-generated tag dictionary or human-tagged sentences. The majority of the system is the same for both kinds of labeled training data, but the following description will point out differences. The system has four main parts, in order:

1. Tag dictionary expansion
2. Weighted model minimization
3. Expectation maximization (EM) HMM training
4. MaxEnt Markov Model (MEMM) training

3.1 Tag dictionary expansion

In a low-resource setting, most word types will not be found in the initial tag dictionary. EM-HMM training uses the tag dictionary to limit ambiguity, so a sparse tag dictionary is problematic because it does not sufficiently confine the parameter space.⁴ Small

⁴This is of course not the case for purely unsupervised taggers, though we also note that it is not at all clear they are actually learning taggers for part-of-speech.

	sent.	tok.	dict.

dictionaries also interact poorly with the model minimization of Ravi et al. (2010): if there are too many unknown words, and every tag must be considered for them, then the minimal model will simply be the one that assumes that they all have the same tag.

For these reasons, we automatically *expand* an initial small dictionary into one that has coverage for most of the vocabulary. We use label propagation (LP)—specifically, the Modified Adsorption (MAD) algorithm (Talukdar and Crammer, 2009)⁵—which is a graph-based technique for spreading labels between related items. Our graphs connect token nodes to each other via feature nodes and are seeded with POS-tag labels from the human-annotated data.

Defining the LP graph Our LP graph has several types of nodes, as shown in Figure 1. The graph contains a TOKEN node for each token of the labeled corpus (when available) and raw corpus. Each word type has one TYPE node that is connected to its TOKEN nodes. Both kinds of nodes are connected with *feature* nodes. The PREVWORD_x and NEXTWORD_x nodes represent the features of a token being preceded by or followed by word type x in the corpus. These *bigram* features capture extremely simple syntactic information. To capture shallow morphological relatedness, we use *prefix* and *suffix* nodes that connect word types that share prefix or suffix character sequences up to length 5. For each node-feature pair, the connecting edge is weighted as $1/N$ where N is the number of nodes connected to the particular feature.

⁵The open-source MAD implementation is provided through Junto: github.com/partthalukdar/junto

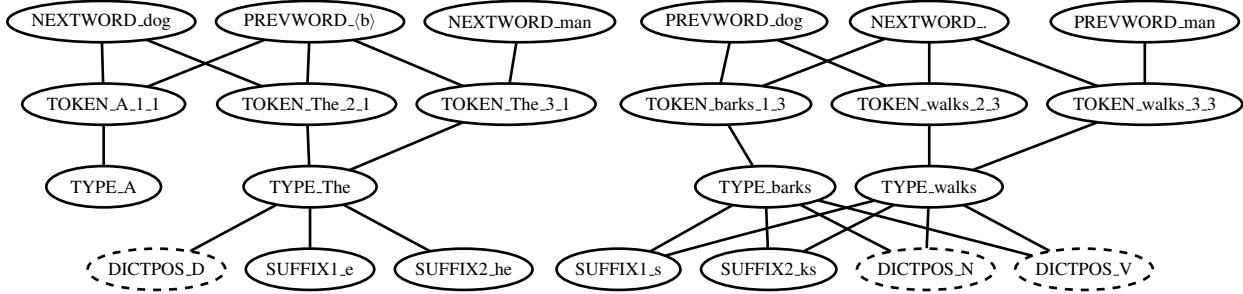

Figure 1: Subsets of the LP graph showing regions of connected nodes. Graph represents the sentences “A dog barks .”, “The dog walks .”, and “The man walks .”

We also explored the effectiveness of using an external dictionary in the graph since this is one of the few available sources of information for many low-resource languages. Though a standard dictionary probably will not use the same POS tag set that we are targeting, it nevertheless provides information about the relatedness of various word types. Thus, we use nodes `DICTPOS_p` that indicate that a particular word type is listed as having POS p in the dictionary. Crucially, *these tags bear no particular connection to the tags we are predicting*: we still target the tags defined by the linguist who annotated the types or tokens used, which may be more or less granular than those provided in the dictionary. As external dictionaries, we use English Wiktionary (614k entries), malagasyworld.org (78k entries), and kinyarwanda.net (3.7k entries).⁶

Seeding the graph is straightforward. With token-supervision, labels for tokens are injected into the corresponding `TOKEN` nodes with a weight of 1.0. In the type-supervised case, any `TYPE` node that appears in the tag dictionary is injected with a uniform distribution over the tags in its tag dictionary entry.

Toutanova and Johnson (2008) (also, Ravi and Knight (2009)) use a simple method for predicting possible tags for unknown words: a set of 100 most common suffixes are extracted and then models of $P(\text{tag}|\text{suffix})$ are built and applied to unknown words. However, these models suffer with an extremely small set of labeled data. Our method uses character affix feature nodes along with *sequence* feature nodes in the LP graph to get distributions over unknown words. Our technique thus subsumes

theirs as it can infer tag dictionary entries for words whose suffixes do not show up in the labeled data (or with enough frequency to be reliable predictors).

Extracting a result from LP LP assigns a label distribution to every node. Importantly, each individual `TOKEN` gets its own distribution instead of sharing an aggregation over the entire word type. From this graph, we extract a new version of the raw corpus that contains tags for each token. This provides the input for model minimization.

We seek a small set of likely tags for each token, but LP gives each token a distribution over the entire set of tags. Most of the tags are simply noise, some of which we remove by normalizing the weights and excluding tags with probability less than 0.1. After applying this cutoff, the weights of the remaining tags are re-normalized. We stress that this tag dictionary cutoff is not like those used in past research, which were done with respect to frequencies obtained from labeled tokens: we use either no word-tag frequency information (type-supervision) or very small amounts of word-tag frequency information indirectly through LP (token-supervision).⁷

Some tokens might not have any associated tag labels after LP. This occurs when there is no path from a `TOKEN` node to any seeded nodes or when all tags for the `TOKEN` node have weights less than the threshold. Since we require a distribution for every token, we use a default distribution for such cases. Specifically, we use the unsupervised emission probability initialization of Garrette and Baldridge (2012), which captures both the estimated *frequency* of a tag and its *openness* using only a

⁶Wiktionary (wiktionary.org) has only 3,365 entries for Malagasy and 9 for Kinyarwanda.

⁷See Banko and Moore (2004) for further discussion of these issues.

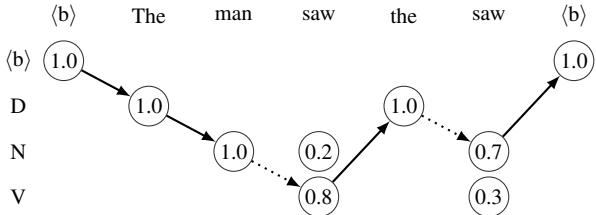

Figure 2: Weighted, greedy model minimization graph showing a potential state between the stages of the tag bigram choosing algorithm. Solid edges: selected bigrams. Dotted edges: holes in the path.

small tag dictionary and unlabeled text.

Finally, we ensure that tokens of words in the original tag dictionary are only assigned tags from its entry. With this filter, LP of course does not add new tags to known words (without it, we found performance drops). If the intersection of the small tag dictionary entry and the token’s resulting distribution from LP (after thresholding) is empty, we fall back to the filtered and renormalized *default* distribution for that token’s type.

The result of this process is a sequence of (initially raw) tokens, each associated with a distribution over a subset of tags. From this we can extract an *expanded* tag dictionary for use in subsequent stages that, crucially, provides tag information for words not covered by the human-supplied tag dictionary. This expansion is simple: an unknown word type’s set of tags is the union of all tags assigned to its tokens. Additionally, we add the full entries of word types given in the original tag dictionary.

3.2 Weighted model minimization

EM-HMM training depends crucially on having a clean tag dictionary and a good starting point for the emission distributions. Given only raw text and a tag dictionary, these distributions are difficult to estimate, especially in the presence of a very sparse or noisy tag dictionary. Ravi and Knight (2009) use model minimization to remove tag dictionary noise and induce tag frequency information from raw text. Their method works by finding a minimal set of tag bigrams needed to explain a raw corpus.

Model minimization is a natural fit for our system since we start with little or no frequency information and automatic dictionary expansion introduces

noise. We extend the greedy model minimization procedure of Ravi et al. (2010), and its enhancements by Garrette and Baldridge (2012), to develop a novel *weighted* minimization procedure that uses the tag weights from LP to find a minimal model that is biased toward keeping tag bigrams that have consistently high weights across the entire corpus. The new weighted minimization procedure fits well in our pipeline by allowing us to carry the tag distributions forward from LP instead of simply throwing that information away and using a traditional tag dictionary.

In brief, the procedure works by creating a graph such that each possible tag of each raw-corpus token is a vertex (see Figure 2). Any edge that would connect two tags of adjacent tokens is a potential tag bigram choice. The algorithm first selects tag bigrams until every token is covered by at least one bigram, then selects tag bigrams that fill gaps between existing edges until there is a complete bigram path for every sentence in the raw corpus.⁸

Ravi et al. (2010) select tag bigrams that cover the most new words (stage 1) or fill the most holes in the tag paths (stage 2). Garrette and Baldridge (2012) introduced the tie-breaking criterion that bigram choices should seek to introduce the smallest number of new *word/tag pairs* possible into the paths. Our criteria adds to this by using the tag weights on each token: a tag bigram b is chosen by summing up the node weights of any not-yet covered words touched by the tag bigram b , dividing this sum by one plus the number of *new* word/tag pairs that would be added by b , and choosing the b that maximizes this value.⁹

Summing node weights captures the intuition of Ravi et al. (2010) that good bigrams are those which have high coverage of new words: each newly covered node contributes additional (partial) counts. However, by using the weights instead of full counts, we also account for the confidence assigned by LP. Dividing by the number of new word/tag pairs added focuses on bigrams that reuse existing tags for words

⁸Ravi et al. (2010) include a third phase of iterative model fitting; however, we found this stage to be not only expensive, but also unhelpful because it frequently yields negative results.

⁹In the case of token-supervision, we pre-select all tag bigrams appearing in the labeled corpus since these are assumed to be known high-quality tag bigrams and word/tag pairs.

and thereby limits the addition of new tags for each word type.

At the start of model minimization, there are no selected tag bigrams, and thus no valid path through any sentence in the corpus. As bigrams are selected, we can begin to cover subsequences and eventually full sentences. There may be multiple valid taggings for a sentence, so after each new bigram is selected, we run the Viterbi algorithm over the raw corpus using the set of selected tag bigrams as a hard constraint on the allowable transitions. This efficiently identifies the highest-weight path through each sentence, if one exists. If such a path is found, we remove the sentence from the corpus and store the tags from the Viterbi tagging. The algorithm terminates when a path is found for every raw corpus sentence. The result of weighted model minimization is this set of tag paths. Since each path represents a valid tagging of the sentence, we use this output as a noisily labeled corpus for initializing EM in stage three.

3.3 Tagger training

Stage one provides an expansion of the initial labeled data and stage two turns that into a corpus of noisily labeled sentences. Stage three uses the EM algorithm initialized by the noisy labeling and constrained by the expanded tag dictionary to produce an HMM.¹⁰ The initial distributions are smoothed with one-count smoothing (Chen and Goodman, 1996). If human-tagged sentences are available as training data, then we use their counts to supplement the noisy labeled text for initialization and we add their counts into every iteration's result.

The HMM produced by stage three is not used directly for tagging since it will contain zero-probabilities for test-corpus words that were unseen during training. Instead, we use it to provide a Viterbi labeling of the raw corpus, following the “auto-supervision” step of Garrette and Baldridge (2012). This material is then concatenated with the token-supervised corpus (when available), and used to train a Maximum Entropy Markov Model tagger.¹¹ The MEMM exploits subword features and

¹⁰An added benefit of this strategy is that the EM algorithm with the expanded dictionary runs much more quickly than without it since it does not have to consider every possible tag for unknown words, averaging 20x faster on PTB experiments.

¹¹We use OpenNLP: opennlp.apache.org.

generally produces 1-2% better results than an HMM trained on the same material.

4 Experiments¹²

Experimental results are shown in Table 2. Each experiment starts with an initial data set provided by annotator A or B. Experiment (1) simply uses EM with the initial small tag dictionary to learn a tagger from the raw corpus. (2) uses LP to infer an expanded tag dictionary and tag distributions over raw corpus tokens, but then takes the highest-weighted tag from each token for use as noisily-labeled training data to initialize EM. (3) performs greedy model-minimization on the LP output to derive that noisily-labeled corpus. Finally, (4) is the same as (3), but additionally uses external dictionary nodes in the LP graph. In the case of token-supervision, we also include (0), in which we simply used the tagged sentences as supervised data for an HMM without EM (followed by MEMM training).

The results show that performance improves with our LP and minimization techniques compared to basic EM-HMM training. LP gives large across-the-board improvements over EM training with only the original tag dictionary (compare columns 1 & 2). Weighted model minimization further improves results for type-supervision settings, but not for token supervision (compare 2 & 3).

Using an external dictionary in the LP graph has little effect for KIN, probably due to the available dictionary's very small size. However, MLG with its larger dictionary obtains an improvement in both scenarios. Results on ENG are mixed; this may be because the PTB tagset has 45 tags (far more than the dictionary) so the external dictionary nodes in the LP graph may consequently serve to collapse distinctions (e.g. singular and plural) in the larger set.

Our results show differences between token- and type-supervised annotations. Tag dictionary expansion is helpful no matter what the annotations look like: in both cases, the initial dictionary is too small for effective EM learning, so expansion is necessary. However, model minimization only benefits the type-supervised scenarios, leaving token-supervised performance unchanged. This suggests

Table 2: Experimental results. Three languages are shown: Kinyarwanda (KIN), Malagasy (MLG), and English (ENG). The letters A and B refer to the annotator. LP(ed) refers to label propagation including nodes from an external dictionary. Each result given as percentages for Total (T), Known (K), and Unknown (U).

that minimization is working as intended: it induces frequency information when none is provided. With token-supervision, the annotator provides some information about which tag transitions are best and which emissions are most likely. This is missing with type-supervision, so model minimization is needed to bootstrap word/tag frequency guesses.

This leads to perhaps our most interesting result: in a time-critical annotation scenario, it seems better to collect a simple tag dictionary than tagged sentences. While the tagged sentences certainly contain useful information regarding tag frequencies, our techniques can learn this missing information automatically. Thus, having wider coverage of word type information, and having that information be focused on the most frequent words, is more important. This can be seen as a validation of the last two decades of work on (simulated) type-supervision learning for POS-tagging—with the caveat that the additional effort we do is needed to realize the benefit.

Our experiments also allow us to compare how the data from different annotators affects the quality of taggers learned. Looking at the direct comparison on English data, annotator B was able to tag more sentences than A, but A produced more tag dictionary entries in the type-supervision scenario. However, it appears, based on the EM-only training, that the annotations provided by B were of higher quality and produced more accurate taggers in both scenarios. Regardless, our full training procedure is able to substantially improve results in all scenarios.

Table 3 gives the recall and precision of the tag

Tag Dictionary Source	R	P
(1) human-annotated TD	18.42	29.33
(2) LP output	35.55	2.62
(3) model min output	30.49	4.63

Table 3: Recall (R) and precision (P) for tag dictionaries versus the test data in a “MLG types B” run.

dictionaries for MLG for settings 1, 2 and 3. The initial, human-provided tag dictionary unsurprisingly has the highest precision and lowest recall. LP expands that data to greatly improve recall with a large drop in precision. Minimization culls many entries and improves precision with a small relative loss in recall. Of course, this is only a rough indicator of the quality of the tag dictionaries since the word/tag pairs of the test set only partially overlap with the raw training data and annotations.

Because gold-standard annotations are available for the English sentences, we also ran *oracle* experiments using labels from the PTB corpus (essentially, the kind of data used in previous work). We selected the same amount of labeled tokens or word/tag pairs as were obtained by the annotators. We found similar patterns of improved performance by using LP expansion and model minimization, and all accuracies are improved compared to their human-annotator equivalents (about 2-6%). Overall accuracy for both type and token supervision comes to 78-80%.

#Errors	11k	6k	5k	4k	3k
Gold	TO	NNP	NN	JJ	NNP
Model	IN	NN	JJ	NN	JJ

Table 4: Top errors from an “ENG types B” run.

Error Analysis One potential source of errors comes directly from the annotators themselves. Though our approach is designed to be robust to annotation errors, it cannot correct all mistakes. For example, for the “ENG types B” experiment, the annotator listed IN (preposition) as the only tag for word type “to”. However, the test set only ever assigns tag TO for this type. This single error accounts for a 2.3% loss in overall tagging accuracy (Table 4).

In many situations, however, we are able to automatically remove improbable tag dictionary entries, as shown in Table 5. Consider the word type “for”. The annotator has listed RP (particle) as a potential tag, but only five out of 4k tokens have this tag. With RP included, EM becomes confused and labels a majority of the tokens as RP when nearly all should be labeled IN. We are able to eliminate RP as a possibility, giving excellent overall accuracy for the type. Likewise for the comma type, the annotator has incorrectly given “:” as a valid tag, and LP, which uses the tag dictionary, pushes this label to many tokens with high confidence. However, minimization is able to correct the problem.

Finally, the word type “opposition” provides an example of the expected behavior for unknown words. The type is not in the tag dictionary, so EM assumes all tags are valid and uses many labels. LP expands the starting dictionary to cover the type, limiting it to only two tags. Minimization then determines that NN is the best tag for each token.

5 Related work

Goldberg et al. (2008) trained a tagger for Hebrew using a manually-created lexicon which was not derived from an annotated corpus. However, their lexicon was constructed by trained lexicographers over a long period of time and achieves very high coverage of the language with very good quality. In contrast, our annotated data was created by untrained linguistics students working alone for just two hours.

tagger from existing linguistic resources, namely a dictionary and a reference grammar, but these resources are not available, much less digitized, for most under-studied languages.

Subramanya et al. (2010) apply LP to the problem of tagging for domain adaptation. They construct an LP graph that connects tokens in low- and high-resource domains, and propagate labels from high to low. This approach addresses the problem of learning appropriate tags for unknown words within a language, but it requires that the language have at least one high-resource domain as a source of high quality information. For low-resource languages that have no significant annotated resources available in *any* domain, this technique cannot be applied.

Das and Petrov (2011) and Täckström et al. (2013) learn taggers for languages in which there are no POS-annotated resources, but for which parallel texts are available between that language and a high-resource language. They project tag information from the high-resource language to the lower-resource language via alignments in the parallel text. However, large parallel corpora are not available for most low-resource languages. These are also expensive resources to create and would take considerably more effort to produce than the monolingual resources that our annotators were able to generate

in a two-hour timeframe. Of course, if they are available, such parallel text links could be incorporated into our approach.

Furthermore, their approaches require the use of a universal tag set shared between both languages. As such, their approach is only able to induce POS tags for the low-resource language if the same tag set is used to tag the high-resource language. Our approach does not rely on any such universal tag set; we learn whichever tags the human annotator chooses to use when they provide their annotations. In fact, in our experiments we learn much more detailed tag sets than the fairly coarse universal tag set used by Das and Petrov (2011) or Täckström et al. (2013): we learn a tagger for the full Penn Treebank tag set of 45 tags versus the 12 tags in the universal set.

Ding (2011) constructed an LP graph for learning POS tags on Chinese text by propagating labels from an initial tag dictionary to a larger set of data. This LP graph contained Wiktionary word/POS relationships as features as well as Chinese-English word alignment information and used it to directly estimate emission probabilities to initialize an EM training of an HMM.

Li et al. (2012) train an HMM using EM and an initial tag dictionary derived from Wiktionary. Like Das and Petrov (2011), they use a universal POS tag set, so Wiktionary can be directly applied as a wide-coverage tag dictionary in their case. Additionally, they evaluate their approach on languages for which Wiktionary has high coverage—which would certainly not get far with Kinyarwanda (9 entries). Our approach does not rely on a high-coverage tag dictionary nor is it restricted to use with a small tag set.

6 Conclusions and future work

With just two hours of annotation, we obtain 71-78% accuracy for POS-tagging across three languages using both type and token supervision. Without tag dictionary expansion and model minimization, performance is much worse, from 63-74%. We dramatically improve performance on unknown words: the range of 37-58% improves to 53-70%.

We also have a provisional answer to whether annotation should be on types or tokens: use type-supervision if you also expand and minimize. These

methods can identify missing word/tag entries and estimate frequency information, and they produce as good or better results compared to starting with token supervision. The case of Kinyarwanda was most dramatic: 71% accuracy for token-supervision compared to 79% for type-supervision. Studies using more annotators and across more languages would be necessary to make any stronger claim about the relative efficacy of the two strategies.

Abstract

Latent-variable PCFGs (L-PCFGs) are a highly successful model for natural language parsing. Recent work (Cohen et al., 2012) has introduced a spectral algorithm for parameter estimation of L-PCFGs, which—unlike the EM algorithm—is guaranteed to give consistent parameter estimates (it has PAC-style guarantees of sample complexity). This paper describes experiments using the spectral algorithm. We show that the algorithm provides models with the same accuracy as EM, but is an order of magnitude more efficient. We describe a number of key steps used to obtain this level of performance; these should be relevant to other work on the application of spectral learning algorithms. We view our results as strong empirical evidence for the viability of spectral methods as an alternative to EM.

1 Introduction

Latent-variable PCFGs (L-PCFGs) are a highly successful model for natural language parsing (Matuszaki et al., 2005; Petrov et al., 2006). Recent work (Cohen et al., 2012) has introduced a spectral learning algorithm for L-PCFGs. A crucial property of the algorithm is that it is guaranteed to provide consistent parameter estimates—in fact it has PAC-style guarantees of sample complexity.¹ This is in contrast to the EM algorithm, the usual method for parameter estimation in L-PCFGs, which has the weaker guarantee of reaching a local maximum of the likelihood function. The spectral algorithm is relatively simple and efficient, relying on a singular value decomposition of the training examples, followed by a single pass over the data where parameter values are calculated.

Cohen et al. (2012) describe the algorithm, and the theory behind it, but as yet no experimental results have been reported for the method. This paper

¹under assumptions on certain singular values in the model; see section 2.3.1.

describes experiments on natural language parsing using the spectral algorithm for parameter estimation. The algorithm provides models with slightly higher accuracy than EM (88.05% F-measure on test data for the spectral algorithm, vs 87.76% for EM), but is an order of magnitude more efficient (9h52m for training, compared to 187h12m, a speed-up of 19 times).

We describe a number of key steps in obtaining this level of performance. A simple backed-off smoothing method is used to estimate the large number of parameters in the model. The spectral algorithm requires functions mapping inside and outside trees to feature vectors—we make use of features corresponding to single level rules, and larger tree fragments composed of two or three levels of rules. We show that it is important to scale features by their inverse variance, in a manner that is closely related to methods used in canonical correlation analysis. Negative values can cause issues in spectral algorithms, but we describe a solution to these problems.

In recent work there has been a series of results in spectral learning algorithms for latent-variable models (Vempala and Wang, 2004; Hsu et al., 2009; Bailly et al., 2010; Siddiqi et al., 2010; Parikh et al., 2011; Balle et al., 2011; Arora et al., 2012; Dhillon et al., 2012; Anandkumar et al., 2012). Most of these results are theoretical (although see Luque et al. (2012) for empirical results of spectral learning for dependency parsing). While the focus of our experiments is on parsing, our findings should be relevant to the application of spectral methods to other latent-variable models. We view our results as strong empirical evidence for the viability of spectral methods as an alternative to EM.

2 Background

In this section we first give basic definitions for L-PCFGs, and then describe the spectral learning algorithm of Cohen et al. (2012).

2.1 L-PCFGs: Basic Definitions

We follow the definition in Cohen et al. (2012) of L-PCFGs. An L-PCFG is an 8-tuple $(\mathcal{N}, \mathcal{I}, \mathcal{P}, m, n, \pi, t, q)$ where:

- \mathcal{N} is the set of non-terminal symbols in the grammar. $\mathcal{I} \subset \mathcal{N}$ is a finite set of *in-terminals*. $\mathcal{P} \subset \mathcal{N}$ is a finite set of *pre-terminals*. We assume that $\mathcal{N} = \mathcal{I} \cup \mathcal{P}$, and $\mathcal{I} \cap \mathcal{P} = \emptyset$. Hence we have partitioned the set of non-terminals into two subsets.
- $[m]$ is the set of possible hidden states.²
- $[n]$ is the set of possible words.
- For all $a \in \mathcal{I}$, $b, c \in \mathcal{N}$, $h_1, h_2, h_3 \in [m]$, we have a context-free rule $a(h_1) \rightarrow b(h_2) c(h_3)$. The rule has an associated parameter $t(a \rightarrow b c, h_2, h_3 | a, h_1)$.
- For all $a \in \mathcal{P}$, $h \in [m]$, $x \in [n]$, we have a context-free rule $a(h) \rightarrow x$. The rule has an associated parameter $q(a \rightarrow x | a, h)$.
- For all $a \in \mathcal{I}$, $h \in [m]$, $\pi(a, h)$ is a parameter specifying the probability of $a(h)$ being at the root of a tree.

A *skeletal tree* (s-tree) is a sequence of rules $r_1 \dots r_N$ where each r_i is either of the form $a \rightarrow b c$ or $a \rightarrow x$. The rule sequence forms a top-down, left-most derivation under a CFG with skeletal rules.

A *full tree* consists of an s-tree $r_1 \dots r_N$, together with values $h_1 \dots h_N$. Each h_i is the value for the hidden variable for the left-hand-side of rule r_i . Each h_i can take any value in $[m]$.

For a given skeletal tree $r_1 \dots r_N$, define a_i to be the non-terminal on the left-hand-side of rule r_i . For any $i \in [N]$ such that r_i is of the form $a \rightarrow b c$, define $h_i^{(2)}$ and $h_i^{(3)}$ as the hidden state value of the left and right child respectively. The model then defines a probability mass function (PMF) as

$$p(r_1 \dots r_N, h_1 \dots h_N) = \pi(a_1, h_1) \prod_{i: a_i \in \mathcal{I}} t(r_i, h_i^{(2)}, h_i^{(3)} | a_i, h_i) \prod_{i: a_i \in \mathcal{P}} q(r_i | a_i, h_i)$$

The PMF over skeletal trees is $p(r_1 \dots r_N) = \sum_{h_1 \dots h_N} p(r_1 \dots r_N, h_1 \dots h_N)$.

²For any integer n , we use $[n]$ to denote the set $\{1, 2, \dots, n\}$.

The parsing problem is to take a sentence as input, and produce a skeletal tree as output. A standard method for parsing with L-PCFGs is as follows. First, for a given input sentence $x_1 \dots x_n$, for any triple (a, i, j) such that $a \in \mathcal{N}$ and $1 \leq i \leq j \leq n$, the marginal $\mu(a, i, j)$ is defined as

$$\mu(a, i, j) = \sum_{t: (a, i, j) \in t} p(t) \quad (1)$$

where the sum is over all skeletal trees t for $x_1 \dots x_n$ that include non-terminal a spanning words $x_i \dots x_j$. A variant of the inside-outside algorithm can be used to calculate marginals. Once marginals have been computed, Goodman's algorithm (Goodman, 1996) is used to find $\arg \max_t \sum_{(a, i, j) \in t} \mu(a, i, j)$.³

2.2 The Spectral Learning Algorithm

We now give a sketch of the spectral learning algorithm. The training data for the algorithm is a set of skeletal trees. The output from the algorithm is a set of parameter estimates for t, q and π (more precisely, the estimates are estimates of linearly transformed parameters; see Cohen et al. (2012) and section 2.3.1 for more details).

The algorithm takes two inputs in addition to the set of skeletal trees. The first is an integer m , specifying the number of latent state values in the model. Typically m is a relatively small number; in our experiments we test values such as $m = 8, 16$ or 32 . The second is a pair of functions ϕ and ψ , that respectively map *inside* and *outside trees* to feature vectors in \mathbb{R}^d and $\mathbb{R}^{d'}$, where d and d' are integers. Each non-terminal in a skeletal tree has an associated inside and outside tree. The inside tree for a node contains the entire subtree below that node; the outside tree contains everything in the tree excluding the inside tree. We will refer to the node above the inside tree that has been removed as the “foot” of the outside tree. See figure 1 for an example.

Section 3.1 gives definitions of $\phi(t)$ and $\psi(o)$ used in our experiments. The definitions of $\phi(t)$ and

³In fact, in our implementation we calculate marginals $\mu(a \rightarrow b c, i, k, j)$ for $a, b, c \in \mathcal{N}$ and $1 \leq i \leq k < j$, and $\mu(a, i, i)$ for $a \in \mathcal{N}$, $1 \leq i \leq n$, then apply the CKY algorithm to find the parse tree that maximizes the sum of the marginals. For simplicity of presentation we will refer to marginals of the form $\mu(a, i, j)$ in the remainder of this paper.

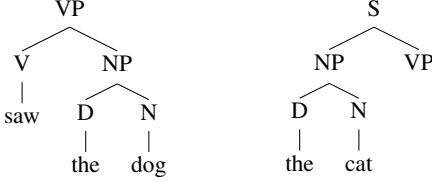

Figure 1: The inside tree (shown left) and outside tree (shown right) for the non-terminal VP in the parse tree $[S [NP [NP [D the] [N cat]] [VP [V saw] [NP [D the] [N dog]]]]]$

$\psi(o)$ are typically high-dimensional, sparse feature vectors, similar to those in log-linear models. For example ϕ might track the rule immediately below the root of the inside tree, or larger tree fragments; ψ might include similar features tracking rules or larger rule fragments above the relevant node.

The spectral learning algorithm proceeds in two steps. In step 1, we learn an m -dimensional representation of inside and outside trees, using the functions ϕ and ψ in combination with a projection step defined through singular value decomposition (SVD). In step 2, we derive parameter estimates directly from training examples.

2.2.1 Step 1: An SVD-Based Projection

For a given non-terminal $a \in \mathcal{N}$, each instance of a in the training data has an associated outside tree, and an associated inside tree. We define O^a to be the set of pairs of inside/outside trees seen with a in the training data: each member of O^a is a pair (o, t) where o is an outside tree, and t is an inside tree.

Step 1 of the algorithm is then as follows:

1. For each $a \in \mathcal{N}$ calculate $\hat{\Omega}^a \in \mathbb{R}^{d \times d'}$ as

$$[\hat{\Omega}^a]_{i,j} = \frac{1}{|O^a|} \sum_{(o,t) \in O^a} \phi_i(t) \psi_j(o)$$

2. Perform an SVD on $\hat{\Omega}^a$. Define $U^a \in \mathbb{R}^{d \times m}$ ($V^a \in \mathbb{R}^{d' \times m}$) to be a matrix containing the m left (right) singular vectors corresponding to the m largest singular values; define $\Sigma^a \in \mathbb{R}^{m \times m}$ to be the diagonal matrix with the m largest singular values on its diagonal.
3. For each inside tree in the corpus with root label a , define

$$Y(t) = (U^a)^\top \phi(t)$$

For each outside tree with a foot node labeled a , define

$$Z(o) = (\Sigma^a)^{-1} (V^a)^\top \psi(o)$$

Note that $Y(t)$ and $Z(o)$ are both m -dimensional vectors; thus we have used SVD to project inside and outside trees to m -dimensional vectors.

2.3 Step 2: Parameter Estimation

We now describe how the functions $Y(t)$ and $Z(o)$ are used in estimating parameters of the model. First, consider the $t(a \rightarrow b c, h_2, h_3 | a, h_1)$ parameters. Each instance of a given rule $a \rightarrow b c$ in the training corpus has an outside tree o associated with the parent labeled a , and inside trees t^2 and t^3 associated with the children labeled b and c . For any rule $a \rightarrow b c$ we define $Q^{a \rightarrow b c}$ to be the set of triples $(o, t^{(2)}, t^{(3)})$ occurring with that rule in the corpus. The parameter estimate is then

$$\hat{c}(a \rightarrow b c, j, k | a, i) = \frac{\text{count}(a \rightarrow b c)}{\text{count}(a)} \times E_{i,j,k}^{a \rightarrow b c} \quad (2)$$

where

$$E_{i,j,k}^{a \rightarrow b c} = \frac{\sum_{(o,t^{(2)},t^{(3)}) \in Q^{a \rightarrow b c}} Z_i(o) \times Y_j(t^{(2)}) \times Y_k(t^{(3)})}{|Q^{a \rightarrow b c}|}$$

Here we use $\text{count}(a \rightarrow b c)$ and $\text{count}(a)$ to refer to the count of the rule $a \rightarrow b c$ and the non-terminal a in the corpus. Note that once the SVD step has been used to compute representations $Y(t)$ and $Z(o)$ for each inside and outside tree in the corpus, calculating the parameter value $\hat{c}(a \rightarrow b c, j, k | a, i)$ is a very simple operation.

Similarly, for any rule $a \rightarrow x$, define $Q^{a \rightarrow x}$ to be the set of outside trees seen with that rule in the training corpus. The parameter estimate is then

$$\hat{c}(a \rightarrow x | a, i) = \frac{\text{count}(a \rightarrow x)}{\text{count}(a)} \times E_i^{a \rightarrow x} \quad (3)$$

$$\text{where } E_i^{a \rightarrow x} = \sum_{o \in Q^{a \rightarrow x}} Z_i(o) / |Q^{a \rightarrow x}|.$$

A similar method is used for estimating parameters $\hat{c}(a, i)$ that play the role of the π parameters (details omitted for brevity; see Cohen et al. (2012)).

2.3.1 Guarantees for the Algorithm

Once the $\hat{c}(a \rightarrow b c, j, k | a, i)$, $\hat{c}(a \rightarrow x | a, i)$ and $\hat{c}(a, i)$ parameters have been estimated from the

training corpus, they can be used in place of the t , q and π parameters in the inside-outside algorithm for computing marginals (see Eq. 1). Call the resulting marginals $\hat{\mu}(a, i, j)$. The guarantees for the parameter estimation method are as follows:

- Define $\Omega^a = \mathbf{E}[\phi(T)(\psi(O))^\top | A = a]$ where A, O, T are random variables corresponding to the non-terminal label at a node, the outside tree, and the inside tree (see Cohen et al. (2012) for a precise definition). Note that $\hat{\Omega}^a$, as defined above, is an estimate of Ω^a . Then if Ω^a has rank m , the marginals $\hat{\mu}$ will converge to the true values μ as the number of training examples goes to infinity, assuming that the training samples are i.i.d. samples from an L-PCFG.
- Define σ to be the m 'th largest singular value of Ω^a . Then the number of samples required for $\hat{\mu}$ to be ϵ -close to μ with probability at least $1 - \delta$ is polynomial in $1/\epsilon$, $1/\delta$, and $1/\sigma$.

Under the first assumption, (Cohen et al., 2012) show that the \hat{c} parameters converge to values that are linear transforms of the original parameters in the L-PCFG. For example, define $c(a \rightarrow b c, j, k | a, i)$ to be the value that $\hat{c}(a \rightarrow b c, j, k | a, i)$ converges to in the limit of infinite data. Then there exist invertible matrices $G^a \in \mathbb{R}^{m \times m}$ for all $a \in \mathcal{N}$ such that for any $a \rightarrow b c$, for any $h_1, h_2, h_3 \in \mathbb{R}^m$,

$$t(a \rightarrow b c, h_2, h_3 | a, h_1) = \sum_{i,j,k} [G^a]_{i,h_1} [(G^b)^{-1}]_{j,h_2} [(G^c)^{-1}]_{k,h_3} c(a \rightarrow b c, j, k | a, i)$$

The transforms defined by the G^a matrices are benign, in that they cancel in the inside-outside algorithm when marginals $\mu(a, i, j)$ are calculated. Similar relationships hold for the π and q parameters.

3 Implementation of the Algorithm

Cohen et al. (2012) introduced the spectral learning algorithm, but did not perform experiments, leaving several choices open in how the algorithm is implemented in practice. This section describes a number of key choices made in our implementation of the algorithm. In brief, they are as follows:

The choice of functions ϕ and ψ . We will describe basic features used in ϕ and ψ (single-level rules, larger tree fragments, etc.). We will also describe a method for scaling different features in ϕ and ψ by their variance, which turns out to be important for empirical results.

Estimation of $E_{i,j,k}^{a \rightarrow b c}$ and $E_i^{a \rightarrow x}$. There are a very large number of parameters in the model, leading to challenges in estimation. The estimates in Eqs. 2 and 3 are unsmoothed. We describe a simple backed-off smoothing method that leads to significant improvements in performance of the method.

Handling positive and negative values. As defined, the \hat{c} parameters may be positive or negative; as a result, the $\hat{\mu}$ values may also be positive or negative. We find that negative values can be a significant problem if not handled correctly; but with a very simple fix to the algorithm, it performs well.

We now turn to these three issues in more detail. Section 4 will describe experiments measuring the impact of the different choices.

3.1 The Choice of Functions ϕ and ψ

Cohen et al. (2012) show that the choice of feature definitions ϕ and ψ is crucial in two respects. First, for all non-terminals $a \in \mathcal{N}$, the matrix Ω^a must be of rank m : otherwise the parameter-estimation algorithm will not be consistent. Second, the number of samples required for learning is polynomial in $1/\sigma$, where $\sigma = \min_{a \in \mathcal{N}} \sigma_m(\Omega^a)$, and $\sigma_m(\Omega^a)$ is the m 'th smallest singular value of Ω^a . (Note that the second condition is stronger than the first; $\sigma > 0$ implies that Ω^a is of rank m for all a .) The choice of ϕ and ψ has a direct impact on the value for σ : roughly speaking, the value for σ can be thought of as a measure of how informative the functions ϕ and ψ are about the hidden state values.

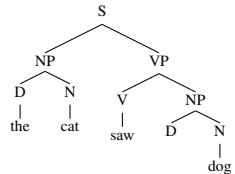

With this in mind, our goal is to define a relatively simple set of features, which nevertheless provide significant information about hidden-state values, and hence provide high accuracy under the model. The inside-tree feature function $\phi(t)$ makes use of the following indicator features (throughout these definitions assume that $a \rightarrow b c$ is at the root of the inside tree t):

- The pair of nonterminals (a, b) . E.g., for the inside tree in figure 1 this would be the pair (VP, V) .

- The pair (a, c) . E.g., (VP, NP) .
- The rule $a \rightarrow b c$. E.g., $VP \rightarrow V NP$.
- The rule $a \rightarrow b c$ paired with the rule at the root of $t^{(i,2)}$. E.g., for the inside tree in figure 1 this would correspond to the tree fragment $(VP (V saw) NP)$.
- The rule $a \rightarrow b c$ paired with the rule at the root of $t^{(i,3)}$. E.g., the tree fragment $(VP V (NP D N))$.
- The head part-of-speech of $t^{(i,1)}$ paired with a .⁴ E.g., the pair (VP, V) .
- The number of words dominated by $t^{(i,1)}$ paired with a (this is an integer valued feature).

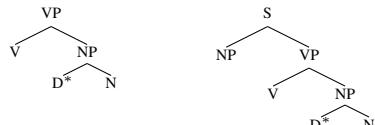

In the case of an inside tree consisting of a single rule $a \rightarrow x$ the feature vector simply indicates the identity of that rule.

To illustrate the function ψ , it will be useful to make use of the following example outside tree:

Note that in this example the foot node of the outside tree is labeled D. The features are as follows:

- The rule above the foot node. We take care to mark which non-terminal is the foot, using a * symbol. In the above example this feature is $NP \rightarrow D^* N$.
- The two-level and three-level rule fragments above the foot node. In the above example these features would be

- The label of the foot node, together with the label of its parent. In the above example this is (D, NP) .
- The label of the foot node, together with the label of its parent and grandparent. In the above example this is (D, NP, VP) .
- The part of speech of the first head word along the path from the foot of the outside tree to the root of the tree which is different from the head node of

⁴We use the English head rules from the Stanford parser (Klein and Manning, 2003).

the foot node. In the above example this is N.

- The width of the span to the left of the foot node, paired with the label of the foot node.
- The width of the span to the right of the foot node, paired with the label of the foot node.

Scaling of features. The features defined above are almost all binary valued features. We scale the features in the following way. For each feature $\phi_i(t)$, define $\text{count}(i)$ to be the number of times the feature is equal to 1, and M to be the number of training examples. The feature is then redefined to be

$$\phi_i(t) \times \sqrt{\frac{M}{\text{count}(i) + \kappa}}$$

where κ is a smoothing term (the method is relatively insensitive to the choice of κ ; we set $\kappa = 5$ in our experiments). A similar process is applied to the ψ features. The method has the effect of decreasing the importance of more frequent features in the SVD step of the algorithm.

The SVD-based step of the algorithm is very closely related to previous work on CCA (Hotelling, 1936; Hardoon et al., 2004; Kakade and Foster, 2009); and the scaling step is derived from previous work on CCA (Dhillon et al., 2011). In CCA the ϕ and ψ vectors are “whitened” in a preprocessing step, before an SVD is applied. This whitening process involves calculating covariance matrices $C_x = \mathbf{E}[\phi\phi^\top]$ and $C_y = \mathbf{E}[\psi\psi^\top]$, and replacing ϕ by $(C_x)^{-1/2}\phi$ and ψ by $(C_y)^{-1/2}\psi$. The exact calculation of $(C_x)^{-1/2}$ and $(C_y)^{-1/2}$ is challenging in high dimensions, however, as these matrices will not be sparse; the transformation described above can be considered an approximation where off-diagonal members of C_x and C_y are set to zero. We will see that empirically this scaling gives much improved accuracy.

3.2 Estimation of $E_{i,j,k}^{a \rightarrow b c}$ and $E_i^{a \rightarrow x}$

The number of $E_{i,j,k}^{a \rightarrow b c}$ parameters is very large, and the estimation method described in Eqs. 2–3 is unsmoothed. We have found significant improvements in performance using a relatively simple back-off smoothing method. The intuition behind this method is as follows: given two random variables X and Y , under the assumption that the random variables are independent, $\mathbf{E}[XY] = \mathbf{E}[X] \times \mathbf{E}[Y]$. It

makes sense to define ‘‘backed off’’ estimates which make increasingly strong independence assumptions of this form.

Smoothing of binary rules For any rule $a \rightarrow b c$ and indices $i, j \in [m]$ we can define a second-order moment as follows:

$$E_{i,j,\cdot}^{a \rightarrow b c} = \frac{\sum_{(o,t^{(2)},t^{(3)})} Z_i(o) \times Y_j(t^{(2)})}{\sum_{\in Q^{a \rightarrow b c}} |Q^{a \rightarrow b c}|}$$

The definitions of $E_{i,\cdot,k}^{a \rightarrow b c}$ and $E_{\cdot,j,k}^{a \rightarrow b c}$ are analogous. We can define a first-order estimate as follows:

$$E_{\cdot,\cdot,k}^{a \rightarrow b c} = \frac{\sum_{(o,t^{(2)},t^{(3)})} Y_k(t^{(3)})}{\sum_{\in Q^{a \rightarrow b c}} |Q^{a \rightarrow b c}|}$$

Again, we have analogous definitions of $E_{i,\cdot,\cdot}^{a \rightarrow b c}$ and $E_{\cdot,j,\cdot}^{a \rightarrow b c}$. Different levels of smoothed estimate can be derived from these different terms. The first is

$$E_{i,j,k}^{2,a \rightarrow b c} = \frac{E_{i,j,\cdot}^{a \rightarrow b c} \times E_{\cdot,\cdot,k}^{a \rightarrow b c} + E_{i,\cdot,k}^{a \rightarrow b c} \times E_{\cdot,j,\cdot}^{a \rightarrow b c} + E_{\cdot,j,k}^{a \rightarrow b c} \times E_{i,\cdot,\cdot}^{a \rightarrow b c}}{3}$$

Note that we give an equal weight of $1/3$ to each of the three backed-off estimates seen in the numerator. A second smoothed estimate is

$$E_{i,j,k}^{3,a \rightarrow b c} = E_{i,\cdot,\cdot}^{a \rightarrow b c} \times E_{\cdot,j,\cdot}^{a \rightarrow b c} \times E_{\cdot,\cdot,k}^{a \rightarrow b c}$$

Using the definition of O^a given in section 2.2.1, we also define

$$F_i^a = \frac{\sum_{(o,t) \in O^a} Y_i(t)}{|O^a|} \quad H_i^a = \frac{\sum_{(o,t) \in O^a} Z_i(o)}{|O^a|}$$

and our next smoothed estimate as $E_{i,j,k}^{4,a \rightarrow b c} = H_i^a \times F_j^b \times F_k^c$.

Our final estimate is

$$\lambda E_{i,j,k}^{a \rightarrow b c} + (1 - \lambda) (\lambda E_{i,j,k}^{2,a \rightarrow b c} + (1 - \lambda) K_{i,j,k}^{a \rightarrow b c})$$

where $K_{i,j,k}^{a \rightarrow b c} = \lambda E_{i,j,k}^{3,a \rightarrow b c} + (1 - \lambda) E_{i,j,k}^{4,a \rightarrow b c}$.

Here $\lambda \in [0, 1]$ is a smoothing parameter, set to $\sqrt{|Q^{a \rightarrow b c}|}/(C + \sqrt{|Q^{a \rightarrow b c}|})$ in our experiments, where C is a parameter that is chosen by optimization of accuracy on a held-out set of data.

Smoothing lexical rules We define a similar method for the $E_i^{a \rightarrow x}$ parameters. Define

$$E_i^a = \frac{\sum_{x'} \sum_{o \in Q^{a \rightarrow x'}} Z_i(o)}{\sum_{x'} |Q^{a \rightarrow x'}|}$$

hence E_i^a ignores the identity of x in making its estimate. The smoothed estimate is then defined as $\nu E_i^{a \rightarrow x} + (1 - \nu) E_i^a$. Here, ν is a value in $[0, 1]$ which is tuned on a development set. We only smooth lexical rules which appear in the data less than a fixed number of times. Unlike binary rules, for which the estimation depends on a high order moment (third moment), the lexical rules use first-order moments, and therefore it is not required to smooth rules with a relatively high count. The maximal count for this kind of smoothing is set using a development set.

3.3 Handling Positive and Negative Values

As described before, the parameter estimates may be positive or negative, and as a result the marginals computed by the algorithm may in some cases themselves be negative. In early experiments we found this to be a significant problem, with some parses having a very large number of negatives, and being extremely poor in quality. Our fix is to define the output of the parser to be $\arg \max_t \sum_{(a,i,j) \in t} |\mu(a, i, j)|$ rather than $\arg \max_t \sum_{(a,i,j) \in t} \mu(a, i, j)$ as defined in Goodman’s algorithm. Thus if a marginal value $\mu(a, i, j)$ is negative, we simply replace it with its absolute value. This step was derived after inspection of the parsing charts for bad parses, where we saw evidence that in these cases the entire set of marginal values had been negated (and hence decoding under Eq. 1 actually leads to the *lowest* probability parse being output under the model). We suspect that this is because in some cases a dominant parameter has had its sign flipped due to sampling error; more theoretical and empirical work is required in fully understanding this issue.

4 Experiments

In this section we describe parsing experiments using the L-PCFG estimation method. We give comparisons to the EM algorithm, considering both speed of training, and accuracy of the resulting model; we also give experiments investigating the various choices described in the previous section.

We use the Penn WSJ treebank (Marcus et al., 1993) for our experiments. Sections 2–21 were used as training data, and sections 0 and 22 were used as development data. Section 23 is used as the final test set. We binarize the trees in training data using the same method as that described in Petrov et al. (2006). For example, the non-binary rule $VP \rightarrow V\ NP\ PP\ SBAR$ would be converted to the structure $[VP\ [\text{@VP}\ [\text{@VP}\ V\ NP]\ PP]\ SBAR]$ where @VP is a new symbol in the grammar. Unary rules are removed by collapsing non-terminal chains: for example the unary rule $S \rightarrow VP$ would be replaced by a single non-terminal $S|VP$.

For the EM algorithm we use the initialization method described in Matsuzaki et al. (2005). For efficiency, we use a coarse-to-fine algorithm for parsing with either the EM or spectral derived grammar: a PCFG without latent states is used to calculate marginals, and dynamic programming items are removed if their marginal probability is lower than some threshold (0.00005 in our experiments).

For simplicity the parser takes part-of-speech tagged sentences as input. We use automatically tagged data from Turbo Tagger (Martins et al., 2010). The tagger is used to tag both the development data and the test data. The tagger was re-trained on sections 2–21. We use the F_1 measure according to the Parseval metric (Black et al., 1991). For the spectral algorithm, we tuned the smoothing parameters using section 0 of the treebank.

4.1 Comparison to EM: Accuracy

We compare models trained using EM and the spectral algorithm using values for m in $\{8, 16, 24, 32\}$.⁵

For EM, we found that it was important to use development data to choose the number of iterations of training. We train the models for 100 iterations, then test accuracy of the model on section 22 (development data) at different iteration numbers. Table 1 shows that a peak level of accuracy is reached for all values of m , other than $m = 8$, at iteration 20–30, with sometimes substantial overtraining beyond that point.

The performance of a regular PCFG model, estimated using maximum likelihood and with no latent

	section 22		section 23	
	EM	spectral	EM	spectral
$m = 8$	86.87	85.60	—	—
$m = 16$	88.32	87.77	—	—
$m = 24$	88.35	88.53	—	—
$m = 32$	88.56	88.82	87.76	88.05

Table 2: Results on the development data (section 22, with machine-generated POS tags) and test data (section 23, with machine-generated POS tags).

states, is 68.62%.

Table 2 gives results for the EM-trained models and spectral-trained models. The spectral models give very similar accuracy to the EM-trained model on the test set. Results on the development set with varying m show that the EM-based models perform better for $m = 8$, but that the spectral algorithm quickly catches up as m increases.

4.2 Comparison to EM: Training Speed

Table 3 gives training times for the EM algorithm and the spectral algorithm for $m \in \{8, 16, 24, 32\}$. All timing experiments were done on a single Intel Xeon 2.67GHz CPU. The implementations for the EM algorithm and the spectral algorithm were written in Java. The spectral algorithm also made use of Matlab for several matrix calculations such as the SVD calculation.

For EM we show the time to train a single iteration, and also the time to train the optimal model (time for 30 iterations of training for $m = 8, 16, 24$, and time for 20 iterations for $m = 32$). Note that this latter time is optimistic, as it assumes an oracle specifying exactly when it is possible to terminate EM training with no loss in performance. The spectral method is considerably faster than EM: for example, for $m = 32$ the time for training the spectral model is just under 10 hours, compared to 187 hours for EM, a factor of almost 19 times faster.⁶

The reason for these speed ups is as follows. Step 1 of the spectral algorithm (feature calculation, transfer + scaling, and SVD) is not required by EM, but takes a relatively small amount of time (about 1.2 hours for all values of m). Once step 1 has been completed, step 2 of the spectral algorithm takes a

⁵Lower values of m , such as 2 or 4, lead to substantially lower performance for both models.

⁶In practice, in order to overcome the speed issue with EM training, we parallelized the E-step on multiple cores. The spectral algorithm can be similarly parallelized, computing statistics and parameters for each nonterminal separately.

	10	20	30	40	50	60	70	80	90	100
$m = 8$	83.51	86.45	86.68	86.69	86.63	86.67	86.70	86.82	86.87	86.83
$m = 16$	85.18	87.94	88.32	88.21	88.10	87.86	87.70	87.46	87.34	87.24
$m = 24$	83.62	88.19	88.35	88.25	87.73	87.41	87.35	87.26	87.02	86.80
$m = 32$	83.23	88.56	88.52	87.82	87.06	86.47	86.38	85.85	85.75	85.57

Table 1: Results on section 22 for the EM algorithm, varying the number of iterations used. Best results in each row are in boldface.

	single EM iter.	EM best model	spectral algorithm					
			total	feature	transfer + scaling	SVD	$a \rightarrow b c$	$a \rightarrow x$
$m = 8$	6m	3h	3h32m			36m	1h34m	10m
$m = 16$	52m	26h6m	5h19m			34m	3h13m	19m
$m = 24$	3h7m	93h36m	7h15m	22m	49m	36m	4h54m	28m
$m = 32$	9h21m	187h12m	9h52m			35m	7h16m	41m

Table 3: Running time for the EM algorithm and the various stages in the spectral algorithm. For EM we show the time for a single iteration, and the time to train the optimal model (time for 30 iterations of training for $m = 8, 16, 24$, time for 20 iterations of training for $m = 32$). For the spectral method we show the following: “total” is the total training time; “feature” is the time to compute the ϕ and ψ vectors for all data points; “transfer + scaling” is time to transfer the data from Java to Matlab, combined with the time for scaling of the features; “SVD” is the time for the SVD computation; $a \rightarrow b c$ is the time to compute the $\hat{c}(a \rightarrow b c, h_2, h_3 | a, h_1)$ parameters; $a \rightarrow x$ is the time to compute the $\hat{c}(a \rightarrow x, h | a, h)$ parameters. Note that “feature” and “transfer + scaling” are the same step for all values of m , so we quote a single runtime for these steps.

single pass over the data: in contrast, EM requires a few tens of passes (certainly more than 10 passes, from the results in table 1). The computations performed by the spectral algorithm in its single pass are relatively cheap. In contrast to EM, the inside-outside algorithm is not required; however various operations such as calculating smoothing terms in the spectral method add some overhead. The net result is that for $m = 32$ the time for training the spectral method takes a very similar amount of time to a single pass of the EM algorithm.

4.3 Smoothing, Features, and Negatives

We now describe experiments demonstrating the impact of various components described in section 3.

The effect of smoothing (section 3.2) Without smoothing, results on section 22 are 85.05% ($m = 8, -1.82$), 86.84% ($m = 16, -1.48$), 86.47% ($m = 24, -1.88$), 86.47% ($m = 32, -2.09$) (in each case we show the decrease in performance from the results in table 2). Smoothing is clearly important.

Scaling of features (section 3.1) Without scaling of features, the accuracy on section 22 with $m = 32$

is 84.40%, a very significant drop from the 88.82% accuracy achieved with scaling.

Handling negative values (section 3.3) Replacing marginal values $\mu(a, i, j)$ with their absolute values is also important: without this step, accuracy on section 22 decreases to 80.61% ($m = 32$). 319 sentences out of 1700 examples have different parses when this step is implemented, implying that the problem with negative values described in section 3.3 occurs on around 18% of all sentences.

The effect of feature functions To test the effect of features on accuracy, we experimented with a simpler set of features than those described in section 3.1. This simple set just includes an indicator for the rule below a nonterminal (for inside trees) and the rule above a nonterminal (for outside trees). Even this simpler set of features achieves relatively high accuracy ($m = 8$: 86.44, $m = 16$: 86.86, $m = 24$: 87.24, $m = 32$: 88.07).

This set of features is reminiscent of a PCFG model where the nonterminals are augmented their parents (vertical Markovization of order 2) and binarization is done while retaining sibling information (horizontal Markovization of order 1). See Klein and Manning (2003) for more information. The per-

formance of this Markovized PCFG model lags behind the spectral model: it is 82.59%. This is probably due to the complexity of the grammar which causes overfitting. Condensing the sibling and parent information using latent states as done in the spectral model leads to better generalization.

It is important to note that the results for both EM and the spectral algorithm are comparable to state of the art, but there are other results previously reported in the literature which are higher. For example, Hiroyuki et al. (2012) report an accuracy of 92.4 F_1 on section 23 of the Penn WSJ treebank using a Bayesian tree substitution grammar; Charniak and Johnson (2005) report accuracy of 91.4 using a discriminative reranking model; Carreras et al. (2008) report 91.1 F_1 accuracy for a discriminative, perceptron-trained model; Petrov and Klein (2007) report an accuracy of 90.1 F_1 , using L-PCFGs, but with a split-merge training procedure. Collins (2003) reports an accuracy of 88.2 F_1 , which is comparable to the results in this paper.

5 Conclusion

The spectral learning algorithm gives the same level of accuracy as EM in our experiments, but has significantly faster training times. There are several areas for future work. There are a large number of parameters in the model, and we suspect that more sophisticated regularization methods than the smoothing method we have described may improve performance. Future work should also investigate other choices for the functions ϕ and ψ . There are natural ways to extend the approach to semi-supervised learning; for example the SVD step, where representations of outside and inside trees are learned, could be applied to unlabeled data parsed by a first-pass parser. Finally, the methods we have described should be applicable to spectral learning for other latent variable models.

Abstract

Topics generated automatically, e.g. using LDA, are now widely used in Computational Linguistics. Topics are normally represented as a set of keywords, often the n terms in a topic with the highest marginal probabilities. We introduce an alternative approach in which topics are represented using images. Candidate images for each topic are retrieved from the web by querying a search engine using the top n terms. The most suitable image is selected from this set using a graph-based algorithm which makes use of textual information from the metadata associated with each image and features extracted from the images themselves. We show that the proposed approach significantly outperforms several baselines and can provide images that are useful to represent a topic.

1 Introduction

Topic models are statistical methods for summarising the content of a document collection using latent variables known as topics (Hofmann, 1999; Blei et al., 2003). Within a model, each topic is a multinomial distribution over words in the collection while documents are represented as distributions over topics. Topic modelling is now widely used in Natural Language Processing (NLP) and has been applied to a range of tasks including word sense disambiguation (Boyd-Graber et al., 2007), multi-document summarisation (Haghghi and Vanderwende, 2009), information retrieval (Wei and Croft, 2006), image labelling (Feng and Lapata, 2010a) and visualisation of document collections (Chaney and Blei, 2012).

Topics are often represented by using the n terms with the highest marginal probabilities in the topic to generate a set of keywords. For example, *wine*, *bottle*, *grape*, *flavour*, *dry*. Interpreting such lists may not be straightforward, particularly since there may be no access to the source collection used to train the model. Therefore, researchers have recently begun developing automatic methods to generate meaningful and representative labels for topics. These techniques have focussed on the creation of textual labels (Mei et al., 2007; Lau et al., 2010; Lau et al., 2011).

An alternative approach is to represent a topic using an illustrative image (or set of images). Images have the advantage that they can be understood quickly and are language independent. This is particularly important for applications in which the topics are used to provide an overview of a collection with many topics being shown simultaneously (Chaney and Blei, 2012; Gretarsson et al., 2012; Hinneburg et al., 2012).

This paper explores the problem of selecting images to illustrate automatically generated topics. Our approach generates a set of candidate images for each topic by querying an image search engine with the top n topic terms. The most suitable image is selected using a graph-based method that makes use of both textual and visual information. Textual information is obtained from the metadata associated with each image while visual features are extracted from the images themselves. Our approach is evaluated using a data set created for this study that was annotated by crowdsourcing. Results of the evaluation show that the proposed method significantly

outperforms three baselines.

The contributions of this paper are as follows: (1) introduces the problem of labelling topics using images; (2) describes an approach to this problem that makes use of multimodal information to select images from a set of candidates; (3) introduces a data set to evaluate image labelling; and (4) evaluates the proposed approach using this data set.

2 Related work

In early research on topic modelling, labels were manually assigned to topics for convenient presentation of research results (Mei and Zhai, 2005; Teh et al., 2006).

The first attempt at automatically assigning labels to topics is described by Mei et al. (2007). In their approach, a set of candidate labels are extracted from a reference collection using chunking and statistically important bigrams. Then, a relevance scoring function is defined which minimises the Kullback-Leibler divergence between word distribution in a topic and word distribution in candidate labels. Candidate labels are ranked according to their relevance and the top ranked label chosen to represent the topic.

Magatti et al. (2009) introduced an approach for labelling topics that relied on two hierarchical knowledge resources labelled by humans, the Google Directory and the OpenOffice English Thesaurus. A *topics tree* is a pre-existing hierarchical structure of labelled topics. The Automatic Labelling Of Topics algorithm computes the similarity between LDA inferred topics and topics in a *topics tree* by computing scores using six standard similarity measures. The label for the most similar topic in the *topic tree* is assigned to the LDA topic.

Lau et al. (2010) proposed selecting the most representative word from a topic as its label. A label is selected by computing the similarity between each word and all the others in the topic. Several sources of information are used to identify the best label including Pointwise Mutual Information scores, WordNet hypernymy relations and distributional similarity. These features are combined in a reranking model to achieve results above a baseline (the most probable word in the topic).

In more recent work, Lau et al. (2011) proposed

a method for automatically labelling topics by making use of Wikipedia article titles as candidate labels. The candidate labels are ranked using information from word association measures, lexical features and an Information Retrieval technique. Results showed that this ranking method achieves better performance than a previous approach (Mei et al., 2007).

Mao et al. (2012) introduced a method for labelling hierarchical topics which makes use of sibling and parent-child relations of topics. Candidate labels are generated using a similar approach to the one used by Mei et al. (2007). Each candidate label is then assigned a score by creating a distribution based on the words it contains and measuring the Jensen-Shannon divergence between this and a reference corpus.

Hulpus et al. (2013) make use of the structured data in DBpedia¹ to label topics. Their approach maps topic words to DBpedia concepts. The best concepts are identified by applying graph centrality measures which assume that words that co-occurring in text are likely to refer to concepts that are close in the DBpedia graph.

Our own work differs from the approaches described above since, to our knowledge, it is the first to propose labelling topics with images rather than text.

Recent advances in computer vision has lead to the development of reliable techniques for exploiting information available in images (Datta et al., 2008; Szeliski, 2010) and these have been combined with NLP (Feng and Lapata, 2010a; Feng and Lapata, 2010b; Agrawal et al., 2011; Bruni et al., 2011). The closest work to our own is the text illustration techniques which have been proposed for story picturing (Joshi et al., 2006) and news articles illustration (Feng and Lapata, 2010b). The input to text illustration models is a textual document and a set of image candidates. The goal of the models is to associate the document with the correct image. Moreover, the problem of ranking images returned from a text query is related to, but different from, the one explored in our paper. Those approaches used queries that were much smaller (e.g. between one and three words) and more focussed than the ones

¹<http://dbpedia.org>

we use (Jing and Baluja, 2008). In our work, the input is a topic and the aim is to associate it with an image, or images, denoting the main thematic subject.

3 Labelling Topics

In this section we propose an approach to identifying images to illustrate automatically generated topics. It is assumed that there are no candidate images available so the first step (Section 3.1) is to generate a set of candidate images. However, when a candidate set is available the first step can be skipped.

3.1 Selecting Candidate Images

For the experiments presented here we restrict ourselves to using images from Wikipedia available under the Creative Commons licence, since this allows us to make the data available. The top-5 terms from a topic are used to query Google using its Custom Search API². The search is restricted to the English Wikipedia³ with image search enabled. The top-20 images retrieved for each search are used as candidates for the topic.

3.2 Feature Extraction

Candidate images are represented by two modalities (textual and visual) and features extracted for each.

3.2.1 Textual Information

Each image’s textual information consists of the metadata retrieved by the search. The assumption here is that image’s metadata is indicative of the image’s content and (at least to some extent) related to the topic. The textual information is formed by concatenating the *title* and the *link* fields of the search result. These represent, respectively, the web page title containing the image and the image file name. The textual information is preprocessed by tokenizing and removing stop words.

3.2.2 Visual Information

Visual information is extracted using low-level image keypoint descriptors, i.e. SIFT features

(Lowe, 1999; Lowe, 2004) sensitive to colour information. SIFT features denote “interesting” areas in an image. Image features are extracted using dense sampling and described using Opponent colour SIFT descriptors provided by the *colordescriptor*⁴ software. Opponent colour SIFT descriptors have been found to give the best performance in object scene and face recognition (Sande et al., 2008). The SIFT features are clustered to form a visual codebook of 1,000 visual words using K-Means such that each feature is mapped to a visual word. Each image is represented as a bag-of-visual words (BOVW).

3.3 Ranking Candidate Images

We rank images in the candidates set using graph-based algorithms. The graph is created by treating images as nodes and using similarity scores (textual or visual) between images to weight the edges.

3.3.1 PageRank

PageRank (Page et al., 1999) is a graph-based algorithm for identifying important nodes in a graph that was originally developed for assigning importance to web pages. It has been used for a range of NLP tasks including word sense disambiguation (Agirre and Soroa, 2009) and keyword extraction (Mihalcea and Tarau, 2004).

Let $G = (V, E)$ be a graph with a set of vertices, V , denoting image candidates and a set of edges, E , denoting similarity scores between two images. For example, $sim(V_i, V_j)$ indicates the similarity between images V_i and V_j . The PageRank score (Pr) over G for an image (V_i) can be computed by the following equation:

$$Pr(V_i) = d \cdot \sum_{V_j \in C(V_i)} \frac{sim(V_i, V_j)}{\sum_{V_k \in C(V_j)} sim(V_j, V_k)} Pr(V_j) + (1 - d)\mathbf{v} \quad (1)$$

where $C(V_i)$ denotes the set of vertices which are connected to the vertex V_i . d is the damping factor which is set to the default value of $d = 0.85$ (Page et al., 1999). In standard PageRank all elements of the vector \mathbf{v} are the same, $\frac{1}{N}$ where N is the number of nodes in the graph.

²<https://developers.google.com/apis-explorer/#s/customsearch/v1>

³<http://en.wikipedia.org>

⁴<http://koen.me/research/colordescriptors>

3.3.2 Personalised PageRank

Personalised PageRank (PPR) (Haveliwala et al., 2003) is a variant of the PageRank algorithm in which extra importance is assigned to certain vertices in the graph. This is achieved by adjusting the values of the vector \mathbf{v} in equation 1 to prefer certain nodes. Nodes that are assigned high values in \mathbf{v} are more likely to also be assigned a high PPR score. We make use of PPR to prefer images with textual information that is similar to the terms in the topic.

3.3.3 Weighting Graph Edges

Three approaches were compared for computing the values of $sim(V_i, V_j)$ in equation 1 used to weight the edges of the graph. Two of these make use of the textual information associated with each image while the final one relies on visual features.

The first approach is **Pointwise Mutual Information** (PMI). The similarity between a pair of images (vertices in the graph) is computed as the average PMI between the terms in their metadata. PMI is computed using word co-occurrence counts over Wikipedia identified using a sliding window of length 20. We also experimented with other word association measures but these did not perform as well. The PageRank over the graph weighted using PMI is denoted as \mathbf{PR}_{PMI} .

The second approach, **Explicit Semantic Analysis** (ESA) (Gabrilovich and Markovitch, 2007), is a knowledge-based similarity measure. ESA transforms the text from the image metadata into vectors that consist of Wikipedia article titles weighted by their relevance. The similarity score between these vectors is computed as the cosine of the angle between them. This similarity measure is used to create the graph and its PageRank is denoted as \mathbf{PR}_{ESA} .

The final approach uses the **visual features** extracted from the images themselves. The visual words extracted from the images are used to form feature vectors and the similarity between a pair of images computed as the cosine of the angle between them. The PageRank of the graph created using this approach is \mathbf{PR}_{vis} and it is similar to the approach proposed by Jing and Baluja (2008) for associating images to text queries.

3.3.4 Initialising the Personalisation Vector

The personalisation vector (see above) is weighted using the similarity scores computed between the topic and its image candidates. Similarity is computed using PMI and ESA (see above). When PMI and ESA are used to weight the personalisation vector they compute the similarity between the top 10 terms for a topic and the textual metadata associated with each image in the set of candidates. We refer to the personalisation vectors created using PMI and ESA as **Per(PMI)** and **Per(ESA)** respectively.

Using PPR allows information about the similarity between the images' metadata and the topics themselves to be considered when identifying a suitable image label. The situation is different when PageRank is used since this only considers the similarity between the images in the candidate set.

The personalisation vector used by PPR is employed in combination with a graph created using one of the approaches described above. For example, the graph may be weighted using visual features and the personalisation vector created using PMI scores. This approach is denoted as $\mathbf{PR}_{\text{vis}} + \text{Per(PMI)}$.

4 Evaluation

This section discusses the experimental design for evaluating the proposed approaches to labelling topics with images. To our knowledge no data set for evaluating these approaches is currently available and consequently we developed one for this study⁵. Human judgements about the suitability of images are obtained through crowdsourcing.

4.1 Data

We created a data set of topics from two collections which cover a broad thematic range:

- **NYT** 47,229 New York Times news articles (included in the GigaWord corpus) that were published between May and December 2010.
- **WIKI** A set of Wikipedia categories randomly selected by browsing its hierarchy in a breadth-first-search manner starting from a few seed

⁵Data set can be downloaded from <http://staffwww.dcs.shef.ac.uk/people/N.Aletras/resources.html>.

police, officer, crime, street, man, city, gang, suspect, arrested, violence

game, season, team, patriot, bowl, nfl, quarterback, week, play, jet

military, afghanistan, force, official, afghan, defense, pentagon, american, war, gates

Figure 1: A sample of topics and their top-3 image candidates (i.e. with the highest average human annotations).

categories (e.g. SPORTS, POLITICS, COMPUTING). Categories that have more than 80 articles associated with them are considered. These articles are collected to produce a corpus of approximately 60,000 articles generated from 1,461 categories.

Documents in the two collections are tokenised and stop words removed. LDA was applied to learn 200 topics from NYT and 400 topics from WIKI. The *gensim* package⁶ was used to implement and compute LDA. The hyperparameters (α, β) were set to $\frac{1}{\text{num_of_topics}}$. Incoherent topics are filtered out by applying the method proposed by Aletras and Stevenson (2013).

We randomly selected 100 topics from NYT and 200 topics from WIKI resulting in a data set of 300 topics. Candidate images for these topics were generated using the approach described in Section 3.1, producing a total of 6,000 candidate images (20 for

each topic).

4.2 Human Judgements of Image Relevance

Human judgements of the suitability of each image were obtained using an online crowdsourcing platform, Crowdflower⁷. Annotators were provided with a topic (represented as a set of 10 keywords) and a candidate image. They were asked to judge how appropriate the image was as a representation of the main subject of the topic and provide a rating on a scale of 0 (completely unsuitable) to 3 (very suitable).

Quality control is important in crowdsourcing experiments to ensure reliability (Kazai, 2011). To avoid random answers, control questions with obvious answer were included in the survey. Annotations by participants that failed to answer these questions correctly or participants that gave the same rating for all pairs were removed.

⁶<http://pypi.python.org/pypi/gensim>

⁷<http://crowdflower.com>

The total number of filtered responses obtained was 62,221 from 273 participants. Each topic-image pair was rated at least by 10 subjects. The average response for each pair was calculated in order to create the final similarity judgement for use as a gold-standard. The average variance across judges (excluding control questions) is 0.88.

Inter-Annotator agreement (IAA) is computed as the average Spearman's ρ between the ratings given by an annotator and the average ratings given by all other annotators. The average IAA across all topics was 0.50 which indicates the difficulty of the task, even for humans.

Figure 1 shows three example topics from the data set together with the images that received the highest average score from the annotators.

4.3 Evaluation Metrics

Evaluation of the topic labelling methods is carried out using a similar approach to the framework proposed by Lau et al. (2011) for labelling topics using textual labels.

Top-1 average rating is the average human rating assigned to the top-ranked label proposed by the system. This provides an indication of the overall quality of the image the system judges as the best one. The highest possible score averaged across all topics is 2.68, since for many topics the average score obtained from the human judgements is lower than 3.

The second evaluation measure is the normalized discounted cumulative gain (**nDCG**) (Järvelin and Kekäläinen, 2002; Croft et al., 2009) which compares the label ranking proposed by the system to the optimal ranking provided by humans. The discounted cumulative gain at position p (DCG_p) is computed using the following equation:

$$DCG_p = rel_1 + \sum_{i=2}^p \frac{rel_i}{\log_2(i)} \quad (2)$$

where rel_i is the relevance of the label to the topic in position i . Then nDCG is computed as:

$$nDCG_p = \frac{DCG_p}{IDCG_p} \quad (3)$$

where $IDCG_p$ is the optimal ranking of the image labels, in our experiments this is the ranking provided by the scores in the human annotated data set.

We follow Lau et al. (2011) in computing **nDCG-1**, **nDCG-3** and **nDCG-5** for the top 1, 3 and 5 ranked system image labels respectively.

4.4 Baselines

Since there are no previous methods for labelling topics using images, we compare our proposed models against three baselines.

The **Random** baseline randomly selects a label for the topic from the 20 image candidates. The process is repeated 10,000 times and the average score of the selected labels is computed for each topic.

The more informed **Word Overlap** baseline selects the image that is most similar to the topic terms by applying a Lesk-style algorithm (Lesk, 1986) to compare metadata for each image against the topic terms. It is defined as the number of common terms between a topic and image candidate normalised by the total number of terms in the topic and image's metadata.

We also compared our approach with the ranking returned by the **Google Image Search** for the top-20 images for a specific topic.

4.5 User Study

A user study was conducted to estimate human performance on the image selection task. Three annotators were recruited and asked to select the best image for each of the 300 topics in the data set. The annotators were provided with the topic (in the form of a set of keywords) and shown all candidate images for that topic before being asked to select exactly one. The Average Top-1 Rating was computed for each annotator and the mean of these values was 2.24.

5 Results

Table 1 presents the results obtained for each of the methods on the collection of 300 topics. Results are shown for both Top-1 Average rating and nDCG.

We begin by discussing the results obtained using the standard PageRank algorithm applied to graphs weighted using PMI, ESA and visual features (PR_{PMI} , PR_{ESA} and PR_{vis} respectively). Results using PMI consistently outperform all baselines and those obtained using ESA. This suggests that distributional word association measures are more suitable for identifying useful images than knowledge-based similarity measures. The best results using

Model	Top-1 Av. Rating	nDCG-1	nDCG-3	nDCG-5
Baselines				
Random	1.79	-	-	-
Word Overlap	1.85	0.69	0.72	0.74
Google Image Search	1.89	0.73	0.75	0.77
PageRank				
PR _{PMI}	1.87	0.70	0.73	0.75
PR _{ESA}	1.81	0.67	0.68	0.70
PR _{vis}	1.96	0.73	0.75	0.76
Personalised PageRank				
PR _{PMI} +Per(PMI)	1.98	0.74	0.76	0.77
PR _{PMI} +Per(ESA)	1.92	0.70	0.72	0.74
PR _{ESA} +Per(PMI)	1.91	0.70	0.72	0.73
PR _{ESA} +Per(ESA)	1.88	0.69	0.72	0.74
PR _{vis} +Per(PMI)	2.00	0.74	0.75	0.76
PR _{vis} +Per(ESA)	1.94	0.72	0.75	0.76
User Study	2.24	-	-	-

Table 1: Results for various approaches to topic labelling.

standard PageRank are obtained when the visual similarity measures are used to weight the graph, with performance that significantly outperforms the word overlap baseline (paired t-test, $p < 0.05$). This demonstrates that visual features are a useful source of information for deciding which images are suitable topic labels.

The Personalised version of PageRank produces consistently higher results compared to standard PageRank, demonstrating that the additional information provided by comparing the image metadata with the topics is useful for this task. The best results are obtained when the personalisation vector is weighted using PMI (i.e. Per(PMI)). The best overall result for the top-1 average rating (2.00) is obtained when the graph is weighted using visual features and the personalisation vector using the PMI scores (PR_{vis}+Per(PMI)) while the best results for the various DCG metrics are produced when both the graph and the personalisation vector are weighted using PMI scores (PR_{PMI}+Per(PMI)). In addition, these two methods, PR_{vis}+Per(PMI) and PR_{PMI}+Per(PMI), perform significantly better than the word overlap and the Google Image Search baselines ($p < 0.01$ and $p < 0.05$ respectively). Weighting the personalisation vector using ESA consistently produces lower performance compared to

PMI. These results indicate that graph-based methods for ranking images are useful for illustrating topics.

6 Discussion

Figure 2 shows a sample of three topics together with the top-3 candidates (left-to-right) selected by applying the PR_{vis}+Per(PMI) approach. Reasonable labels have been selected for the first two topics. On the other hand, the images selected for the third topic do not seem to be as appropriate.

We observed that inappropriate labels can be generated for two reasons. Firstly, the topic may be abstract and difficult to illustrate. For example, one of the topics in our data set refers to the subject ALGEBRAIC NUMBER THEORY and contains the terms *number, ideal, group, field, theory, algebraic, class, ring, prime, theorem*. It is difficult to find a representative image for topics such as this one. Secondly, there are topics for which none of the candidate images returned by the search engine is relevant. An example of a topic like this in our data set is one that refers to PLANTS and contains the terms *family, sources, plants, familia, order, plant, species, taxonomy, classification, genera*. The images returned by the search engine include pictures of the Sagrada Familia cathedral in Barcelona, a car called “Familia”

dance, ballet, dancer, swan, company, dancing, nutcracker, balanchine, ballerina, choreographer					
2.3	2.7	2.5	2.8	2.8	2.73
wine, bottle, grape, flavor, dry, vineyard, curtis, winery, sweet, champagne					
2.1	2.6	2.7	2.83	2.8	2.8
haiti, haitian, earthquake, paterson, jean, prince, governor, au, cholera, country					
1.0	1.2	0.2	1.91	1.7	1.6

and pictures of families but no pictures of plants.

7 Conclusions

This paper explores the use of images to represent automatically generated topics. An approach to selecting appropriate images was described. This begins by identifying a set of candidate images using a search engine and then attempts to select the most suitable. Images are ranked using a graph-based method that makes use of both textual and visual information. Evaluation is carried out on a data set created for this study. The results show that the visual features are a useful source of information for this task while the proposed graph-based method significantly outperforms several baselines.

This paper demonstrates that it is possible to identify images to illustrate topics. A possible application for this technique is to represent the contents of large document collections in a way that supports

rapid interpretation and can be used to enable navigation (Chaney and Blei, 2012; Gretarsson et al., 2012; Hinneburg et al., 2012). We plan to explore this possibility in future work. Other possible extensions to this work include exploring alternative approaches to generating candidate images and developing techniques to automatically identify abstract topics for which suitable images are unlikely to be found, thereby avoiding the problem cases described in Section 6.

Acknowledgments

The research leading to these results was carried out as part of the PATHS project (<http://paths-project.eu>) funded by the European Community’s Seventh Framework Programme (FP7/2007-2013) under grant agreement no. 270082.

Abstract

Multi-dimensional latent text models, such as *factorial LDA* (f-LDA), capture multiple factors of corpora, creating structured output for researchers to better understand the contents of a corpus. We consider such models for clinical research of new recreational drugs and trends, an important application for mining current information for healthcare workers. We use a “three-dimensional” f-LDA variant to jointly model combinations of drug (marijuana, salvia, etc.), aspect (effects, chemistry, etc.) and route of administration (smoking, oral, etc.) Since a purely unsupervised topic model is unlikely to discover these specific factors of interest, we develop a novel method of incorporating prior knowledge by leveraging user generated tags as priors in our model. We demonstrate that this model can be used as an exploratory tool for learning about these drugs from the Web by applying it to the task of extractive summarization. In addition to providing useful output for this important public health task, our prior-enriched model provides a framework for the application of f-LDA to other tasks.

1 Introduction

Topic models aid exploration of the main thematic elements of large text corpora by revealing latent structure and producing a high level semantic view (Blei et al., 2003). Topic models have been used for understanding the contents of a corpus and identifying interesting aspects of a collection for more in-depth analysis (Talley et al., 2011; Mimno, 2011). While standard topic models assume a flat semantic structure, there are potentially many dimensions of a corpus that contribute to word choice,

such as sentiment, perspective and ideology (Mei et al., 2007; Paul and Girju, 2010; Eisenstein et al., 2011). Rather than studying these factors in isolation, **multi-dimensional** topic models can consider multiple factors jointly.

Paul and Dredze (2012b) introduced *factorial LDA* (f-LDA), a general framework for multi-dimensional text models that capture an arbitrary number of factors (explained in §3). While a standard topic model learns distributions over “topics” in documents, f-LDA learns distributions over combinations of multiple factors (e.g. topic, perspective) called tuples (e.g. (HEALTHCARE,LIBERAL)). While f-LDA can model factors without supervision, it has not been used in situations where the user has prior information about the factors.

In this paper we consider a setting where the user has prior knowledge about the end application: mining recreational drug trends from user forums, an important clinical research problem (§2). We show how to incorporate available information from these forums into f-LDA as a novel hierarchical prior over the model parameters, guiding the model toward the desired output (§3.1).

We then demonstrate the model’s utility in exploring a corpus in a targeted manner by using it to automatically extract interesting sentences from the text, a simple form of extractive multi-document summarization (Goldstein et al., 2000). In the same way that topic models can be used for aspect-specific summarization (Titov and McDonald, 2008; Haghghi and Vanderwende, 2009), we use f-LDA to extract snippets corresponding to fine-grained information patterns. Our results demonstrate that our multi-dimensional modeling approach targets more informative text than a simpler model (§4).

2 Analyzing Drug Trends on the Web

Recreational drug use imposes a significant burden on the health infrastructure of the United States and other countries. Accurate information on drugs, usage profiles and side effects are necessary for supporting a range of healthcare activities, such as addiction treatment programs, toxin diagnosis, prevention and awareness campaigns, and public policy. These activities rely on up-to-date information on drug trends, but it is increasingly difficult to keep up with current drug information, as distribution and information-sharing of novel drugs is easier than ever via the web (Wax, 2002). For the third consecutive year, a record number of new drugs (49) were detected in Europe in 2011 (EMCDDA, 2012). About two-thirds of these new drugs were synthetic cannabinoids (used as legal marijuana substitutes), which led to 11,000 hospitalizations in the U.S. in 2010 (SAMHSA, 2012). Treatment is complicated by the fact that novel substances like these may have unknown side effects and other properties.

Accurate information on drug trends can be obtained by speaking directly with users, e.g. focus groups and interviews (Reyes et al., 2012; Hout and Bingham, 2012), but such studies are slow and costly, and can fail to identify the emergence of new drug classes, such as mephedrone (Dunn et al., 2011). More recently, researchers have begun to recognize clinical value in information obtained from the web (Corazza et al., 2011). By (manually) analyzing YouTube videos, Drugs-Forum (discussed below), and other social media websites and online communities, researchers have uncovered details about the use, effects, and popularity of a variety of new and emerging drugs (Morgan et al., 2010; Corazza et al., 2012; Gallagher et al., 2012), and comprehensive drug reviews now include non-standard sources such as web forums in addition to standard sources (Hill and Thomas, 2011).

Organizing and understanding forums requires significant effort. We propose automated tools to aid in the exploration and analysis of these data. While topic models are a natural fit for corpus exploration (Eisenstein et al., 2012; Chaney and Blei, 2012), and have been used for similar public health applications (Paul and Dredze, 2011), online forums can be organized in many ways beyond topic. Guided by do-

Factor	Components
<i>Drug</i>	ALCOHOL AMPHETAMINES BETA-KETONES CANNABINOIDS CANNABIS COCAINE DMT DOWNERS DXM ECSTASY GHB HERBAL ECSTASY KETAMINE KRATOM LSA LSD NOOTROPICS OPIATES PEYOTE PHENETHYLAMINES SALVIA TOBACCO
<i>Route</i>	INJECTION ORAL SMOKING SNORTING
<i>Aspect</i>	CHEMISTRY (Pharmacology, TEK) CULTURE (Culture, Setting, Social, Spiritual) EFFECTS (Effects) HEALTH (Health, Overdose, Side effects) USAGE (Dose, Storing, Weight)

Table 1: The three factors of our model (details in §3.1). The forum tags shown in parentheses are grouped together to form aspects.

main experts, we seek to model forums as a combination of drug type, route of intake (oral, injection, etc.) and aspect (cultural settings, drug chemistry, etc.) A multi-dimensional topic model can jointly capture these factors, providing a more informative understanding of the data, and can be used to produce fine-grained information such as the effects of taking a particular drug orally. Our hope is that models such as f-LDA can lead to exploratory tools that aide researchers in learning about new drugs.

2.1 Corpus: Drugs-Forum

Our data set is taken from drugs-forum.com, a site active for more than 10 years with over 100,000 members and more than 1 million monthly readers. The site is an information hub where people can freely discuss recreational drugs with psychoactive effects, ranging from coffee to heroin, hosting information and discussions on specific drugs, as well as drug-related politics, law, news, recovery and addiction. With current information on a variety of drugs and an extensive archive, Drugs-Forum provides an ideal information source for public health researchers (Corazza et al., 2012).

Discussion threads are organized into numerous forums, including drugs, the law, addiction, etc. Since we are modeling drug use, we focus on the drug forums. Each thread is assigned to a specific forum or subforum (drug) and each thread has a user specified tag, which can indicate categories like “Effects” as well as routes of administration like “Oral.” We organized the tags and subforum categorizations into factors and components, as shown in Table 1. We make use of these tags in §3.1.

3 Multi-Dimensional Text Models

Clinical researchers are interested in specific information about drug usage, including **drug** type, **route** of administration, and other **aspects** of drug use (e.g. dosage, side effects). Rather than considering these factors independently, we would like to model these in a way that can capture interesting interactions between all three factors, because the effects and other aspects of drugs can vary by route of administration. Oral consumption of drugs often produces longer lasting but milder effects than injection or smoking, for example. Many mephedrone users report nose bleeds and nasal pain as a health effect of snorting the drug: this could be modeled as the triple (MEPHEDRONE,SNORTING,HEALTH), a particular combination of all three factors.

To this end, we utilize the multi-dimensional text model **factorial LDA** (f-LDA) (Paul and Dredze, 2012b), which jointly models multiple semantic *factors* or dimensions. In this section we summarize f-LDA, then we describe an extension which incorporates user-generated metadata into the model (§3.1).

In a standard topic model such as LDA (Blei et al., 2003), each word token is associated with a latent “topic” variable. f-LDA is conceptually similar to LDA except that rather than a single topic variable, each token is associated with a K -dimensional **vector** of latent variables. In a three-dimensional f-LDA model, each token has three latent variables—drug, route, and aspect in this case.

In f-LDA, each document has a distribution over all possible K -tuples (rather than topics), and each K -tuple is associated with its own word distribution. Under this model, words are generated by first sampling a tuple from the document’s tuple distribution, then sampling a word from that tuple’s word distribution. In our three-dimensional model, we will consider **triples** such as (CANNABIS,SMOKING,EFFECTS).

Formally, each document has a distribution $\theta^{(d)}$ over triples, and each token is associated with a latent vector \vec{z} of size $K=3$. (We’ll describe the model in terms of the three factors we are modeling in this paper, but f-LDA generalizes to K dimensions.) The Cartesian product of the three factors forms a set of triples and the vector \vec{z} references three discrete components to form a triple $\vec{t} = (t_1, t_2, t_3)$. The car-

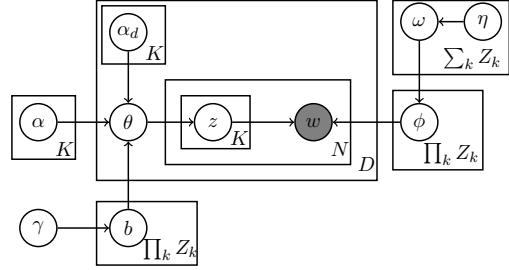

Figure 1: The graphical model for f-LDA augmented with priors η learned from labeled data (§3.1). In this work, $K = 3$.

dinality of each dimension (denoted Z_k) is the number of drugs, routes, and aspects, as shown in Table 1. Each triple has a corresponding word distribution $\phi_{\vec{t}}$. The graphical model is shown in Figure 1.

One would expect that triples that have components in common should have similar word distributions: (CANNABIS,SMOKING,EFFECTS) is expected to have some commonalities with (CANNABIS,ORAL,EFFECTS). f-LDA models this intuition by sharing parameters across priors for triples which share components: all triples with CANNABIS as the drug include cannabis-specific parameters in the prior, and all triples with SMOKING as the route have smoking-specific parameters. Formally, $\phi_{\vec{t}}$ (the word distribution for tuple \vec{t}) has a Dirichlet($\hat{\omega}^{(\vec{t})}$) prior, where for each word w in the vector, $\hat{\omega}_w^{(\vec{t})}$ is a log-linear function:

$$\hat{\omega}_w^{(\vec{t})} \triangleq \exp\left(\omega^{(B)} + \omega_w^{(0)} + \omega_{t_1 w}^{(\text{drug})} + \omega_{t_2 w}^{(\text{route})} + \omega_{t_3 w}^{(\text{aspect})}\right) \quad (1)$$

where $\omega^{(B)}$ is a corpus-wide precision scalar (the bias), $\omega_w^{(0)}$ is a corpus-specific bias for word w , and $\omega_{t_k w}^{(k)}$ is a bias parameter for word w for component t_k of the k th factor. That is, each drug, route, and aspect has a weight vector over the vocabulary, and the prior for a particular triple is influenced by the weight vectors of each of the three factors. The ω parameters are all independent and normally distributed around 0 (effectively L2 regularization).

The prior over each document’s distribution over triples has a similar log-linear prior, where weights for each factor are combined to influence the distribution. Under our model, $\theta^{(d)}$ is drawn from Dirichlet($\mathbf{B} \cdot \hat{\alpha}^{(d)}$), where \cdot denotes an element-wise product between \mathbf{B} (described below) and $\hat{\alpha}^{(d)}$, with

$\hat{\alpha}_{\vec{t}}^{(d)}$ for each triple \vec{t} defined as:

$$\begin{aligned}\hat{\alpha}_{\vec{t}}^{(d)} \triangleq \exp & \left(\alpha^{(B)} + \alpha_{t_1}^{(\mathcal{D}, \text{drug})} + \alpha_{t_1}^{(d, \text{drug})} \right. \\ & + \alpha_{t_2}^{(\mathcal{D}, \text{route})} + \alpha_{t_2}^{(d, \text{route})} \\ & \left. + \alpha_{t_3}^{(\mathcal{D}, \text{aspect})} + \alpha_{t_3}^{(d, \text{aspect})} \right) \quad (2)\end{aligned}$$

Similar to the ω formulation, $\alpha^{(B)}$ is a global bias parameter, while the $\alpha^{\mathcal{D}}$ vectors are corpus-wide weight vectors and α^d are document-specific weight vectors over the components of each factor. Structuring the prior in this way models the intuition that if a triple with a particular component has high probability, other triples containing that component are likely to also have high probability. For example, if a message discusses triples of the form (CANNABIS, *, EFFECTS), it is more likely to discuss (CANNABIS, *, HEALTH) than (COCAINE, *, HEALTH), because the message is about cannabis.

Finally, \mathbf{B} is a 3-dimensional array that encodes a sparsity pattern over the space of possible triples. This is used to accommodate triples that can be generated by the model but are not supported by the data. For example, not all routes of administration may be applicable to certain drugs, or certain aspects of a drug may happen to not be discussed in the forum. Each element $b_{\vec{t}}$ of the array is a real-valued scalar in (0, 1) which is multiplied with $\hat{\alpha}_{\vec{t}}^{(d)}$ to adjust the prior for that triple. If the b value is near 0 for a particular triple, then it will have very low prior probability. The b values have Beta(γ_0, γ_1) priors ($\gamma < 1$) which encourage them to be near 0 or 1, so that they function as binary variables.

Posterior inference and parameter estimation consist of a Monte Carlo EM algorithm that alternates between an iteration of collapsed Gibbs sampler on the \vec{z} variables (E-step), and an iteration of gradient ascent on the α and ω hyperparameters (M-step). See Paul and Dredze (2012b) for more details.

3.1 Tags and Word Priors

In an unsupervised setting, there is no reason f-LDA would actually infer parameters corresponding to the three factors we have been describing. However, the forums include metadata that can help guide the model: the messages are organized into forums corresponding to drug type (factor 1), and some threads

COCAINE	SNORTING	HEALTH	
η (Prior over ω)			
coke	snort	kidney	
cocaine	snorting	hcv	
crack	snorted	pains	
cola	nose	symptoms	
blow	nasal	guidelines	
lines	drip	diet	
			COCAINE SNORTING HEALTH
ω (Prior over ϕ)			ϕ (Posterior)
coke	snort	symptoms	nose
cocaine	snorting	long-term	cocaine
crack	snorted	depression	coke
cola	passages	disorder	blood
rocks	nostril	schizophrenia	water
coca	insufflating	severe	pain

Figure 2: Example of parameters learned by f-LDA. The highest weight words in the ω and η vectors for three components are shown on the left. These are combined to form the prior for the word distribution ϕ . The tripling of (COCAINE, SNORTING, HEALTH) results in high probability words about nose bleeds and nasal damage.

are tagged with labels corresponding to routes of administration and other aspects (factors 2 and 3). Tags for aspects are manually grouped into components: e.g. USAGE (tags: Dose, Storing, Weight). Table 1 shows the factors and components in our model.

One could simply use these tags as labels in a simple supervised model—this will be our experimental baseline (§4.1). However, this approach has limitations in that most documents are missing labels (less than a third of our corpus contains one of the labels in Table 1) and many messages discuss several components, not just the one implied by the tag. For example, a message tagged “Side effects” may talk about both side effects and dosage. While a supervised classifier may attribute all words to a single tag, f-LDA learns per-token assignments.

We will instead use the tags to inform the priors over our f-LDA word distribution parameters. We do this with a two-stage approach. First, we use the tags to train parameters of a related but simplified model. We then use the learned parameters as priors over the corresponding f-LDA parameters.

In particular, we will place priors on the ω vectors, the Dirichlet hyperparameters which influence the word distributions. Suppose that we are given a vector $\eta^{(0)}$ which is believed to contain desirable values for $\omega^{(0)}$, the weight vector over words in the corpus, and similarly we are given vectors $\eta_i^{(f)}$ over the vocabulary for the i th component of factor f , which are believed to be good values for $\omega_i^{(f)}$. One option

is to fix ω as η , forcing the component weights to match the provided weights. However, in our case η will only be an approximation of the optimal component parameters since it is estimated from incomplete data (only some messages have tags) and the η vectors are learned using an approximate model (see below). Instead, these weight vectors will merely guide learning as prior knowledge over model parameters ω . While f-LDA assumes each ω is drawn from a 0-mean Gaussian, we alter the means of the appropriate ω parameters to use η .

$$\omega_w^{(0)} \sim \mathcal{N}(\eta_w^{(0)}, \sigma^2); \omega_{iw}^{(k)} \sim \mathcal{N}(\eta_{iw}^{(k)}, \sigma^2) \quad (3)$$

Recall that $\omega_w^{(0)}$ are corpus-wide bias parameters for each word and $\omega_{iw}^{(k)}$ are component-specific parameters for each word. This yields a hierarchical prior in which η parameterizes the prior over ω , while ω parameterizes the prior over ϕ (the word distributions). The resulting ω parameters can vary from the provided priors to adapt to the data. An example of learned parameters is shown in Figure 2, illustrating the hierarchical process behind this model.

Learning the Priors In various applications, priors can come from many different sources, such as labeled data (Jagarlamudi et al., 2012). We learn the prior means η from tagged messages. However, these parameters imply a latent division of responsibility for observed words: some are present because of the tag while others are general words in the corpus. As a result, they must be estimated.

We learn these parameters from the tagged messages using SAGE, which model words in a document as combinations of background and topic word distributions. Eisenstein et al. (2011) present SAGE models for Naive Bayes (one class per document), admixture models (one class per token), and admixture models where tokens come from multiple factors. We combine the first and third models, such that a document has multiple factors which are given as labels across the entire document—the drug type and the tag, which could correspond to a component of either the route or aspect factors. We posit the following model of text generation per document:

$$P(\text{word } w | \text{drug} = i, \text{factor } f = j) \quad (4)$$

$$= \frac{\exp(\eta_w^{(0)} + \eta_{iw}^{(\text{drug})} + \eta_{jw}^{(f)})}{\sum_{w'} \exp(\eta_{w'}^{(0)} + \eta_{iw'}^{(\text{drug})} + \eta_{jw'}^{(f)})}$$

This log-linear model has a similar form as Eq. 1, but with two factors instead of three, and it is a distribution rather than a Dirichlet vector. As in SAGE, we fix $\eta^{(0)}$ to be the observed vector of corpus log-frequencies over the vocabulary, which acts as an “overall” weight vector, while parameter estimation yields $\eta_i^{(f)}$, the logit parameters for the i th component of factor f .¹ These parameters are then used as the mean of the Gaussian priors over ω .

Standard optimization methods can be used to estimate these parameters. The partial derivative of the likelihood with respect to the parameter $\eta_{iw}^{(\text{drug})}$ is:

$$\frac{\partial}{\partial \eta_{iw}^{(\text{drug})}} = \sum_f \sum_{j \in f} c(i, j, w) - \pi(i, j, w) c(i, j, *) \quad (5)$$

where $c(i, j, w)$ is the number of times word w appears in documents labeled with i (drug) and j (tag), and $\pi(i, j, w)$ denotes the probability given by (4). The partial derivative of each $\eta_j^{(f)}$ is similar.

4 Experiments with Topic Modeling for Extractive Summarization

Our corpus consists of messages from [drugs-forum.com](#) (§2.1). The site categorizes threads into many forums and subforums, including some on specific drugs, which are categorized hierarchically. We treated higher-level categories with pharmacologically similar drugs as a single drug type (e.g. OPIOIDS, AMPHETAMINES); for others we took the finest-granularity subforum as the drug type. We selected 22 popular drugs and from these forums we crawled 410K messages. We selected a subset of tags to form components for the route and aspect factors. (Some tags were too general or infrequent to be useful.) A list of the tags and drugs used appears in Table 1. We also included a GENERAL component in the latter two factors to model word usage which does not pertain to a particular route or aspect; the prior parameters η for these components were simply set to 0.

We wish to demonstrate that our modified f-LDA model can be used to discover useful information in the text. One way to demonstrate this is by using the model to extract relevant snippets of text from the

¹SAGE models sparsity on the weights via a Laplacian prior. Such sparsity is not modeled in f-LDA, so we ignore this here.

forums, which will form the basis of our evaluation experiments. Our goal is not to build a complete summarization system, but rather to use the model to direct researchers to interesting messages.

While we model all 22 drugs, our summarization experiments will focus on five drugs which have been studied only relatively recently: mephedrone and MDPV (β -ketones), Bromo-Dragonfly (synthetic phenethylamines), Spice/K2 (synthetic cannabinoids), and salvia divinorum. We will consider these drugs in particular because these are the five drugs for which technical reports were created by the EU Psychonaut Project (Schifano et al., 2006), an online database of novel and emerging drugs, whose information is collected by reading drug websites, including Drugs-Forum. Extensive technical reports were written about these five popular drugs, and we can use these reports to produce reference summaries for our experiments (§4.2).

Of these five drugs, only salvia has its own subforum; the others belong to subforums representing the broader categories shown in parentheses. We simply model the drug type as a proxy for the specific drug, as most of the drugs in each category have similar effects and properties. The first two drugs are both in the same subforum, so for the purpose of our model we treat mephedrone and MDPV as the single drug type, β -ketones. These two drugs are grouped together during summarization (§4.2), but the corresponding reference summaries incorporate excerpts from the technical reports on both drugs.

4.1 Model Setup

Of the four drug types being considered for summarization, our data set contains 12K messages with one of the tags in Table 1 and 30K without. Of those without tags, we set aside 5K as development data. There are also over 300K messages (140K tagged) from the remaining 18 drug types: some of these messages are utilized when training f-LDA. Even though we only consider four drug types in our experiments, our intuition is that it can be beneficial to model other drugs as well, because this will help to learn parameters for the various aspects and routes of administration. Our model of the effects of mephedrone can be informed by also modeling the effects of other stimulants such as cocaine.

Each message was treated as a document, and we

only used documents with at least five word tokens after stop words, low-frequency words, and punctuation were removed. The preprocessed data sets contained an average of 45 tokens per document.

Below, we describe two f-LDA variants as well as the baseline used in our experiments.

Baseline Our baseline model is a unigram language model trained on the subset of messages which are tagged. We treat the drug subforum as a label for the drug factor, and each message’s tag is used as a label for either the route or aspect factor. For example, the word distribution for the pair (SALVIA,EFFECTS) is estimated as the empirical distribution from messages posted in the salvia forum and tagged with “Effects.” We use add- λ smoothing where λ is chosen to optimize likelihood on the held-out development set.

This is a two-dimensional model, since we explicitly model pairs such as (MEPHEDRONE,SNORTING) or (SALVIA,EFFECTS). However, we also created word distributions for triples such as (SALVIA,ORAL,EFFECTS) by taking a mixture of the corresponding pairs: in this example, we estimate the unigram distribution from salvia documents tagged with either “Oral” or “Effects.”

Factorial LDA Because f-LDA does not rely on tagged data (the tags are only used to create priors), we can run inference on larger sets of data. The drawback is that despite these priors, it is still mostly unsupervised and we want to be careful to ensure the model will learn the patterns we care about. We thus add some reasonable constraints to the parameter space to guide the model further.

First, we treat the drug type as an observed variable based on the subforum the message comes from, just as with the baseline. For example, only tuples of the form (SALVIA,*,*) can be assigned to tokens in the salvia forum. Second, we restrict the set of possible routes of administration that can be assigned to tokens in particular drug forums, since most drugs can be taken through only a subset of routes. For example, marijuana is typically smoked or eaten orally, but rarely injected. We therefore restrict each drug’s allowable set of administration routes to those which are tagged (e.g. with “Oral” or “Snorting”) in at least 1% of that drug’s data. Similar ideas are used in Labeled LDA (Ramage et al.,

Reference Text	System Snippet
Mephedrone (β -ketones/Bath salts)	
It is recommended by users that Mephedrone be taken on an empty stomach. Doses usually vary between 100mg-1g.	<ul style="list-style-type: none"> If it is SWIY's first time using Mephedrone SWIM recommends a 100mg oral dose on an empty stomach.
Reported negative side effects include: <ul style="list-style-type: none"> Loss of appetite. Dehydration and dry mouth Tense jaw, mild muscle clenching, stiff neck, and bruxia (teeth grinding) Anxiety and paranoia Increase in mean body temperature (sweating/Mephedrone sweat and hot flushes) Elevated heart rate (tachycardia) and blood pressure, and chest pains Dermatitis like symptoms (Itch and rash) 	<ul style="list-style-type: none"> Neutral side effects: Lack of appetite, occasional loss of visual focus, [...] weight loss, possible diuretic. Negative side effects: Grinding teeth, "Cotton mouth", unable to achieve orgasm Aside from his last session he has never experienced any negative symptoms at all, no raised heart beat, vasoconstriction , sweating, headaches, paranoia e.t.c nothing at all except sometimes cold hands the next day. lot of people report that anxiety and paranoia are some of the side effects of taking mephedrone [...] is it also possible that alot of the chest pains people are experiencing is due to anxiety? moisturize the affected areas of skin twice daily with E45 or a similar unperfumed dermatological lotion.
Salvia divinorum	
Sublingual ingestion of the leaf (quid): reduces intensity of effects and can taste disgusting. When Salvia is consumed as a smokeable formulation the duration of the trip lasts 30 minutes or less, whereas if Salvia is consumed sublingually the effects last for 1 hour or more.	<ul style="list-style-type: none"> The taste of sublingual salvia is foul and it is easy to have a dud trip unless large amounts of it are used. SWIM has heard from many other users that chewing the fresh leaves of the Salvia plant allow for a much longer and mellower trip. [...] SWIM has read that a trip this way can last anywhere from a half an hour or longer.
Dried leaves and/or salvia extract are smoked (using a butane lighter) either by pipe (considered to be the most effective but is considered to be quite painful) or water bong.	<ul style="list-style-type: none"> 2. Use a water pipe. Its harsh and needs to be smoked hot so this should be self explanatory. 3. Use a torch style lighter [...] Salvinorin A has a VERY high boiling point (around 700 degrees F I believe) so a regular bic just wont do it
Salvia is appealing to recreational users because of intense, unique, hallucinatory effects. Brief hallucinations occur rapidly after administration and are typically very vivid. Users report weird thoughts, feelings of unreality, feelings of immersion in bizarre non-Euclidian dimensions/geometries, feelings of floating.	<ul style="list-style-type: none"> He noticed very clear [closed eye visuals], which looked similar to patterns on a persian rug, or ethnic oriental design. SWIM felt as if he was moving around, that he had got up and run and fallen, and that falling had shattered the space around his body as if I'd fallen through many glass framed pictures [...] I was aware of my body and my friends and my life below, but I was [...] standing outside of time and outside of space.

Figure 3: Example snippets generated by f-LDA along with the corresponding reference text. For space, the references and snippets shown have been shortened in some cases. "SWIM" and "SWIY" stand for "someone who isn't me/you" and are used to avoid self-incrimination on the web forum.

2009), in which tags are used to restrict the space of allowed topics in a document.

We use f-LDA as a three-dimensional model which explicitly models triples, but we also obtain distributions for pairs such as (SALVIA,EFFECTS) by marginalizing across all distributions of the form (SALVIA,*,EFFECTS). We trained f-LDA on two different data sets, yielding the following models:

- f-LDA-1:** We use the 12K messages with tags and fill the set out with 13K messages with tags uniformly sampled from the 18 other drugs, for a total of 25K messages.

- f-LDA-2:** We use all 37K messages (many without tags) and fill the set out with 63K messages with tags uniformly sampled from the 18 other drugs, for a total of 100K messages.

All f-LDA instances are run with 5000 iterations alternating between a sweep of Gibbs sampling followed by a step of gradient ascent on the hyperparameters. While we do not use the tags as strict labels during sampling, we initialize the Gibbs sampler so that each token in a document is assigned to its label given by the tag, when available. In the absence of tags (in f-LDA-2), we initialize tokens

to the GENERAL components. We initialized ω to its prior mean (Eq. 3), while the variance σ^2 and the initialization of bias $\omega^{(B)}$ are chosen to optimize likelihood on the held-out development set.

We optimized the hyperparameters and sparsity array using gradient descent after each Gibbs sweep. We use a decreasing step size of $a/(t+1000)$, where t is the current iteration and $a=10$ for α and 1 for ω and the sparsity values. To learn priors η , we ran our version of SAGE for 100 iterations of gradient ascent (fixed step size of 0.1). See Paul and Dredze (2012a) for examples of parameters (the top words associated with various triples) learned by this model on this corpus.

4.2 Summary Generation

We created twelve reference summaries by editing together excerpts from the five Psychonaut Project reports ((Psychonaut), 2009). Each reference is matched to drug-specific pairs and triples. For example, a paragraph describing the differences in effects of salvia between smoking and oral routes was matched to distributions for (SALVIA,EFFECTS), (SALVIA,SMOKING,EFFECTS), (SALVIA,ORAL,EFFECTS). Descriptions of creating tinctures and blotters for oral consumption were matched to (SALVIA,ORAL,CHEMISTRY). We consider pairs in addition to triples because not all summaries correspond to particular routes or aspects.

For each tuple-specific word distribution (a pair or a triple), we create a “summary” by extracting a set of five text snippets which minimize KL-divergence to the target word distribution. We consider all overlapping text windows of widths $\{10,15,20\}$ in the corpus as candidate snippets. Following Haghghi and Vanderwende (2009), we greedily add snippets one by one with the lowest KL-divergence at each step until we have added five.

We only considered candidate snippets within the subforum for the particular drug, and snippets are based on the preprocessed topic model input with no stop words. Before presenting snippets to users, we then map the snippets back to the raw text by taking all sentences which are at least partly spanned by the window of tokens. Because each reference may be matched to more than one tuple, there may be more than five snippets which correspond to a reference.

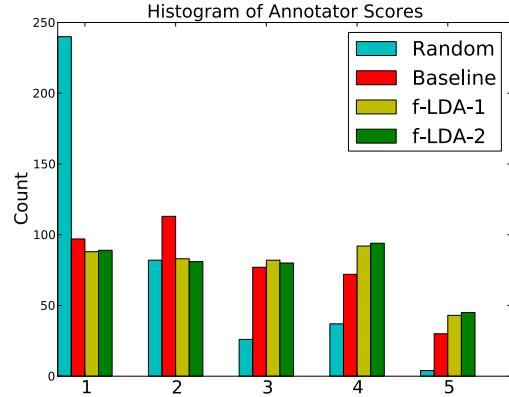

Figure 4: The distribution of annotator scores (§4.3.1). The “Random” counts have been scaled to fit the same range as the other systems, since fewer random snippets were shown to annotators.

4.3 Experimental Results

Recall that the reports used as reference summaries were themselves created by reading web forums. Our hypothesis is that f-LDA could be used as an exploratory tool to expedite the creation of these reports. Thus in our evaluation we want to measure how useful the extracted snippets would be in informing the writing of such reports. We performed both human and automatic evaluation on the summaries generated by f-LDA (variants 1 and 2) as well as our baseline. We also included randomly selected snippets as a control (five per reference).

Example output is shown in Figure 3.

4.3.1 Human Judgments of Quality

Three annotators were presented snippets pooled from all four systems we are evaluating alongside the corresponding reference text. Within each set corresponding to a reference summary, the snippets were shown in a random order. Annotators were asked to judge each snippet independently on a 5-point Likert scale as to how useful each snippet would be in writing the reference text.

The distribution of scores is shown in Figure 4 and summarized in Table 2. Annotators generally agreed on the relative quality of snippets: the average correlation of scores between each pair of annotators was 0.49. Snippets produced by f-LDA were given more high scores and fewer low scores than the baseline, while the two f-LDA variants were rated comparably. The breakdown is more interesting when we compare scores for snippets that were matched

	Rand.	Base.	f-LDA-1	f-LDA-2
Annotator Scores				
Mean	1.67	2.55	2.79	2.81
Pairs only	n/a	2.58	2.79	2.72
Triples only	n/a	2.50	2.80	2.95
ROUGE				
1-gram	.112	.326	.355	.327
2-gram	.023	.072	.085	.084

Table 2: Summary quality evaluation across four systems.

to word distributions for pairs versus word distributions for triples. The gap in scores between f-LDA and the baseline increases when we look at the scores for only triples: f-LDA beats the baseline by a margin of 0.45 for snippets matched to triples and 0.21 for pairs. This suggests that we produce better triples by modeling them jointly. For triples, f-LDA-2 (which uses more data) beats f-LDA-1 (which uses only tagged data), while the reverse is true for pairs.

While some of the randomly selected control snippets happened to be useful, the scores for these snippets were much lower than those extracted through model-based systems. This suggests that exploring the forums in a targeted way (e.g. through our topic model approach) would be more efficient than exploring the data in a non-targeted way (akin to the random approach).

Finally, we asked two expert annotators (faculty members in psychiatry and behavioral pharmacology, who have used drug forums in the past to study emerging drugs) to rate the snippets corresponding to mephedrone/MDPV. The best f-LDA system had an average score of 2.57 compared to a baseline score of 2.45 and random score of 1.63.

4.3.2 Automatic Evaluation of Recall

The human judgments effectively measured a form of precision, as the quality of snippets were judged by their correspondence to the reference text, without regard to how much of the reference text was covered by all snippets. We also used the automatic evaluation metric ROUGE (Lin, 2004) as a rough estimate of summary recall: this metric computes the percentage of n -grams in the reference text that appeared in the generated summaries.

We computed ROUGE for both 1-grams and 2-grams. When computing n -gram counts, we applied Porter’s stemmer to all tokens. We excluded stop

words from 1-gram counts but included them in 2-gram counts where we care about longer phrases.²

Results are shown in Table 2. We find that f-LDA-1 has the highest score for both 1- and 2-grams, suggesting that it is extracting a more diverse set of relevant snippets. When performing a paired t-test across the 12 reference summaries, we find that f-LDA is better than the baseline with p -values 0.14 and 0.10 for 1-gram and 2-gram recall, respectively. f-LDA’s recall advantage may come from the fact that it learns from a larger amount of data and it may learn more diverse word distributions by directly modeling triples. f-LDA-1 had slightly better recall (under ROUGE), while f-LDA-2 was slightly better according to the human annotators.

5 Conclusion

We have proposed exploratory tools for the analysis of online drug communities. Such communities are an emerging source of drug research, but manually browsing through large corpora is impractical and important information could be missed. We have demonstrated that topic models are capable of modeling informative portions of text, and in particular multi-dimensional topic models can target desired structures such as the combination of aspect and route of administration for each drug. We have presented an extension to factorial LDA tailored to a particular application and data set which was demonstrated to induce desired properties. As a technical contribution, this study lays out practical guidelines for customizing and incorporating prior knowledge into multi-dimensional text models.

Acknowledgments

We are grateful to Dr. Margaret S. Chisolm and Dr. Ryan Vandrey from the Johns Hopkins School of Medicine for providing the mephedrone/MDPV annotations, and Alex Lamb and Hieu Tran for assisting with the full annotations. We also thank Dr. Matthew W. Johnson for additional advice, and the anonymous reviewers for helpful feedback and suggestions. This research was partly supported by an NSF Graduate Research Fellowship.

²In both cases, ROUGE scores were higher when stop words were included. f-LDA beats the baseline by similar margins regardless of whether we include stop words.

Towards Topic Labeling with Phrase Entailment and Aggregation

Yashar Mehdad Giuseppe Carenini Raymond T. Ng Shafiq Joty

Abstract

We propose a novel framework for topic labeling that assigns the most representative phrases for a given set of sentences covering the same topic. We build an entailment graph over phrases that are extracted from the sentences, and use the entailment relations to identify and select the most relevant phrases. We then aggregate those selected phrases by means of phrase generalization and merging. We motivate our approach by applying over conversational data, and show that our framework improves performance significantly over baseline algorithms.

1 Introduction

Given text segments about the same topic written in different ways (*i.e.*, language variability), topic labeling deals with the problem of automatically generating semantically meaningful labels for those text segments. The potential of integrating topic labeling as a prerequisite for higher-level analysis has been reported in several areas, such as summarization (Harabagiu and Lacatusu, 2010; Kleinbauer et al., 2007; Dias et al., 2007), information extraction (Allan, 2002) and conversation visualization (Liu et al., 2012). Moreover, the huge amount of textual data generated everyday specifically in conversations (*e.g.*, emails and blogs) calls for automated methods to analyze and re-organize them into meaningful coherent clusters.

Table 1 shows an example of two human written topic labels for a topic cluster collected from a blog¹,

Text: a: Where do you think the term “Horse laugh” comes from?

b: And that rats also giggled when tickled.

c: My hypothesis- if an animal can play, it can “laugh” or at least it is familiar with the concept of “laughing”.

Many animals play. There are various sorts of humour though. Some involve you laughing because your brain suddenly made a lots of unexpected connections.

Possible extracted phrases: animals play, rats have, laugh, Horse laugh, rats also giggle, rats

Human-authored topic labels: animals which laugh, animal laughter

Table 1: Topic labeling example.

and possible phrases that can be extracted from the topic cluster using different approaches. This example demonstrates that although most approaches (Mei et al., 2007; Lau et al., 2011; Branavan et al., 2007) advocate extracting phrase-level topic labels from the text segments, topically related text segments do not always contain one keyword or key phrase that can capture the meaning of the topic. As shown in this example, such labels do not exist in the original text and cannot be extracted using the existing probabilistic models (*e.g.*, (Mei et al., 2007)). The same problem can be observed with many other examples. This suggests the idea of aggregating and generating topic labels, instead of simply extracting them, as a challenging scenario for this field of research.

Moreover, to generate a label for a topic we have to be able to capture the overall meaning of a topic. However, most current methods disregard semantic relations, in favor of statistical models of word distributions and frequencies. This calls for the integra-

¹<http://slashdot.org>

tion of semantic models for topic labeling.

Towards the solution of the mentioned problems, in this paper we focus on two novel contributions:

1. Phrase aggregation. We propose to generate topic labels using the extracted information by producing the most representative phrases for each text segment. We perform this task in two steps. First, we generalize some lexically diverse concepts in the extracted phrases. Second, we aggregate and generate new phrases that can semantically imply more than one original extracted phrase. For example, the phrase “*rats also giggle*” and “*horse laugh*” should be merged into a new phrase “*animals laugh*”. Although our method is still relying on extracting phrases, we move beyond current extractive approaches, by generating new phrases through generalization and aggregation of the extracted ones.

2. Building a multidirectional entailment graph over the extracted phrases to identify and select the relevant information. We set such problem as an application-oriented variant of the Textual Entailment (TE) recognition task (Dagan and Glickman, 2004), to identify the information that are semantically equivalent, novel, or more informative with respect to the content of the others. In this way, we prune the redundant and less informative text portions (*e.g.*, phrases), and produce semantically informed phrases for the generation phase. In the case of the example in Table 1, we eliminate phrases such as “*rats have*”, “*rats*” and “*laugh*” while keeping “*animal play*”, “*Horse laugh*” and “*rats also giggle*”.

The experimental results over conversational data sets show that, in all cases, our approach outperforms other models significantly. Although conversational data are known to be challenging (Carenini et al., 2011), we choose to test our method on conversations because this is a genre in which topic modeling is critically needed, as conversations lack the structure and organization of, for instance, edited monologues. The results indicate that our framework is sufficiently robust to deal with topic labeling in less structured, informal genres (when compared with edited monologues). As an additional result of our experiments, we show that the identification and selection phase using semantic relations (entailment graph) is a necessary step to perform the final step (*i.e.*, the phrase aggregation).

2 Topic Labeling Framework

Each topic cluster contains the sentences that can semantically represent a topic. The task of clustering the sentences into a set of coherent topic clusters is called topic segmentation (Joty et al., 2011), which is out of the scope of this paper. Our goal is to generate an understandable label (*i.e.*, a sequence of words) that could capture the semantic of the topic, and distinguish a topic from other topics (based on definition of a good topic label by (Mei et al., 2007)), given a set of topic clusters. Among possible choices of word sequences as topic labels, in order to balance the granularity, we set phrases as valid topic labels.

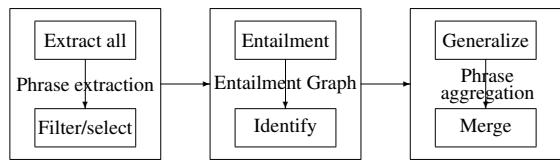

Figure 1: Topic labeling framework.

As shown in Figure 1, our framework consists of three main components that we describe in more details in the following sections.

2.1 Phrase extraction

We tokenize and preprocess each cluster in the collection of topic clusters with lemmas, stems, part-of-speech tags, sense tags and chunks. We also extract n-grams up to length 5 which do not start or end with a stop word. In this phase, we do not include any frequency count feature in our candidate extraction pipeline. Once we have built the candidates pool, the next step is to identify a subset containing the most significant of those candidates. Since most top systems in key phrase extraction use supervised approaches, we follow the same method (Kim et al., 2010b; Medelyan et al., 2008; Frank et al., 1999).

Initially, we consider a set of features used in the other systems to determine whether a phrase is likely to be a key phrase. However, since our dataset is conversational (more details in Section 3), and the text segments are not long, we aim for a classifier with high recall. Thus, we only use TFxIDF (Salton and McGill, 1986), position of the first occurrence (Frank et al., 1999) and phrase length as our features. We merge the training and test data released

for SemEval-2010 Task #5 (Kim et al., 2010b), which consists of 244 scientific articles and 3705 key phrases, to train a Naive Bayes classifier in order to learn a supervised model. We then apply our model to extract the candidate phrases from the collected candidates pool.

As a further step, to increase the coverage (recall) of our extracted phrases and to reduce the number of very short phrases (frequent keywords), we choose the chunks containing any of the extracted keywords. We add those chunks to our extracted phrases and eliminate the associated keywords.

2.2 Entailment graph

So far, we have extracted a pool of key phrases from each topic cluster. Many such phrases include redundant information which are semantically equivalent but vary in lexical choices. By identifying the semantic relations between the phrases we can discover the information in one phrase that is semantically equivalent, novel, or more/less informative with respect to the content of the other phrase.

We set this problem as a variant of the Textual Entailment (TE) recognition task (Mehdad et al., 2010b; Adler et al., 2012; Berant et al., 2011). We build an entailment graph for each topic cluster, where nodes are the extracted phrases and edges are the entailment relations between nodes. Given two phrases (ph_1 and ph_2), we aim at identifying and handling the following cases:

- i) ph_1 and ph_2 express the same meaning (*bidirectional* entailment). In such cases one of the phrases should be eliminated;
 - ii) ph_1 is more informative than ph_2 (*unidirectional* entailment). In such cases, the entailing phrase should replace or complement the entailed one;
 - iii) ph_1 contains facts that are not present in ph_2 , and vice-versa (the “*unknown*” cases in TE parlance). In such cases, both phrases should remain.

Figure 2 shows how entailment relations can help in selecting the phrases by removing the redundant and less informative ones. For example, the phrase “*animals laugh*” entails “*rats giggle*”, “*Horse laugh*” and “*Mice chuckle*”,² but not “*Animals play*”.

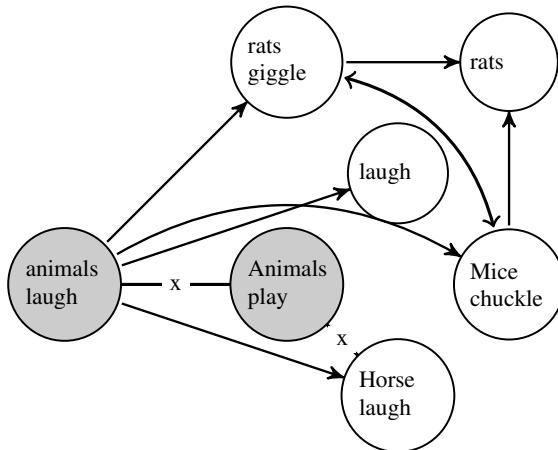

Figure 2: Building an entailment graph over phrases. Arrows and “x” represent the entailment direction and unknown cases respectively.

So we can keep “*animals laugh*” and “*Animals play*” and eliminate others. In this way, TE-based phrase identification method can be designed to distinguish meaning-preserving variations from true divergence, regardless of lexical choices and structures.

Similar to previous approaches in TE (*e.g.*, (Berant et al., 2011; Mehdad et al., 2010b; Mehdad et al., 2010a)), we use supervised method. To train and build the entailment graph, we perform the following three steps.

2.2.1 Training set collection

In the last few years, TE corpora have been created and distributed in the framework of several evaluation campaigns, including the Recognizing Textual Entailment (RTE) Challenge³ and Cross-lingual textual entailment for content synchronization⁴ (Negri et al., 2012). However, such datasets cannot directly support our application. Specifically, our entailment graph is built over the extracted phrases (with max. length of 5 tokens per phrase), while the RTE datasets are composed of longer sentences and paragraphs (Bentivogli et al., 2009; Negri et al., 2011).

In order to collect a dataset which is more similar to the goal of our entailment framework, we decide to select a subset of the sixth and seventh RTE challenge main task (*i.e.*, RTE within a Corpus). Our

²Assuming that “animals laugh” is interpreted as “all animals laugh”.

³<http://pascallin.ecs.soton.ac.uk/Challenges/RTE/>

⁴<http://www.cs.york.ac.uk/semeval-2013/task8/>

dataset choice is based on the following reasons: *i*) the length of sentence pairs in RTE6 and RTE7 is shorter than the others, and *ii*) RTE6 and RTE7 main task datasets are originally created for summarization purpose which is closer to our work. We sort the RTE6 and RTE7 dataset pairs based on the sentence length and choose the first 2000 samples with an equal number of positive and negative examples. The average length of words in our training data is 6.7 words. There are certainly some differences between our training set and our phrases. However, the collected training samples was the closest available dataset to our purpose.

2.2.2 Feature representation and training

Working at the phrase level imposes another constraint. Phrases are short and in terms of syntactic structure, they are not as rich as sentences. This limits our features to the lexical level. Lexical models, on the other hand, are less computationally expensive and easier to implement and often deliver a strong performance for RTE (Sammons et al., 2011).

Our entailment decision criterion is based on similarity scores calculated with a phrase-to-phrase matching process. Each example pair of phrases (ph_1 and ph_2) is represented by a feature vector, where each feature is a specific similarity score estimating whether ph_1 entails ph_2 .

We compute 18 similarity scores for each pair of phrases. In order to adapt the similarity scores to the entailment score, we normalize the similarity scores by the length of ph_2 (in terms of lexical items), when checking the entailment direction from ph_1 to ph_2 . In this way, we can check the portion of information/facts in ph_2 which is covered by ph_1 .

The first 5 scores are computed based on the exact lexical overlap between the phrases: word overlap, edit distance, ngram-overlap, longest common subsequence and Lesk (Lesk, 1986). The other scores were computed using lexical resources: WordNet (Fellbaum, 1998), VerbOcean (Chklovski and Pantel, 2004), paraphrases (Denkowski and Lavie, 2010) and phrase matching (Mehdad et al., 2011). We used WordNet to compute the word similarity as the least common subsumer between two words considering the synonymy-antonymy, hypernymy-hyponymy, and meronymy relations. Then, we calculated the sentence similarity as the sum of the sim-

ilarity scores of the word pairs in Text and Hypothesis, normalized by the number of words in Hypothesis. We also use phrase matching features described in (Mehdad et al., 2011) which consists of phrasal matching at the level on ngrams (1 to 5 grams). The rationale behind using different entailment features is that combining various scores will yield a better model (Berant et al., 2011).

To combine the entailment scores and optimize their relative weights, we train a Support Vector Machine binary classifier, SVMlight (Joachims, 1999), over an equal number of positive and negative examples. This results in an entailment model with 95% accuracy over 2-fold and 5-fold cross-validation, which further proves the effectiveness of our feature set for this lexical entailment model. The reason that we gained a very high accuracy is because our selected sentences are a subset of RTE6 and RTE7 with a shorter length (less number of words) which makes the entailment recognition task much easier than recognizing entailment between paragraphs or complex long sentences.

2.2.3 Graph edge labeling

We set the edge labeling problem as a two-way classification task. Two-way classification casts multidirectional entailment as a unidirectional problem, where each pair is analyzed checking for entailment in both directions (Mehdad et al., 2012). In this condition, each original test example is correctly classified if both pairs originated from it are correctly judged (“YES-YES” for bidirectional, “YES-NO” and “NO-YES” for unidirectional entailment and “NO-NO” for unknown cases). Two-way classification represents an intuitive solution to capture multidimensional entailment relations. Moreover, since our training examples are labeled with binary judgments, we are not able to train a three-way classifier.

2.2.4 Identification and selection

Assigning all entailment relations between the extracted phrase pairs, we are aiming at identifying relevant phrases and eliminating the redundant (in terms of meaning) and less informative ones. In order to perform this task we follow a set of rules based on the graph edge labels. Note that since entailment

#	Merging patterns
1	merge ($cw1_{(CPOS=[N V J])}..w1_n, cw2_{(CPOS=[N V J])}..w2_n$) = $w1..w1_n$ and $w2..w2_n$
E.g.	merge (<i>challenging situation</i> , <i>challenging problem</i>) = <i>challenging situation and problem</i>
2	merge ($w1_1..cw1_{n(CPOS=[N V J])}, w2_1..cw2_{n(CPOS=[N V J])}$) = $w1..w1_{n-1}$ and $w2..w2_n$
E.g.	merge (<i>wet Mars</i> , <i>warm Mars</i>) = <i>wet and warm Mars</i>
3	merge ($w1_1..cw1_{n(CPOS=[N V J])}, cw2_{(CPOS=[N V J])}..w2_n$) = $w1..w1_n w2..w2_n$
E.g.	merge (<i>interesting story</i> , <i>story continues</i>) = <i>interesting story continues</i>
4	merge ($cw1_{(CPOS=[N V J])}..w1_n, w2_1..cw2_{n(CPOS=[N V J])}$) = $w2..w2_n w1..w1_n$
E.g.	merge (<i>LHC shutting down</i> , <i>details about LHC</i>) = <i>details about LHC shutting down</i>
5	merge ($w1_{Cpos}, cw1_{2(CPOS=[N V J])}, w1_{3Cpos}, w2_{1Cpos}, cw2_{2(CPOS=[N V J])}, w2_{3Cpos}$) = $w1$ and $w2..w2_n$
E.g.	merge (<i>technology grow fast</i> , <i>media grow exponentially</i>) = <i>technology and media grow exponentially and fast</i>

Table 2: Phrase merging patterns.

is a transitive relation, our entailment graph is transitive *i.e.*, if entail(ph_1, ph_2) and entail(ph_2, ph_3) then entail(ph_1, ph_3) (Berant et al., 2011).

Rule 1) If there is a chain of entailing nodes, we keep the one which is in the root of the chain and eliminate others (e.g. “*animals laugh*” in Figure 2);

Rule 2) Among the nodes that are connected with bidirectional entailment (semantically equivalent nodes) we keep only the one with more outgoing bidirectional and unidirectional entailment relations, respectively;

Rule 3) Among the nodes that are connected with unknown entailment (novel information with respect to others) we keep the ones with no incoming entailment relation (e.g., “*Animals play*” in Figure 2).

Although deleting might be harsh, in our current framework, we only rely on the performance of an entailment model which gives us a yes/no entailment decision. In future, we are planning to improve our entailment graph by weighting the edges. In this way, we can take advantage of the weights to make a more conservative decision in pruning the entailment chains.

2.3 Phrase aggregation

Once we have identified and selected the informative phrases, the generation of topic labels can be done in two steps. First, we generalize the phrases containing the concepts that are lexically connected. Second, we merge the phrases with a set of hand written linguistically motivated patterns.

2.3.1 Phrase generalization

In this step, we generalize phrases that contain concepts which are lexically connected. For this

purpose, we search in phrases for different words with the same part-of-speech and sense tag. Then, we find the link between those words in WordNet. If they are connected and the shortest path connecting them is less than 3 (estimated over the development set), we replace both by their common parent in the WordNet. In the case that they belong to the same synset, we can replace one by another. Note that we limit our search to nouns and verbs. For example, “*rat*” and “*horse*” can be replaced by “*animal*”, or “*giggle*” and “*chuckle*” can be replaced by “*laugh*”. The motivation behind the generalization step is to enrich the common terms between the phrases in favor of increasing the chance that they could merge to a single phrase. This also helps to move beyond the limitation of original lexical choices.

2.3.2 Phrase merging

The goal is to merge the phrases that are connected, and to generate a human readable phrase that contains more information than a single extracted phrase. Several approaches have been proposed to aggregate and merge sentences in Natural Language Generation (NLG) (*e.g.* (Barzilay and Lapata, 2006; Cheng and Mellish, 2000)), however most of them use syntactic structure of the sentences. To merge phrases at the lexical level, we set few common linguistically motivated aggregation patterns such as: simple conjunction, and conjunction via shared participants (Reiter and Dale, 2000).

Table 2 demonstrates the merging patterns, where w_{ij} is the j th word (or segment) in phrase i , cw is the common word (or segment) in both phrases and $CPOS$ is the common part-of-speech tag of the corresponding word. To illustrate, pattern 1

looks for the first segment of each phrase (w_{i1}). If they are same (cw_{i1}) and share the same POS tag (C_{POS}), then we aggregate the first phrase ($w_{11}..w_{1n}$) and the second phrase removing the first element ($w_{21}..w_{2n}$) by using the connective “*and*”. For instance, the aggregation of “*animals laugh*” and “*animals play*” results in “*animals laugh and play*”. The rest of the patterns follow the same logic and for the sake of brevity we avoid illustrating each pattern. These patterns are among the most common domain and application independent methods by which two phrases/sentences can be aggregated, as described in the NLG literature (Reiter and Dale, 2000).

In our aggregation pipeline, we group the phrases based on their lexical overlap (number of common words). The merging process is conducted over each group in descending order (larger number of words in common), in order to increase the chance of merging rules application. Then, we perform the merging over the resulting generated phrases from each group. If our phrases cannot be merged (*i.e.*, do not match merging patterns), we select them as labels for the topic cluster.

3 Datasets and Evaluation Metrics

3.1 Datasets

To verify the effectiveness of our approach, we experiment with two different conversational datasets. Our interest in dealing with conversational texts derives from two reasons. First, the huge amount of textual data generated everyday in these conversations validates the need of text analysis frameworks to process such conversational texts effectively. Second, conversational texts pose challenges to the traditional techniques, including redundancies, disfluencies, higher language variabilities and ill-formed sentence structure (Liu et al., 2011).

Our conversational datasets are from two different asynchronous media: email and blog. For email, we use the dataset presented in (Joty et al., 2010), where three individuals annotated the publicly available BC3 email corpus (Ulrich et al., 2008) with topics. The corpus contains 40 email threads (or conversations) at an average of 5 emails per thread. On average it has 26.3 sentences and 2.5 topics per thread. A topic has an average length of 12.6 sentences. In total, the three annotators found 269 topics in a cor-

pus of 1,024 sentences.

There are no publicly available blog corpora annotated with topics. For this study, we build our own blog corpus containing 20 blog conversations of various lengths from Slashdot, each annotated with topics by three human annotators.⁵ The number of comments per conversation varies from 30 to 101 with an average of 60.3 and the number of sentences per conversation varies from 105 to 430 with an average of 220.6. The annotators first read a conversation and list the topics discussed in the conversation by a short description (*e.g.*, Game contents or size, Bugs or faults) which provides a high-level overview of the topic. Then, they assign the most appropriate topic to each sentence in the conversation. The short high-level descriptions of the topics serve as reference (or gold) topic labels in our experiments. The target number of topics was not given in advance and the annotators were instructed to find as many topics as needed to convey the overall content structure of the conversation. The annotators found 5 to 23 topics per conversation with an average of 10.77. The number of sentences per topic varies from 11.7 to 61.2 with an average of 27.16. In total, the three annotators found 512 topics in our blog corpus containing 4,411 sentences overall.

Note that our annotators performed topic segmentation and labeling independently. In the email corpus, the three annotators found 100, 77 and 92 topics respectively (269 in total), and in the blog corpus, they found 251, 119 and 192 topics respectively (562 in total). For the evaluation, there is a single gold standard per topic written by each annotator. Table 1 shows a case in which two annotators selected the same topical cluster and so we have two labels for the same cluster.

3.2 Evaluation metrics

Traditionally, key phrase extraction is evaluated using precision, recall and f-measure based on exact matches on all the extracted key phrases with gold standards for a given text. However, as claimed by (Kim et al., 2010a), this approach is not flexible enough as it ignores the near-misses. Moreover, in the case of topic labeling, most of the human written

⁵The new blog corpus annotated with topics will be made publicly available for research purposes.

topic labels cannot be found in the text. Recently, (Kim et al., 2010a) evaluated the utility of different n-gram-based metrics for key phrase extraction and showed that the metric *R-precision* correlates most with human judgments. *R-precision* normalizes the approximate matching score by the maximum number of words in the reference and candidate phrases. Since this penalize our aggregation phase, where the phrases tend to be longer than original extracted phrase, we decide to use *R-f1* as our evaluation metric which considers length of both reference and candidate phrases.

$$\begin{aligned} R\text{-}precision &= \frac{1}{k} \sum_{i=1}^k \frac{\text{overlap}(cand_i, ref)}{\#\text{words}(cand_i)} \\ R\text{-}recall &= \frac{1}{k} \sum_{i=1}^k \frac{\text{overlap}(cand_i, ref)}{\#\text{words}(ref)} \\ R\text{-}f1 &= \frac{2 * R\text{-}precision * R\text{-}recall}{(R\text{-}precision + R\text{-}recall)} \end{aligned}$$

The metric described above only considers word overlap and ignores other semantic relations (e.g., synonymy, hypernymy) between words. However, annotators write labels of their own and may use words that are not directly from the conversation but are semantically related. Therefore, we propose to also use another variant of *R-f1* that incorporates semantic relation between words. To calculate the *Semantic R-f1*, we count the number of overlaps not only when they have the same form, but also when they are connected in WordNet with a synonymy, hypernymy, hyponymy and entailment relation.

Its worth noting that the generalizations phase and the evaluation method are completely independent. In the generalization step, we try to generalize the phrases which are automatically extracted from the text segments. While, in the evaluation, we compare the human written gold standards with the system output. Therefore, using WordNet in the generalization step does not bias the results in the evaluation.

4 Experiments and Results

4.1 Experimental settings

We conduct our experiments over the blog and email datasets described in Section 3.1, after eliminating the development set from the test datasets. In our ex-

periments, the development set was used for the pattern extraction and the shortest path threshold connecting the words in Wordnet in the generalization phase. Our test dataset consists of 461 topics (*i.e.*, clusters and their associated topic labels) from 20 blog conversations and 242 topics from 40 email conversations.

For preprocessing our dataset we use OpenNLP⁶ for tokenization, part-of-speech tagging and chunking. For sense disambiguation, we use the extended gloss overlap measure with the window size of 5, developed by (Pedersen et al., 2005). We also apply Snowball algorithm (Porter, 2001) for stemming.

We compare our approach with two strong baselines. The first baseline Freq-BL ranks the words according to their frequencies and select the top 5 candidates applying Maximum Marginal Relevance algorithm (Carbonell and Goldstein, 1998) using the same pre- and post-processing as the work by (Mihalcea and Tarau, 2004). The second baseline Lead-BL, ranks the words based on their relevance to the leading sentences.⁷ The ranking criteria is $\log(tf_{w,L_t} + 1) \times \log(tf_{w,t} + 1)$, where tf_{w,L_t} and $tf_{w,t}$ are the number of times word w appears in a set of leading sentences L_t and topic cluster t , respectively (Allan, 2002). The log expressions, as the ranking criterion, assign more weights to the words in the topic segment, that also appear in the leading sentences. This is because topics tend to be introduced in the first few sentences of a topical cluster. We also measure the performance of our framework at each step in order to compare the effectiveness of each phase independently or in combination.

4.2 Results

We evaluate the performance of different models using the metrics *R-f1* and *Semantic R-f1* (*Sem-R-f1*), described in Section 3.2. Table 4 shows the results in percentage for different models. The results show that our framework outperforms the baselines signif-

⁶<http://opennlp.sourceforge.net/>

⁷The key intuitions for this baseline is the leading sentences of a topic cluster carry the most informative clues for the topic labels. Based on our development set, when we consider the first three sentences, the coverage of content words that appear in human labeled topics are 39% and 49% for blog and email, respectively.

Blog		Email	
Human-authored	system generated	Human-authored	system generated
<i>Shutting down the LHC</i>	<i>story about the LHC shutting down (#3)</i>	<i>How it affects coding</i>	<i>it screws my coding</i>
<i>typical shutdown and upgrade times</i>	<i>typical and scheduled shutdown (#2)</i>	<i>Opinions and preferences of tools</i>	<i>opinion about what tools</i>
<i>MARS was warm and wet 3B years ago</i>	<i>Mars was warm and wet early history (#3)</i>	<i>white on black for disabled users</i>	<i>white text on black background (#3)</i>
<i>Moon Treaty and outer space treaty</i>	<i>Moon and Outer Space Treaty (#2)</i>	<i>Contact with Steven</i>	<i>email to Steven Pemberton (#3)</i>

Table 3: Successful examples of human-authored and system generated labels for blog and email datasets. The number near some examples refers to the aggregation patterns in Table 2.

Models	R-f1		Sem-R-f1	
	blog	email	blog	email
Lead-BL	13.5	14.0	34.5	30.1
Freq-BL	15.3	13.1	34.7	29.1
Extraction-BL	13.9	16.0	31.6	33.2
Entailment	12.2	15.6	30.8	33.3
Extraction+Aggregation	15.1	18.5	35.5	37.6
Extraction+Entailment+Aggregation	17.9	20.4	38.7	41.6

Table 4: Results for candidate topic labels on blog and email corpora.

icantly⁸ in both datasets.

On the blog corpus, our key phrase extraction method (*Extraction-BL*) fails to beat the other baselines (Lead-BL and Freq-BL) in majority of cases (except R-f1 for Lead-BL). However, in the email dataset, it improves the performance over both baselines in both evaluation metrics. This might be due to the shorter topic clusters (in terms of number of sentences) in email corpus which causes a smaller number of phrases to be extracted.

We also observe the effectiveness of the aggregation phase. In all cases, there is a significant improvement ($p < 0.05$) after applying the aggregation phase over the extracted phrases (*Extraction+Aggregation*).

Note that there is no improvement over the extraction phase after the entailment (*Entailment* row). This is mainly due to the fact that the entailment phase filters the equivalent phrases. This affects the results negatively when such filtered phrases share many common words with our human-authored phrases. However, the results improve more significantly ($p < 0.01$) when the aggregation is conducted after the entailment. This demonstrates that, the combination of these two steps are beneficial for topic labeling over conversational datasets.

In addition, the differences between the results us-

ing *R-f1* and *Sem-R-f1* metrics suggests the need for more flexible automatic evaluation methods for this task. Moreover, although the same trend of improvement is observed in blog and email corpora, the differences between their performance suggest the investigation of specialized methods for various conversational modalities.

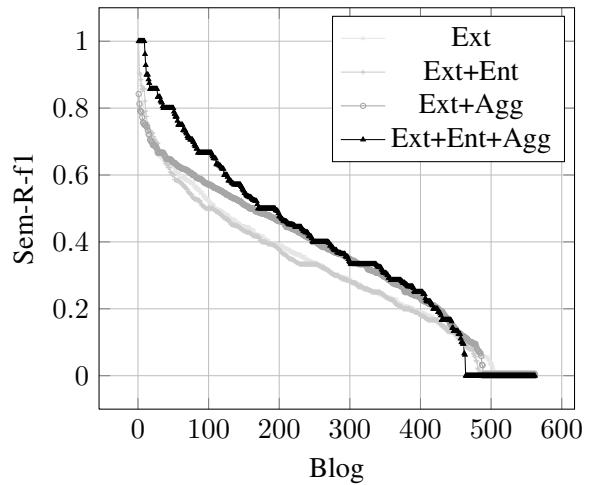

Figure 3: *Sem-R-f1* results distribution after each phase of our pipeline for blog corpus. The x-axis represents the examples sorted based on their *Sem-R-f1* score.

To further analyze the performance, in Figure 3, we show the *Sem-R-f1* results distribution for our blog dataset.⁹ We can observe that the aggregation after the entailment phase (bold curve) clearly increase the number of correct labels, while such improvement can be only achieved when the entailment relations is used to identify the relevant phrases. This further highlights the need of semantics in this task. Comparing both datasets, this effect is more dominant in blogs. We believe that this is due to the length of topic clusters. Presumably, building an entailment graph over a greater pool of

⁸The statistical significance tests was calculated by approximate randomization described in (Yeh, 2000).

⁹For brevity's sake we do not show the email dataset graph.

original phrases is more effective to filter the redundant information and identify the relevant phrases.

5 Discussion

After analyzing the results and through manual verification of some cases, we observe that our approach led to some interestingly successful examples. Table 3 shows few generated labels and the human written topics for such cases.

In general, given that the results are expressed in percentage, it appears that the performance is still far from satisfactory level. This leaves an interesting challenge for the research community to tackle. However, this is not always due to the weakness of our proposed model. We have identified three different system independent sources of error:¹⁰

Type 1: Abstractive human-authored labels: the nature of our method is based on extraction (with the exception of our simple generalization phase) and in many cases the human-written labels cannot be extracted from the text and require more complex generalizations. In fact, only 9.81% of the labels in blog and 12.74% of the labels in email appear verbatim in their respective conversations. For example:

Human-authored label: *meeting schedule and location*

Generated phrases: *meeting, Boston area, mid October*

Type 2: Evaluation methods: in this work, we proposed a semantic method to evaluate our system. However, the current evaluation methods fail to capture the meaning. For example:

Human-authored label: *Food choices*

Generated phrase: *I would ask what people want to eat*

Type 3: Subjective topic labels: often is not easy for human to agree on one label for a topic cluster.¹¹

For example:

Human-authored label 1: *Member introduction*

Human-authored label 2: *Bio of Len*

Generated phrases: *own intro, Len Kasday, chair*

In light of this analysis, we conclude that a more comprehensive evaluation method (e.g., human evaluation) could better reveal the potential of our sys-

¹⁰There are many examples of such cases, however for brevity we just mention one example for each type.

¹¹The mean R-precision agreements computed based on one-to-one mappings of the topic clusters are 20.22 and 36.84 on blog and email data sets, respectively.

tem in dealing with topic labeling, specially on conversational data.

6 Conclusion

In this paper, we study the problem of automatic topic labeling, and propose a novel framework to label topic clusters with meaningful readable phrases. Within such framework, this paper makes two main contributions. First, in contrast with most current methods based on fully extractive models, we propose to aggregate topic labels by means of generalizing and merging techniques. Second, beyond current approaches which disregard semantic information, we integrate semantics by means of building textual entailment graphs over the topic clusters. To achieve our objectives, we successfully applied our framework over two challenging conversational datasets. Coherent results on both datasets demonstrate the potential of our approach in dealing with topic labeling task.

Future work will address both the improvement of our aggregation phase and ranking the output candidate phrases for each topic cluster. On one hand, we plan to accommodate more sophisticated NLG techniques for the aggregation and generation phase. Incorporating a better source of prior knowledge in the generalization phase (e.g., YAGO or DBpedia) is also an interesting research direction towards a better phrase aggregation step. On the other hand, we plan to apply a ranking strategy to select the top candidate phrases generated by our framework.

Abstract

We present a new hierarchical Bayesian model for unsupervised topic segmentation. This new model integrates a point-wise boundary sampling algorithm used in Bayesian segmentation into a structured topic model that can capture a simple hierarchical topic structure latent in documents. We develop an MCMC inference algorithm to split/merge segment(s). Experimental results show that our model outperforms previous unsupervised segmentation methods using only lexical information on Choi’s datasets and two meeting transcripts and has performance comparable to those previous methods on two written datasets.

1 Introduction

Documents are usually comprised of topically coherent text segments, each of which contains some number of text passages (*e.g.*, sentences or paragraphs) (Salton et al., 1996). Within each topically coherent segment, one would expect that the word usage demonstrates more consistent lexical distributions (known as lexical cohesion (Eisenstein and Barzilay, 2008)) than that across segments. A linear partition of texts into topic segments may reveal information about, for example, themes of segments and the overall thematic structure of the text, and can subsequently be useful for text analysis tasks, such as information retrieval (*e.g.*, passage retrieval (Salton et al., 1996)), document summarisation and discourse analysis (Galley et al., 2003).

In this paper we consider how to automatically find a topic segmentation. It involves identifying

the most prominent topic changes in a sequence of text passages, and splits those passages into a sequence of topically coherent segments (Hearst, 1997; Beeferman et al., 1999). This task can be cast as an unsupervised machine learning problem: placing topic boundaries in unannotated text.

Although a variety of cues in text can be used for topic segmentation, such as cue phases (Beeferman et al., 1999; Reynar, 1999; Eisenstein and Barzilay, 2008)) and discourse information (Galley et al., 2003), in this paper, we focus on lexical cohesion and use it as the primary cue in developing an unsupervised segmentation model. The effectiveness of lexical cohesion has been demonstrated by Text-Tiling (Hearst, 1997), c99 (Choi, 2000), MinCut (Malioutov and Barzilay, 2006), PLDA (Purver et al., 2006), Bayesseg (Eisenstein and Barzilay, 2008), TopicTiling (Riedl and Biemann, 2012), *etc.*

Our work uses recent progress in hierarchical topic modelling with non-parametric Bayesian methods (Du et al., 2010; Chen et al., 2011; Du et al., 2012a), and is based on Bayesian segmentation methods (Goldwater et al., 2009; Purver et al., 2006; Eisenstein and Barzilay, 2008) using topic models. This can also be viewed as a multi-topic extension of hierarchical Bayesian segmentation (Eisenstein, 2009), although our use of hierarchies is used to improve the performance of linear segmentation, rather than develop hierarchical segmentation.

Recently, topic models are increasingly used in various text analysis tasks including topic segmentation. Previous work (Purver et al., 2006; Misra et al., 2008; Sun et al., 2008; Misra et al., 2009; Riedl and Biemann, 2012) has shown that using

topic assignments or topic distributions instead of word frequency can significantly improve segmentation performance. Here we consider more advanced topic models that model dependencies between (sub-)sections in a document, such as structured topic models (STMs) presented in (Du et al., 2010; Du et al., 2012b). STMs treat each text as a sequence of segments, each of which is a set of text passages (*e.g.*, a paragraph or sentence). Text passages in a segment share the same prior distribution on their topics. The topic distributions of segments in a single document are then encouraged to be similar via a hierarchical prior. This gives a substantial improvement in modelling accuracy. However, instead of explicitly learning the segmentation, STMs just leverage the existing structure of documents from the given segmentation.

Given a sequence of text passages, how can we automatically learn the segmentation? The word boundary sampling algorithm introduced in (Goldwater et al., 2009) uses point-wise sampling of word boundaries after phonemes in an utterance. Similarly, the segmentation method of PLDA (Purver et al., 2006) samples segment boundaries, but also jointly samples a topic model. This is different to other topic modelling approaches that run LDA as a precursor to a separate segmentation step (Misra et al., 2009; Riedl and Biemann, 2012). While conceptually similar to PLDA, our non-parametric approach built on STM required new methods to implement, but the resulting improvement by the standard segmentation scores is substantial.

This paper presents a new hierarchical Bayesian unsupervised topic segmentation model, integrating a point-wise boundary sampling algorithm with a structured topic model. This new model takes advantage of the high modelling accuracy of structured topic models (Du et al., 2010) to produce a topic segmentation based on the distribution of latent topics. We show that this model provides high quality segmentation performance on Choi’s dataset, as well as two sets of meeting transcripts and written texts.

In the following sections we describe our topic segmentation model and an MCMC inference algorithm for the non-parametric split/merge process. The rest of the paper is organised as follows. In Section 2 we review recent related work in the topic segmentation literature. Section 3 presents the new

topic segmentation model, followed by the derivation of a sampling algorithm in Section 4. We report the experimental results by comparing several related topic segmentation methods in Section 5. Section 6 concludes the paper.

2 Related Work

We are interested in unsupervised topic segmentation in either written or spoken language. There is a large body of work on unsupervised topic segmentation of text based on lexical cohesion. It can be characterised by how lexical cohesion is modelled.

One branch of this work represents the lexical cohesion in a vector space by exploring the word co-occurrence patterns, *e.g.*, TF or TF-IDF. Work following this line includes TextTiling (Hearst, 1997), which calculates the cosine similarity between two adjacent blocks of words purely based on the word frequency; C99 (Choi, 2000), an algorithm based on divisive clustering with a matrix-ranking scheme; LSeg (Galley et al., 2003), which uses a lexical chain to identify and weight word repetitions; U00 (Utiyama and Isahara, 2001), a probabilistic approach using dynamic programming to find a segmentation with a minimum cost; MinCut (Malioutov and Barzilay, 2006), which casts segmentation as a graph cut problem, and APS (Kazantseva and Szpakowicz, 2011), which uses affinity propagation to learn clustering for segmentation.

The other branch of this work characterises the lexical cohesion using topic models, to which the model introduced in Section 3 belongs. Lexical cohesion in this line of research is modelled by a probabilistic generative process. PLDA presented by Purver et al. (2006) is an unsupervised topic modelling approach for segmentation. It chains a set of LDAs (Blei et al., 2003) by assuming a Markov structure on topic distributions. A binary topic shift variable is attached to each text passage (*i.e.*, an utterance in (Purver et al., 2006)). It is sampled to indicate whether the j^{th} text passage shares the topic distribution with the $(j - 1)^{th}$ passage.

Using a similar Markov structure, SITS (Nguyen et al., 2012) chains a set of HDP-LDAs (Teh et al., 2006). Unlike PLDA, SITS assumes each text passage is associated with a speaker identity that is attached to the topic shift variable as supervising in-

formation. SITS further assumes speakers have different topic change probabilities that work as priors on topic shift variables. Instead of assuming documents in a dataset share the same set of topics, Bayesseg (Eisenstein and Barzilay, 2008) treats words in a segment generated from a segment specific multinomial language model, *i.e.*, it assumes each segment is generated from one topic, and a later hierarchical extension (Eisenstein, 2009) assumes each segment is generated from one topic or its parents. Other methods using as input the output of topic models include (Sun et al., 2008), (Misra et al., 2009), and (Riedl and Biemann, 2012).

In this paper we take a generative approach lying between PLDA and SITS. In contrast to PLDA, which uses a flat topic model (*i.e.*, LDA), we assume each text has a latent topic structure that can reflect the topic coherence pattern, and the model adapts its parameters to the segments to further improve performance. Unlike SITS that targets analysing multi-party meeting transcripts, where speaker identities are available, we are interested in more general texts and assume each text has a specific topic change probability, since (1) the identity information is not always available for all kinds of texts (*e.g.*, continuous broadcast news transcripts (Allan et al., 1998)), (2) even for the same author, topic change probabilities for his/her different articles might be different.

3 Segmentation with Topic Models

In documents, topically coherent segments usually encapsulate a set of consecutive passages that are semantically related (Wang et al., 2011). However, the topic boundaries between segments are often unavailable *a priori*. Thus we treat all passage boundaries (*e.g.*, sentence boundaries, paragraph boundaries or pauses between utterances) as possible topic boundaries. To recover the topic boundaries we develop a structured topic segmentation model by integrating ideas from the segmented topic model (Du et al., 2010, STM) and Bayesian segmentation models.

The basic idea of our model is that each document consists of a set of segments where text passages in the same segment are generated from the same topic distribution, called segment level topic distribution. The segment level topic distribution is drawn from a topic distribution associated with the

whole document, called document level topic distribution. The relationships between the levels is managed using Bayesian non-parametric methods and a significant change in segment level topic distribution indicates a segment change.

Our unsupervised topic segmentation model is based on the premise that using a hierarchical topic model like the STM with a point-wise segment sampling algorithm should allow better detection of topic boundaries. We believe that (1) segment change should be associated with significant change in the topic distribution, (2) topic cohesion can be reflected in document topic structure, (3) the log-likelihood of a topically coherent segment is typically higher than an incoherent segment (Misra et al., 2008).

Assume we have a corpus of D documents, each document d consists of a sequence of U_d text passages, and each passage u contains a set of $N_{d,u}$ words denoted by $w_{d,u}$ that are from a vocabulary W . Our model consists of:

Modelling topic boundary: We assume each document has its own topic shift probability π_d , a Beta distributed random variable, *i.e.*, $\pi_d \sim Beta(\lambda_0, \lambda_1)$. Then, we associate a boundary indicator variable $\rho_{d,u}$ with u , like the topic shift variable in PLDA and SITS. $\rho_{d,u}$ is Bernoulli distributed with parameter π_d , *i.e.*, $\rho_{d,u} \sim Bernoulli(\pi_d)$. It indicates whether there is a topic boundary after text passage u or not. To sample $\rho_{d,u}$, we use a point-wise sampling algorithm. Consequently, a sequence of ρ 's defines a set of segments, *i.e.*, a topic segmentation of d . For example, let a ρ vector $\rho = (0, 0, 1, 0, 1, 0, 0, 1)^T$, it gives us three segments, which are $\{1, 2, 3\}$, $\{4, 5\}$ and $\{6, 7, 8\}$.

Modelling topic structure: Following the idea of the STM, we assume each document d is associated with a document level topic distribution μ_d , which is drawn from a Dirichlet distribution with parameter α ; and text passages in topic segment s in d are generated from $\nu_{d,s}$, a segment level topic distribution. The number of segments S_d can be computed as $S_d = 1 + \sum_{u=1}^{U_d-1} \rho_{d,u}$. Then, a Pitman-Yor

¹The last 1 in ρ is the document boundary that is known *a priori*. This means one does not need to sample it.

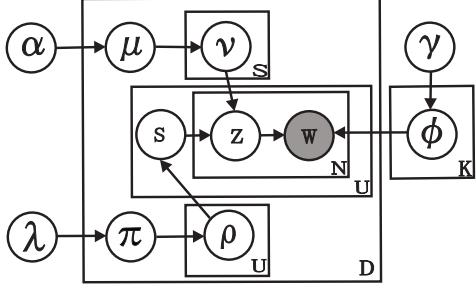

Figure 1: The topic segmentation model

process with a discount parameter a and a concentration parameter b is used to link μ_d and $\nu_{d,s}$ by $\nu_{d,s} \sim \text{PYP}(a, b, \mu_d)$, which forms a simple topic hierarchy. The idea here is that topics discussed in segments can be variants of topics of the whole document. Du *et al.* (2010) have shown that this topic structure can significantly improve the modelling accuracy, which should contribute to more accurate segmentation. This generative process is different from PLDA. PLDA does not assume the document level topic distribution and each time generates the segment level topic distribution directly from a Dirichlet distribution.

The complete probabilistic generative process, shown as a graph in Figure 1 is as follows:

1. For each topic $k \in \{1, \dots, K\}$, draw a word distribution $\phi_k \sim \text{Dirichlet}_W(\gamma)$.
2. For each document $d \in \{1, \dots, D\}$,
 - (a) Draw topic shift probability $\pi_d \sim \text{Beta}(\lambda_0, \lambda_1)$.
 - (b) Draw $\mu_d \sim \text{Dirichlet}_K(\alpha)$.
 - (c) For each text passage (except last) $u \in \{1, \dots, U_d - 1\}$, draw $\rho_{d,u} \sim \text{Bernoulli}(\pi_d)$.
 - (d) Compute S_d the number of segments as $1 + \sum_{u=1}^{U_d-1} \rho_{d,u}$.
 - (e) For each segment $s \in \{1, \dots, S_d\}$, draw $\nu_{d,s} \sim \text{PYP}(a, b, \mu_d)$.
 - (f) For each text passage $u \in \{1, \dots, U_d\}$,
 - i. Set segment $s_{d,u} = 1 + \sum_{v=1}^{u-1} \rho_{d,v}$.
 - ii. For each word index $n \in \{1, \dots, N_{d,u}\}$,
 - A. Draw topic $z_{d,u,n} \sim \text{Discrete}_K(\nu_{d,s_{d,u}})$.
 - B. Draw word $w_{d,u,n} \sim \text{Discrete}_K(\phi_{z_{d,u,n}})$.

where $s_{d,u}$ indicates which segment text passage u belongs to. We assume the dimensionality of the Dirichlet distribution (*i.e.*, the number of topics) is known and fixed, and word probabilities are parameterized with a $K \times W$ matrix $\Phi = (\phi_1, \dots, \phi_K)$. In future work we plan to investigate replace the

Table 1: List of statistics

$M_{k,w}$	total number of words with topic k .
M_k	a vector of $M_{k,w}$.
$n_{d,s,k}$	total number of words with topic k in segment s in document d .
$N_{d,s}$	total number of words in segment s .
$t_{d,s,k}$	table count of topic k in the CRP for segment s in document d .
$\mathbf{t}_{d,s}$	a vector of $t_{d,s,k}$ for segment s in d .
$T_{d,s}$	total table count in segment s .
$c_{d,1}$	total number of topic boundaries in d .
$c_{d,0}$	total number of non-topic boundaries in d .

Dirichlet prior α on μ with a Pitman-Yor prior (Pitman and Yor, 1997) to make the model fully non-parametric, like SITS.

4 Posterior Inference

In this section we develop a collapsed Gibbs sampling algorithm to do an approximate inference by integrating out some latent variables (*i.e.*, μ 's, ν 's and π_d 's). The hierarchy in our model can be well explained with the Chinese restaurant franchise metaphor introduced in (Teh *et al.*, 2006). For easier understanding, terminologies of the Chinese Restaurant Process (CRP) will be used throughout this section, *i.e.*, customers, dishes and restaurants, correspond to words, topics, and segments respectively. Statistics used are listed in Table 1.

To integrate out the $\nu_{d,s}$'s generated from the PYP, we use the technique presented in (Chen *et al.*, 2011), which computes the joint posterior for the PYP by summing out all the possible seating arrangements for a sequence of customers (Teh, 2006). In this technique an auxiliary binary variable, called *table indicator* ($\delta_{d,u,n}$), is introduced to facilitate computing table count $t_{d,s,k}$ for topic k . This method has two effects: (1) faster mixing of the sampler, and (2) elimination of the need for dynamic memory to store the populations/counts of each table in the CRP. In the CRP each word $w_{d,u,n}$ in topic k (*i.e.*, where $z_{d,u,n}=k$) contributes a count to $n_{d,s,k}$ for $u \in s$; and, if $w_{d,u,n}$, as a customer, also opens a new table to the CRP, it leads to increasing $t_{d,s,k}$ by one. In this case, $\delta_{d,u,n}=1$ indicates $w_{d,u,n}$ is the first customer on the table, called *table head*. Thus,

$$t_{d,s,k} = \sum_{u \in s} \sum_{n=1}^{N_{d,u}} \delta_{d,u,n} \mathbb{1}_{z_{d,u,n}=k}. \quad (1)$$

Note the two constraints on these two counts, *i.e.*,

$$n_{d,s,k} \geq t_{d,s,k} \geq 0 \text{ and } t_{d,s,k} = 0 \text{ iff } n_{d,s,k} = 0 \quad (2)$$

can be replaced by a simpler constraint in the table indicator representation.

The sampler we develop is an MCMC sampler on the space $\theta = \{z, \delta, \rho\}$ where z defines the topic assignments of words, δ maintains the needed CRP configuration (from which t is derived) and ρ defines the segmentation. Moreover, it is not a traditional Gibbs sampler changing one variable at a time, but is a block Gibbs sampler where two different kinds of blocks are used. The first block is $(z_{d,u,n}, \delta_{d,u,n})$ (for each word $w_{d,u,n}$), which can be sampled with a table indicator variant of a hierarchical topic sampler (Du et al., 2010), described in Section 4.1. This corresponds to Equation (6) in (Purver et al., 2006). The second kind of block is a boundary indicator $\rho_{d,u}$ together with a particular constrained set of table counts designed to handle splitting and merging, which corresponds to Equation (7) in (Purver et al., 2006). Sampling this second kind of block is harder in our non-parametric model requiring a potentially exponential summation, a problem we overcome using symmetric polynomials, shown in Section 4.2.

4.1 Sampling Topics

One step in our model is to sample the assignments of topics to words conditioned on all ρ 's. As discussed in Section 3, given the sequence of $\rho_{d,u}$'s, ρ_d , one can figure out which segment s text passage u belongs to. Thus, conditioned on a set of segments s given by ρ , the joint posterior distribution of w, z and δ is computed as $p(z, w, \delta | \rho, \Phi, a, b, \gamma)$

$$= \prod_d \frac{\text{Beta}_K(\alpha + \sum_s t_{d,s})}{\text{Beta}_K(\alpha)} \prod_k \frac{\text{Beta}_W(\gamma + M_k)}{\text{Beta}_W(\gamma)} \\ \prod_d \prod_{s \in s} \frac{(b|a)_{T_{d,s}}}{(b)_{N_{d,s}}} \prod_k S_{t_{d,s}, k, a}^{n_{d,s,k}} \binom{n_{d,s,k}}{t_{d,s,k}}^{-1}, \quad (3)$$

where $\text{Beta}_K(\cdot)$ is a K -dimension Beta function, $(x|y)_n$ the Pochhammer symbol², and $S_{t,a}^n$ the generalised Stirling number of the second kind (Hsu and Shiue, 1998)³ precomputed in a table so cost-

²The Pochhammer symbol $(x|y)_n$ denotes the rising factorial with a specified increment, i.e., y . It is defined as $(x|y)_n = x(x+y)\dots(x+(n-1)y)$.

³A Stirling number of the second kind is used to study the number of ways of partitioning a set of n objects into k nonempty subsets. The generalised version given by Hsu and Shiue (1998) has a linear recursion which in our case is $S_{m,a}^{n+1} = S_{m-1,a}^n + (n-m)aS_{m,a}^n$.

ing $O(1)$ to use (Buntine and Hutter, 2012). Eq (3) is an indicator variant of Eq (1) in (Du et al., 2010) with applying Theorem 1 in (Chen et al., 2011).

Given the current segmentation and topic assignments for all other words, using Bayes rule, we can derive the following two conditionals from Eq (3):

1. The joint probability of assigning topic k to word $w_{d,u,n}$ and $w_{d,u,n}$ being a *table head*, $p(z_{d,u,n} = k, \delta_{d,u,n} = 1 | \theta')$

$$= \frac{\gamma_{w_{i,j,n}} + M_{k,w_{i,j,n}}}{\sum_w (\gamma_w + M_{k,w})} \frac{\alpha_k + \sum_s t_{d,s,k}}{\sum_k \alpha_k + \sum_{s,k} t_{d,s,k}} \\ \frac{b + a T_{d,s}}{b + N_{d,s}} \frac{S_{t_{d,s}, k+1, a}^{n_{d,s,k}+1}}{S_{t_{d,s}, k, a}^{n_{d,s,k}}} \frac{t_{d,s,k} + 1}{n_{d,s,k} + 1} \quad (4)$$

2. The joint probability of assigning k to $w_{d,u,n}$ and $w_{d,u,n}$ not being a *table head*, $p(z_{d,u,n} = k, \delta_{d,u,n} = 0 | \theta')$

$$= \frac{\gamma_{w_{i,j,l}} + M_{k,w_{i,j,l}}}{\sum_w \gamma_w + M_{k,w}} \\ \frac{1}{b + N_{d,s}} \frac{S_{t_{d,s}, k, a}^{n_{d,s,k}+1}}{S_{t_{d,s}, k, a}^{n_{d,s,k}}} \frac{n_{d,s,k} + 1 - t_{d,s,k}}{n_{d,s,k} + 1} \quad (5)$$

where $\theta' = \{z^{-z_{d,u,n}}, w, \delta^{-\delta_{d,u,n}}, \rho, \alpha, a, b, \gamma\}$. From the two conditionals, we develop a blocked Gibbs sampling algorithm for $(z_{d,u,n}, \delta_{d,u,n})$.

4.2 Sampling Segmentation Boundaries

In our model, each segment corresponds to a Chinese restaurant in the CRP. Sampling topic boundaries corresponds to splitting/merging restaurant(s). This is different from the split-merge process proposed by Jian and Neal (2004), where one actually splits/merges table(s). To our knowledge, there has been no method developed to split/merge restaurant(s). We tried different approximations, such as the minimum-path-assumption (Wallach, 2008), which in our case assumes one table for each topic k , and all words in k are placed in the same table. Although this simplifies the split-merge process, it yielded poor results. We instead developed a novel approximate block Gibbs sampling algorithm using symmetric polynomials. Its segmentation performance worked well in our development dataset.

For simplicity, we consider a passage u in document d , and assume: (1) If $\rho_{d,u}=1$, there are two segments, s_l and s_r ; s_l ends at text passage u , and s_r starts at text passage $u+1$. (2) If $\rho_{d,u}=0$, there is one

segment, s_m , where u is somewhere in the middle of s_m . The split-merge choice we sample is one to many, for a given split pair (s_l, s_r) we consider a set of merged states s_m (represented by different possible table counts). Then, to compute the Gibbs probability for splitting/merging restaurant(s), we consider the probability of the single split, the probability of the corresponding set of merges, and then if a merge is selected, we have to sample from the set of merges. These are as follows:

Splitting: split s_m into s_r and s_l by placing a boundary after u . Since passages have a fixed order in each document, all the words are put into s_r and s_l based on which passages they belong to. Then, given all the topic assignments, we first sample all table indicators $\delta_{d,u',n}$, for $n \in \{1, \dots, N_{d,u'}\}$ and $u' \in s_m$ using Bernoulli sampling without replacement. It runs as follows: 1) sample $\delta_{d,u',n}$ according to probability $t_{d,s_m,k}/n_{d,s_m,k}$; 2) decrease $t_{d,s_m,k}$ if $\delta_{d,u',n} = 1$, otherwise, just decrease $n_{d,s_m,k}$. Using the sampled $\delta_{d,u',n}$'s we compute the inferred table counts $t_{d,s,k}$ (from Eq (1)) and customer counts $n_{d,s,k}$ respectively for segments $s=s_l$ and s_r and topics k . The computation may result in the following cases: for a given topic k ,

- (I) Both s_l and s_r have $n_{d,s,k}>0$ and $t_{d,s,k}\geq 1$, which means both segments have words assigned to k and words being labelled with *table head*. According to constraints (2), after splitting, restaurants corresponding to s_l and s_r are valid. We do not make any change on table counts.
- (II) Either s_l or s_r has $n_{d,s,k}=0$ and $t_{d,s,k}=0$. In this case, for example, all the words assigned to k in s_m are in s_l after splitting, and all those labelled with *table head* should also be in s_l . s_r has no words assigned to k . Thus, there is no need to change table counts.
- (III) Either s_l or s_r has $n_{d,s,k}>0$ and $t_{d,s,k}=0$. Both segments have words assigned to k , but those labelled with *table head* only exist in one segment. For instance, if they only exist in s_l then s_r has no table head, which means the restaurant of s_r has customers eating a dish, but no tables serving that dish. Thus, we set $t_{d,s_r,k}=1$ to make the constraints (2) satisfied.

The Gibbs probability for splitting a segment is

$$p(\rho_{d,u} = 1 | \boldsymbol{\theta}'') \propto \frac{\lambda_1 + c_{d,1}}{\lambda_0 + \lambda_1 + c_{d,0} + c_{d,1}} \Beta_K(\boldsymbol{\alpha} + \sum_{s=1}^{S_d} \mathbf{t}_{d,s}) \prod_{s \in \{s_l, s_r\}} \frac{(b|a)_{T_{d,s}}}{(b)_{N_{d,s}}} \prod_k \mathcal{S}_{t_{d,s},k,a}^{n_{d,s,k}}, \quad (6)$$

where $\boldsymbol{\theta}'' = \{\mathbf{z}, \mathbf{w}, \mathbf{t}, \boldsymbol{\rho}^{-\rho_{d,u}}, \boldsymbol{\alpha}, a, b, \lambda_0, \lambda_1\}$.

Merging: remove the boundary after u , and merge s_r and s_l to one segment s_m . For this case, both s_r and s_l satisfy constraints (2) for all k 's, and set $n_{d,s_m,k} = n_{d,s_r,k} + n_{d,s_l,k}$. The following cases are considered: for a topic k

- (I) Both s_l and s_r have $n_{d,s,k}>0$ and $t_{d,s,k}>1$. We compute $t_{d,s_m,k}$ using Eq (7). Thus table counts before and after merging are equal.
- (II) Either s_l or s_r has $n_{d,s,k}=0$ and $t_{d,s,k}=0$. Similar to the above case, we use Eq (7).
- (III) Both s_l and s_r have $n_{d,s,k}>0$, and either of them has $t_{d,s,k}=1$ or both. We have to choose between Eq (7) and Eq (8), i.e., to decide whether a table should be removed or not.

$$t_{d,s_m,k} = t_{d,s_l,k} + t_{d,s_r,k} \quad (7)$$

$$t_{d,s_m,k} = t_{d,s_l,k} + t_{d,s_r,k} - 1 \quad (8)$$

Note that choosing Eq (8) means we need to decrease the table count $t_{d,s_m,k}$ by one. The idea here is that we sample to decide whether the remove table was added due to splitting case (III) or not. Clearly, we have a one-to-many split-merge choice. To compute the probability of a set of possible merges, we use elementary symmetric polynomials as follows: let \mathcal{KS} be a set of topic-segment combinations that satisfy the condition in merging case (III), for $(k, s) \in \mathcal{KS}$, we sample either Eq (7) or Eq (8). Let $\mathcal{T} = \{t_{d,s,k} : (k, s) \in \mathcal{KS}\}$ be the set of table counts affected by the changes of Eq (7) or Eq (8). The Gibbs probability for merging two segments is

$$p(\rho_{d,u} = 0 | \boldsymbol{\theta}''') = \sum_{\mathcal{T}} p(\rho_{d,u} = 0, \mathcal{T} | \boldsymbol{\theta}''') \quad (9)$$

$$\propto \sum_{\mathcal{T}} \left(\frac{\lambda_0 + c_{d,0}}{\lambda_0 + \lambda_1 + c_{d,0} + c_{d,1}} \Beta_K(\boldsymbol{\alpha} + \sum_{s=1}^{S_d} \mathbf{t}_{d,s}) \frac{(b|a)_{T_{d,s_m}}}{(b)_{N_{d,s_m}}} \prod_k \mathcal{S}_{t_{d,s_m,k},a}^{n_{d,s_m,k}} \right),$$

where $\boldsymbol{\theta}''' = \{\mathbf{z}, \mathbf{w}, \mathbf{t} - \mathcal{T}, \boldsymbol{\rho}^{-\rho_{d,u}}, \boldsymbol{\alpha}, a, b, \lambda_0, \lambda_1\}$. This is converted to a sum on $|\mathcal{T}|$ booleans with independent terms and evaluated recursively in $O(|\mathcal{T}|^2)$ by symmetric polynomials. If a merge is chosen, one then samples according to the terms in the sum using a similar recursion.

5 Experiments

To demonstrate the effectiveness of our model (denoted by TSM) in topic segmentation tasks, we

evaluate it on three different kinds of corpora⁴: a set of synthetic documents, two meeting transcripts and two sets of text books (see Tables 2 and 3); and compare TSM with the following methods: two baselines (the Random algorithm that places topic boundaries uniformly at random, and the Even algorithm that places a boundary after every m^{th} text passage, where m is the average gold-standard segment length (Beeferman et al., 1999)), C99, MinCut, Bayesseg, APS (Kazantseva and Szpakowicz, 2011), and PLDA.

Metrics: We evaluated the segmentation performance with PK (Beeferman et al., 1999) and WindowDiff (WD^r) (Pevzner and Hearst, 2002), which are two common metrics used in topic segmentation. Both move a sliding window of fixed size k over the document, and compare the inferred segmentation with the gold-standard segmentation for each window. The window size is usually set to the half of the average gold-standard segment size (Pevzner and Hearst, 2002). In addition, we also used an extended WindowDiff proposed by Lamprier *et al.* (2007), denoted by WD^e. One problem of WD^r is that errors near the two ends of a text are penalised less than those in the middle. To solve the problem WD^e adds k fictive text passages at the beginning and the end of the text when computing the score. We evaluated all the methods with the same Java code for the three metrics.

Parameter Settings: In order to make all the methods comparable, we chose for each method the parameter settings that give the gold-standard number of segments⁵. Specifically, we used a 11×11 rank mask for C99, as suggested by Choi (2000), the configurations included in the code (<http://groups.csail.mit.edu/rbg/code>) for Bayesseg and manually tuned parameters for MinCut. For APS, a greedy approach was used to search parameter settings that can approximately give the gold-standard number of segments. For PLDA, two randomly initialised Gibbs chains were used. Each chain ran for 75,000 burn-in iterations, then 1000 samples were drawn at a lag of 25 from each chain. For TSM, 10 randomly initialised

⁴For preprocessing, we only removed stop words.

⁵The segments learnt by those methods will differ, but just the segment count will be the same as the gold-standard count.

Table 2: The Choi’s dataset

Range of n		3-11	3-5	6-8	9-11

	std	8.2	2.6	2.9	3.5
SegLen	mean	7	4	7	10
	std	2.57	0.84	0.87	1.03

Table 3: Real dataset statistics

		ICSI	Election	Fiction	Clinical
# doc		25	4	84	227
DocLen	mean	994.5	144.3	325.0	139.5
	std	354.5	16.4	230.1	110.4
SegLen	mean	188	7	22	35
	std	219.1	8.9	23.8	41.7

Gibbs chains were used. Each chain ran for 30,000 iterations with 25,000 for burn-in, then 200 samples were drawn. The concentration parameter b in TSM was sampled using the Adaptive-Reject sampling scheme introduced in (Du et al., 2012b), the discount parameter $a = 0.2$, and $\lambda_0 = \lambda_1 = 0.1$. To derive the final segmentation for PLDA and TSM, we first estimated the marginal probabilities of placing boundaries after text passages from the total of 2000 samples. These probabilities were then thresholded to give the gold-standard number of segments. Precisely, we apply a small amount of Gaussian smoothing to the marginal probabilities (except for Choi’s dataset), like Puverer *et al.* (2006) does. Finally, we used a symmetric Dirichlet prior in PLDA and STM, the one on topic distributions is $\alpha = 0.1$, the other on word distributions $\gamma = 0.01$.

5.1 Evaluation on Choi’s Dataset

Choi’s dataset (Choi, 2000) is commonly used in evaluating topic segmentation methods. It consists of 700 documents, each being a concatenation of 10 segments. Each segment is the first n sentences of a randomly selected document from the Brown corpus, *s.t.* $3 \leq n \leq 11$. Those documents are divided into 4 subsets with different range of n , as shown in Table 2. We ran PLDA and STM with 50 topics. Results in Table 4 show that our model significantly outperforms all the other methods on the four subsets over all the metrics. Furthermore, comparing to other published results, this also outperforms (Misra et al., 2009) (see their table 2), and (Riedl and Biemann, 2012) (they report an average of 1.04 and 1.06 in Tables 1 and 2, whereas TSM averages 0.93). This gives TSM the best reported results to date.

Table 4: Comparison on Choi’s datasets with WD and PK (%)

	3-11			3-5			6-8			9-11

Note the lexical transitions in these concatenated documents are very sharp (Malioutov and Barzilay, 2006). The sharp transitions lead to significant change in segment level topic distributions, which further implies the variance of these distributions is large. In TSM, a large variance causes a small concentration parameter b . We observed that the sampled b ’s (about 0.1) are indeed small for the four subsets, which shows there is no topic sharing among segments. Therefore, TSM is able to recognise the segments are unrelated text.

5.2 Evaluation on Meeting Transcripts

We applied our model to segmenting the two meeting transcripts, which are the ICSI meeting transcripts (Janin et al., 2003) and the 2008 presidential election debates (Boydston et al., 2011). The ICSI meeting has 75 transcripts, we used the 25 annotated transcripts provided by Galley et al. (2003) for evaluation. For the election debates, we used the four annotated debates used in (Nguyen et al., 2012). The statistics are shown in Table 3. PLDA and TSM were trained with 10 topics on the ICSI and 50 on the Election. In this set of experiments, we show that our model is robust to meeting transcripts.

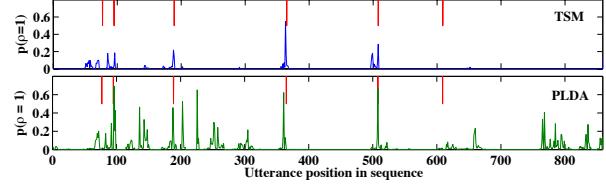

Figure 2: Probability of a topic boundary, compared with gold-standard segmentation (shown in red and at the top of each diagram) on one ICSI transcript.

As shown in Table 5, topic modelling based methods (*i.e.*, Bayesseg, PLDA and TSM) outperform those using either TF or TF-IDF, which is consistent with previously reported results (Misra et al., 2009; Riedl and Biemann, 2012). Among the topic model based methods, TSM achieves the best results on all the three metrics. On the ICSI transcripts, TSM performs 6.8%, 9.7% and 3.4% better than Bayesseg on the WD^r, WD^e and PK metrics respectively. Figure 2 shows an example of how the inferred topic boundary probabilities at utterances compare with the gold-standard boundaries on one ICSI meeting transcript. The gold-standard segmentation is {77, 95, 189, 365, 508, 609, 860}, TSM and PLDA infer {85, 96, 188, 363, 499, 508, 860} and {96, 136,

Table 6: Sampled concentration parameters

	Choi	ICSI	Election	Fiction	Clinical
b	0.1	5.2	5.4	18.4	4.8

203, 226, 361, 508, 860} respectively. Both models miss the boundary after the 609th utterance, but put a boundary after the 508th utterance. Note the boundaries placed by TSM are always within 10 utterances with respect to the gold standard.

Although TSM still performs the best on the debates, all the methods have relatively worse performance than on the ICSI meeting transcripts. Nguyen *et al.* (2012) pointed out that the ICSI meetings are characterised by pragmatic topic changes, in contrast, the debates are characterised by strategic topic changes with strong rewards for setting the agenda, dodging a question, *etc.* Thus, considering the properties of debates might further improve the segmentation performance.

5.3 Evaluation on Written Texts

We further tested TSM on two written text datasets, Clinical (Eisenstein and Barzilay, 2008) and Fiction (Kazantseva and Szpakowicz, 2011). The statistics are shown in Table 3. Each document in the Clinical dataset is a chapter of a medical textbook. Section breaks are selected to be the true topic boundaries. For the Fiction dataset, each document is a fiction downloaded from Project Gutenberg, the true topic boundaries are chapter breaks. We trained PLDA and TSM with 25 topics on the Fiction and 50 on the Clinical. Results are shown in Table 5. TSM compares favourably with Bayesseg and outperforms the other methods on the Clinical dataset, but it does not perform as well as Bayesseg on the Fiction dataset.

In fiction books, the topic boundaries between sections are usually blurred by the authors for reasons of continuity (Reynar, 1999). We observed that the sampled concentration (or inverse variance) parameter b in TSM is about 18.4 on Fiction, but 4.8 on Clinical, as shown in Table 6. This means the variance of segment level topic distributions ν learnt by TSM is not large for the fiction, so chapter breaks may not necessarily indicate topic changes. For example, there is a document in the Fiction dataset where gold-standard topic boundaries are placed after each block of text. In contrast, Bayesseg assumes

each segment has its own distribution over words, *i.e.*, one topic per segment, which means topics are not shared among segments. We hypothesize that for certain kinds of documents where the change in topic distribution is subtle, such as fiction, assuming one topic per segment can capture subtle changes in word usage. This is an area for future investigation.

6 Conclusion

In this paper, we have presented a hierarchical Bayesian model for unsupervised topic segmentation. This new model takes advances of both Bayesian segmentation and structured topic modelling. It uses a point-wise boundary sampling algorithm to sample a topic segmentation, while concurrently building a structured topic model. We have developed a novel approximation to compute the Gibbs probabilities of splitting/merging segment(s). Our model shows prominent segmentation performance on both written or spoken texts.

In future work, we would like to make the model fully nonparametric and investigate the effects of adding different cues in texts, such as cue phrases, pronoun usage, prosody, *etc.* Currently, our model uses marginal boundary probabilities to generate the final segmentation. Instead, we could develop a Metropolis-Hastings sampling algorithm to move one boundary at a time, given the gold-standard number of segments. To further study the effectiveness of our model, we would like to compare it with other methods, like SITS (Nguyen et al., 2012) and to run on more datasets, like email (Joty et al., 2010). For example, in order to compare with SITS, one can make an assumption that each document just has one speaker.

Text Alignment for Real-Time Crowd Captioning

Iftekhar Naim, Daniel Gildea, Walter Lasecki and Jeffrey P. Bigham

Department of Computer Science

University of Rochester

Rochester, NY 14627

Abstract

The primary way of providing real-time captioning for deaf and hard of hearing people is to employ expensive professional stenographers who can type as fast as natural speaking rates. Recent work has shown that a feasible alternative is to combine the partial captions of ordinary typists, each of whom types part of what they hear. In this paper, we describe an improved method for combining partial captions into a final output based on weighted A* search and multiple sequence alignment (MSA). In contrast to prior work, our method allows the tradeoff between accuracy and speed to be tuned, and provides formal error bounds. Our method outperforms the current state-of-the-art on Word Error Rate (WER) (29.6%), BLEU Score (41.4%), and F-measure (36.9%). The end goal is for these captions to be used by people, and so we also compare how these metrics correlate with the judgments of 50 study participants, which may assist others looking to make further progress on this problem.

1 Introduction

Real-time captioning provides deaf or hard of hearing people access to speech in mainstream classrooms, at public events, and on live television. To maintain consistency between the captions being read and other visual cues, the latency between when a word was said and when it is displayed must be under five seconds. The most common approach to real-time captioning is to recruit a trained stenographer with a special purpose phonetic keyboard, who transcribes the speech to text within approximately 5 seconds. Unfortunately, professional captionists are quite expensive (\$150 per hour), must be recruited in blocks of an hour or more, and are difficult to schedule on short notice. Automatic speech recognition (ASR) (Saraclar et al., 2002) attempts to solve this

Merging Incomplete Captions

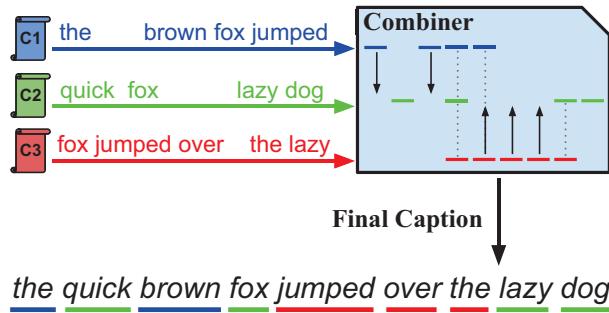

Figure 1: General layout of crowd captioning systems. Captionists (C1, C2, C3) submit partial captions that are automatically combined into a high-quality output.

problem by converting speech to text completely automatically. However, the accuracy of ASR quickly plummets to below 30% when used on an untrained speaker’s voice, in a new environment, or in the absence of a high quality microphone (Wald, 2006b).

An alternative approach is to combine the efforts of multiple non-expert captionists (anyone who can type) (Lasecki et al., 2012; Lasecki and Bigham, 2012; Lasecki et al., 2013). In this approach, multiple non-expert human workers transcribe an audio stream containing speech in real-time, and their partial input is combined to produce a final transcript (see Figure 1). This approach has been shown to dramatically outperform ASR in terms of both accuracy and Word Error Rate (WER), even when using captionists drawn from Amazon’s Mechanical Turk. Furthermore, recall approached and even exceeded that of a trained expert stenographer with seven workers contributing, suggesting that the information is present to meet the performance of a stenographer. However, combining these captions involves real-time alignment of partial captions that may be incomplete and that often have spelling errors and inconsistent timestamps. In this paper, we present a more accurate combiner that leverages

Multiple Sequence Alignment (MSA) and Natural Language Processing to improve performance.

Gauging the quality of captions is not easy. Although word error rate (WER) is commonly used in speech recognition, it considers accuracy and completeness, not readability. As a result, a lower WER does not always result in better understanding (Wang et al., 2003). We compare WER with two other commonly used metrics: BLEU (Papineni et al., 2002) and F-measure (Melamed et al., 2003), and report their correlation with that of 50 human evaluators.

The key contributions of this paper are as follows:

- We have implemented an A*-search based Multiple Sequence Alignment algorithm (Lermen and Reinert, 2000) that can trade-off speed and accuracy by varying the heuristic weight and chunk-size parameters. We show that it outperforms previous approaches in terms of WER, BLEU score, and F-measure.
- We propose a beam-search based technique using the timing information of the captions that helps to restrict the search space and scales effectively to align longer sequences efficiently.
- We evaluate the correlation of WER, BLEU, and F-measure with 50 human ratings of caption readability, and found that WER was more highly correlated than BLEU score (Papineni et al., 2002), implying it may be a more useful metric overall when evaluating captions.

2 Related Work

Most of the previous research on real-time captioning has focused on Automated Speech Recognition (ASR) (Saraclar et al., 2002; Cooke et al., 2001; Pražák et al., 2012). However, experiments show that ASR systems are not robust enough to be applied for arbitrary speakers and in noisy environments (Wald, 2006b; Wald, 2006a; Bain et al., 2005; Bain et al., 2012; Cooke et al., 2001).

2.1 Crowd Captioning

To address these limitations of ASR-based techniques, the Scribe system collects partial captions from the crowd and then uses a graph-based incremental algorithm to combine them on the fly (Lasecki et al., 2012). The system incrementally

builds a chain graph, where each node represents a set of equivalent words entered by the workers and the link between nodes are adjusted according to the order of the input words. A greedy search is performed to identify the path with the highest confidence, based on worker input and an n-gram language model. The algorithm is designed to be used online, and hence has high speed and low latency. However, due to the incremental nature of the algorithm and due to the lack of a principled objective function, it is not guaranteed to find the globally optimal alignment for the captions.

2.2 Multiple Sequence Alignment

The problem of aligning and combining multiple transcripts can be mapped to the well-studied Multiple Sequence Alignment (MSA) problem (Edgar and Batzoglou, 2006). MSA is an important problem in computational biology (Durbin et al., 1998). The goal is to find an optimal alignment from a given set of biological sequences. The pairwise alignment problem can be solved efficiently using dynamic programming in $O(N^2)$ time and space, where N is the sequence length. The complexity of the MSA problem grows exponentially as the number of sequences grows, and has been shown to be NP-complete (Wang and Jiang, 1994). Therefore, it is important to apply some heuristic to perform MSA in a reasonable amount of time.

Most MSA algorithms for biological sequences follow a progressive alignment strategy that first performs pairwise alignment among the sequences, and then builds a guide tree based on the pairwise similarity between these sequences (Edgar, 2004; Do et al., 2005; Thompson et al., 1994). Finally, the input sequences are aligned according to the order specified by the guide tree. While not commonly used for biological sequences, MSA with A*-style search has been applied to these problems by Horton (1997) and Lermen and Reinert (2000).

Lasecki et al. explored MSA in the context of merging partial captions by using the off-the-shelf MSA tool *MUSCLE* (Edgar, 2004), replacing the nucleotide characters by English characters (Lasecki et al., 2012). The substitution cost for nucleotides was replaced by the ‘keyboard distance’ between English characters, learned from the physical layout of a keyboard and based on common spelling

errors. However, MUSCLE relies on a progressive alignment strategy and may result in suboptimal solutions. Moreover, it uses characters as atomic symbols instead of words. Our approach operates on a per-word basis and is able to arrive at a solution that is within a selectable error-bound of optimal.

3 Multiple Sequence Alignment

We start with an overview of the MSA problem using standard notations as described by Lermen and Reinert (2000). Let $S_1, \dots, S_K, K \geq 2$, be the K sequences over an alphabet Σ , and having length N_1, \dots, N_K . The special gap symbol is denoted by ‘–’ and does not belong to Σ . Let $A = (a_{ij})$ be a $K \times N_f$ matrix, where $a_{ij} \in \Sigma \cup \{-\}$, and the i^{th} row has exactly $(N_f - N_i)$ gaps and is identical to S_i if we ignore the gaps. Every column of A must have at least one non-gap symbol. Therefore, the j^{th} column of A indicates an alignment state for the j^{th} position, where the state can have one of the $2^K - 1$ possible combinations. Our goal is to find the optimum alignment matrix A_{OPT} that minimizes the sum of pairs (SOP) cost function:

$$c(A) = \sum_{1 \leq i \leq j \leq K} c(A_{ij}) \quad (1)$$

where $c(A_{ij})$ is the cost of the pairwise alignment between S_i and S_j according to A . Formally, $c(A_{ij}) = \sum_{l=1}^{N_f} \text{sub}(a_{il}, a_{jl})$, where $\text{sub}(a_{il}, a_{jl})$ denotes the cost of substituting a_{jl} for a_{il} . If a_{il} and a_{jl} are identical, the substitution cost is usually zero. For the caption alignment task, we treat each individual word as a symbol in our alphabet Σ . The substitution cost for two words is estimated based on the edit distance between two words. The exact solution to the SOP optimization problem is NP-Complete, but many methods solve it approximately. In this paper, we adapt weighted A* search for approximately solving the MSA problem.

3.1 A* Search for MSA

The problem of minimizing the SOP cost function for K sequences is equivalent to estimating the shortest path between a single source and single sink node in a K -dimensional lattice. The total number of nodes in the lattice is $(N_1 + 1) \times (N_2 +$

Algorithm 1 MSA-A* Algorithm

Require: K input sequences $\mathcal{S} = \{S_1, \dots, S_K\}$ having length N_1, \dots, N_K , heuristic weight w , beam size b

```

3:  $Q \leftarrow \{start\}$ 
4: while  $Q \neq \emptyset$  do
5:    $n \leftarrow \text{EXTRACT-MIN}(Q)$ 
6:   for all  $s \in \{0, 1\}^K - \{0^K\}$  do
7:      $n_i \leftarrow n + s$ 
8:     if  $n_i = goal$  then
9:       Return the alignment matrix for the reconstructed
          path from  $start$  to  $n_i$ 
10:      else if  $n_i \notin \text{Beam}(b)$  then
11:        continue;
12:      else
13:         $g(n_i) \leftarrow g(n) + c(n, n_i)$ 
14:         $f(n_i) \leftarrow g(n_i) + w \times h(n_i)$ 
15:         $\text{INSERT-ITEM}(Q, n_i, f(n_i))$ 
16:      end if
17:    end for
18:  end while

```

$1) \times \dots \times (N_K + 1)$, each corresponding to a distinct position in K sequences. The source node is $[0, \dots, 0]$ and the sink node is $[N_1, \dots, N_K]$. The dynamic programming algorithm for estimating the shortest path from source to sink treats each node position $[n_1, \dots, n_K]$ as a state and calculates a matrix that has one entry for each node. Assuming the sequences have roughly same length N , the size of the dynamic programming matrix is $O(N^K)$. At each vertex, we need to minimize the cost over all its $2^K - 1$ predecessor nodes, and, for each such transition, we need to estimate the SOP objective function that requires $O(K^2)$ operations. Therefore, the dynamic programming algorithm has time complexity of $O(K^2 2^K N^K)$ and space complexity of $O(N^K)$, which is infeasible for most practical problem instances. However, we can efficiently solve it via heuristic A* search (Lermen and Reinert, 2000).

We use A* search based MSA (shown in Algorithm 1, illustrated in Figure 2) that uses a priority queue Q to store dynamic programming states corresponding to node positions in the K dimensional lattice. Let $n = [n_1, \dots, n_K]$ be any node in the lattice, s be the source, and t be the sink. The A* search can find the shortest path using a greedy Best First Search according to an evaluation function $f(n)$, which is the summation of the cost func-

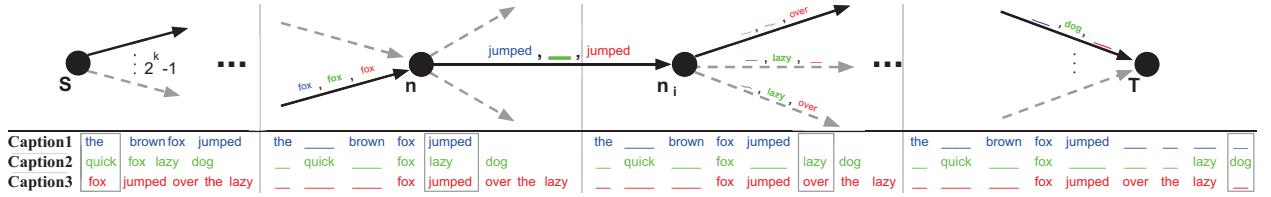

Figure 2: A^* MSA search algorithm. Each branch is one of $2^K - 1$ possible alignments for the current input. The branch with minimum sum of the current alignment cost and the expected heuristic value h_{pair} (precomputed).

tions $g(n)$ and the heuristic function $h(n)$ for node n . The cost function $g(n)$ denotes the cost of the shortest path from the source s to the current node n . The heuristic function $h(n)$ is the approximate estimated cost of the shortest path from n to the destination t . At each step of the A^* search algorithm, we extract the node with the smallest $f(n)$ value from the priority queue Q and expand it by one edge. The heuristic function $h(n)$ is admissible if it never overestimates the cost of the cheapest solution from n to the destination. An admissible heuristic function guarantees that A^* will explore the minimum number of nodes and will always find the optimal solution. One commonly used admissible heuristic function is $h_{pair}(n)$:

$$h_{pair}(n) = L(n \rightarrow t) = \sum_{1 \leq i < j \leq K} c(A_p^*(\sigma_i^n, \sigma_j^n)) \quad (2)$$

where $L(n \rightarrow t)$ denotes the lower bound on the cost of the shortest path from n to destination t , A_p^* is the optimal pairwise alignment, and σ_i^n is the suffix of node n in the i -th sequence. A^* search using the pairwise heuristic function h_{pair} significantly reduces the search space and also guarantees finding the optimal solution. We must be able to estimate $h_{pair}(n)$ efficiently. It may appear that we need to estimate the optimal pairwise alignment for all the pairs of suffix sequences at every node. However, we can precompute the dynamic programming matrix over all the pair of sequences (S_i, S_j) once from the backward direction, and then reuse these values at each node. This simple trick significantly speeds up the computation of $h_{pair}(n)$.

Despite the significant reduction in the search space, the A^* search may still need to explore a large number of nodes, and may become too slow for real-time captioning. However, we can further improve the speed by following the idea of *weighted* A^* search (Pohl, 1970). We modify the evaluation

function $f(n) = g(n) + h_{pair}(n)$ to a weighted evaluation function $f'(n) = g(n) + wh_{pair}(n)$, where $w \geq 1$ is a weight parameter. By setting the value of w to be greater than 1, we increase the relative weight of the estimated cost to reach the destination. Therefore, the search prefers the nodes that are closer to the destination, and thus reaches the goal faster. Weighted A^* search can significantly reduce the number of nodes to be examined, but it also loses the optimality guarantee of the admissible heuristic function. We can trade-off between accuracy and speed by tuning the weight parameter w .

3.2 Beam Search using Time-stamps

The computational cost of the A^* search algorithm grows exponentially with increase in the number of sequences. However, in order to keep the crowd-sourced captioning system cost-effective, only a small number of workers are generally recruited at a time (typically $K \leq 10$). We, therefore, are more concerned about the growth in computational cost as the sequence length increases.

In practice, we break down the sequences into smaller chunks by maintaining a window of a given time interval, and we apply MSA only to the smaller chunks of captions entered by the workers during that time window. As the window size increases, the accuracy of our MSA based combining system increases, but so does the computational cost and latency. Therefore, it is important to apply MSA with a relatively small window size for real-time captioning applications. Another interesting application can be the offline captioning, for example, captioning an entire lecture and uploading the captions later.

For the offline captioning problem, we can focus less on latency and more on accuracy by aligning longer sequences. To restrict the search space from exploding with sequence length (N), we apply a beam constraint on our search space using the time stamps of each captioned words. For example, if we

Figure 3: An example of applying MSA-A* (threshold $t_v = 2$) to combine 6 partial captions (first 6 lines) by human workers to obtain the final output caption (C).

set the beam size to be 20 seconds, then we ignore any state in our search space that aligns two words having more than 20 seconds time lag. Given a fixed beam size b , we can restrict the number of priority queue removals by the A* algorithm to $O(Nb^K)$. The maximum size of the priority queue is $O(Nb^K)$. For each node in the priority queue, for each of the $O(2^K)$ successor states, the objective function and heuristic estimation requires $O(K^2)$ operations and each priority queue insertion requires $O(\log(Nb^K))$ i.e. $O(\log N + K \log b)$ operations. Therefore, the overall worst case computational complexity is $O(Nb^K 2^K (K^2 + \log N + K \log b))$. Note that for fixed beam size b and number of sequences K , the computational cost grows as $O(N \log N)$ with the increase in N . However, in practice, weighted A* search explores much smaller number of states compared to this beam-restricted space.

3.3 Majority Voting after Alignment

After aligning the captions by multiple workers in a given chunk, we need to combine them to obtain the final caption. We do that via majority voting at each position of the alignment matrix containing a non-gap symbol. In case of tie, we apply the language model to choose the most likely word.

Often workers type in nonstandard symbols, abbreviations, or misspelled words that do not match with any other workers' input and end up as a single word aligned to gaps in all the other sequences. To filter out such spurious words, we apply a voting threshold (t_v) during majority voting and filter out words having less than t_v votes. Typically we set $t_v = 2$ (see the example in Figure 3). While applying the voting threshold improves the word error rate and readability, it runs the risk of loosing correct words if they are covered by only a single worker.

3.4 Incorporating an N-gram Language Model

We also experimented with a version of our system designed to incorporate the score from an n -gram language model into the search. For this purpose, we modified the alignment algorithm to produce a hypothesized output string as it moves through the input strings, as opposed to using voting to produce the final string as a post-processing step. The states for our dynamic programming are extended to include not only the current position in each input string, but also the last two words of the hypothesis string (i.e. $[n_1, \dots, n_K, w_{i-1}, w_{i-2}]$) for use in computing the next trigram language model probability. We replace our sum-of-all-pairs objective function with the sum of the alignment cost of each input with the hypothesis string, to which we add the log of the language model probability and a feature for the total number of words in the hypothesis. Mathematically, we consider the hypothesis string to be the 0th row of the alignment matrix, making our objective function:

$$c(A) = \sum_{1 \leq i \leq K} c(A_{0,i}) + w_{len} \sum_{l=1}^{N_f} I(a_{0,l} \neq -) \\ + w_{lm} \sum_{l=1}^{N_f} \log P(a_{0,l} | a_{0,l-2}, a_{0,l-1})$$

where w_{lm} and w_{len} are negative constants indicating the relative weights of the language model probability and the length penalty.

Extending states with two previous words results in a larger computational complexity. Given K sequences of length N each, we can have $O(NK)$ distinct words. Therefore, the number distinct states is $O(Nb^K (NK)^2)$ i.e. $O(N^3 K^2 b^K)$. Each state can have $O(K2^K)$ successors, giving an overall computational complexity of $O(N^3 K^3 b^K 2^K (K^2 + \log N + \log K + K \log b))$. Alternatively, if the vo-

cabulary size $|V|$ is smaller than NK , the number of distinct states is bounded by $O(Nb^K|V|^2)$.

3.5 Evaluation Metric for Speech to Text Captioning

Automated evaluation of speech to text captioning is known to be a challenging task (Wang et al., 2003). Word Error Rate (WER) is the most commonly used metric that finds the best pairwise alignment between the candidate caption and the ground truth reference sentence. WER is estimated as $\frac{S+I+D}{N}$, where S , I , and D is the number of incorrect word substitutions, insertions, and deletions required to match the candidate sentence with reference, and N is the total number of words in the reference. WER has several nice properties such as: 1) it is easy to estimate, and 2) it tries to preserve word ordering. However, WER does not account for the overall ‘readability’ of text and thus does not always correlate well with human evaluation (Wang et al., 2003; He et al., 2011).

The widely-used BLEU metric has been shown to agree well with human judgment for evaluating translation quality (Papineni et al., 2002). However, unlike WER, BLEU imposes no explicit constraints on the word ordering. BLEU has been criticized as an ‘under-constrained’ measure (Callison-Burch et al., 2006) for allowing too much variation in word ordering. Moreover, BLEU does not directly estimate recall, and instead relies on the brevity penalty. Melamed et al. (2003) suggest that a better approach is to explicitly measure both precision and recall and combine them via F-measure.

Our application is similar to automatic speech recognition in that there is a single correct output, as opposed to machine translation where many outputs can be equally correct. On the other hand, unlike with ASR, out-of-order output is frequently produced by our alignment system when there is not enough overlap between the partial captions to derive the correct ordering for all words. It may be the case that even such out-of-order output can be of value to the user, and should receive some sort of partial credit that is not possible using WER. For this reason, we wished to systematically compare BLEU, F-measure, and WER as metrics for our task.

We performed a study to evaluate the agreement of the three metrics with human judgment. We ran-

Metric	Spearman Corr.	Pearson Corr.
1-WER	0.5258	0.6282
BLEU	0.3137	0.6181
F-measure	0.4389	0.6240

Table 1: The correlation of average human judgment with three automated metrics: 1-WER, BLEU, and F-measure.

domly extracted one-minute long audio clips from four MIT OpenCourseWare lectures. Each clip was transcribed by 7 human workers, and then aligned and combined using four different systems: the graph-based system, and three different versions of our weighted A* algorithm with different values of tuning parameters. Fifty people participated in the study and were split in two equal sized groups. Each group was assigned two of the four audio clips, and each person evaluated all four captions for both clips. Each participant assigned a score between 1 to 10 to these captions, based on two criteria: 1) the overall estimated agreement of the captions with the ground truth text, and 2) the readability and understandability of the captions.

Finally, we estimated the correlation coefficients (both Spearman and Pearson) for the three metrics discussed above with respect to the average score assigned by the human participants. The results are presented in Table 1. Among the three metrics, WER had the highest agreement with the human participants. This indicates that reconstructing the correct word order is in fact important to the users, and that, in this aspect, our task has more of the flavor of speech recognition than of machine translation.

4 Experimental Results

We experiment with the MSA-A* algorithm for captioning different audio clips, and compare the results with two existing techniques. Our experimental set up is similar to the experiments by Lasecki et al. (2012). Our dataset consists of four 5-minute long audio clips extracted from lectures available on MIT OpenCourseWare. The audio clips contain speech from electrical engineering and chemistry lectures. Each audio clip is transcribed by ten non-expert human workers in real-time. We then combine these inputs using our MSA-A* algorithm, and also compare with the existing graph-based system and mul-

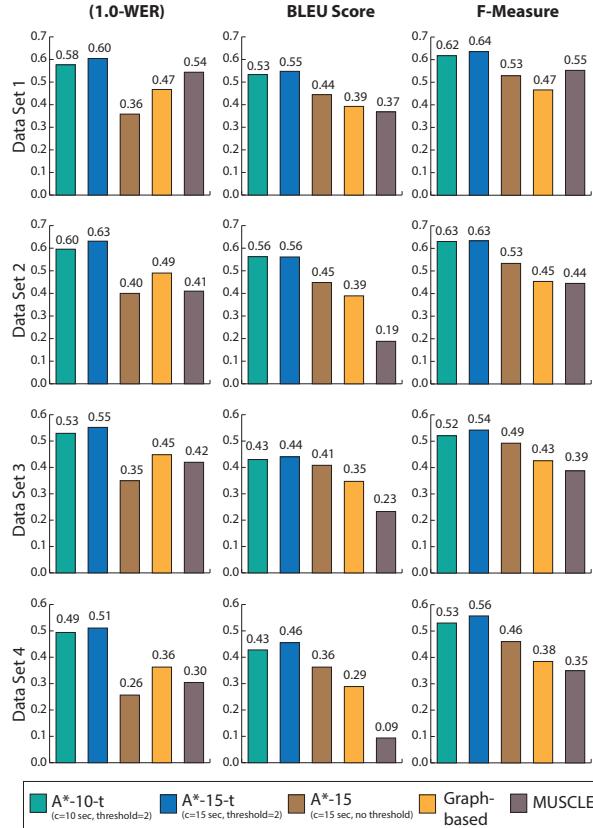

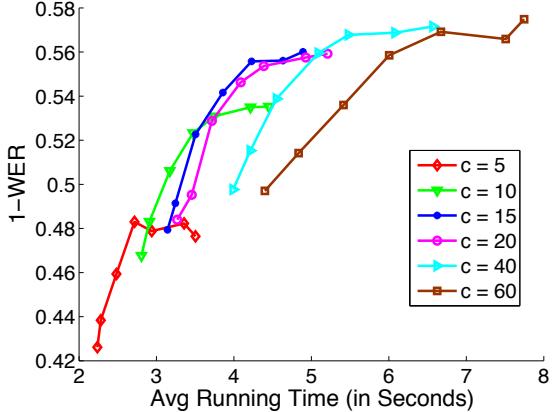

Figure 4: Evaluation of different systems on using three different automated metrics for measuring transcription quality: 1- Word Error Rate (WER), BLEU, and F-measure on the four audio clips.

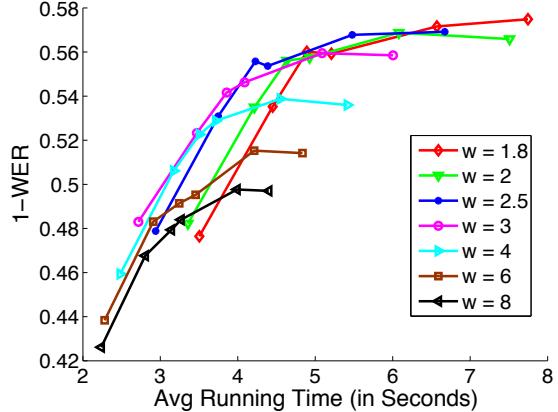

multiple sequence alignment using MUSCLE.

As explained earlier, we vary the four key parameters of the algorithm: the chunk size (c), the heuristic weight (w), the voting threshold (t_v), and the beam size (b). The heuristic weight and chunk size parameters help us to trade-off between speed versus accuracy; the voting threshold t_v helps improve precision by pruning words having less than t_v votes, and beam size reduces the search space by restricting states to be inside a time window/beam. We use affine gap penalty (Edgar, 2004) with different gap opening and gap extension penalty. We set gap opening penalty to 0.125 and gap extension penalty to 0.05. We evaluate the performance using the three standard metrics: Word Error Rate (WER), BLEU, and F-measure. The performance in terms of these metrics using different systems is presented in Figure 4.

Out of the five systems in Figure 4, the first three are different versions of our A^* search based MSA algorithm with different parameter settings: 1) A^* -10-t system ($c = 10$ seconds, $t_v = 2$), 2) A^* -15-t ($c = 15$ seconds, $t_v = 2$), and 3) A^* -15 (i.e. no pruning while voting). For all three systems, the heuristic weight parameter w is set to 2.5 and beam size $b = 20$ seconds. The other two systems are the existing graph-based system and multiple sequence alignment using MUSCLE. Among the three A^* based algorithms, both A^* -15-t and A^* -10-t produce better quality transcripts and outperform the existing algorithms. Both systems apply the voting threshold that improves precision. The system A^* -15 applies no threshold and ends up producing many spurious words having poor agreement among the workers, and hence it scores worse in all the three metrics. The A^* -15-t achieves 57.4% average accuracy in terms of (1-WER), providing 29.6% improvement with respect to the graph-based system (average accuracy 42.6%), and 35.4% improvement with respect to the MUSCLE-based MSA system (average accuracy 41.9%). On the same set of audio clips, Lasecki et al. (2012) reported 36.6% accuracy using ASR (Dragon Naturally Speaking, version 11.5 for Windows), which is worse than all the crowd-based based systems used in this experiment. To measure the statistical significance of this improvement, we performed a t -test at both the dataset level ($n = 4$ clips) and the word level ($n = 2862$ words). The improvement over the graph-based model was statistically significant with dataset level p -value 0.001 and word level p -value smaller than 0.0001. The average time to align each 15 second chunk with 10 input captions is ~ 400 milliseconds. We have also experimented with a trigram language model, trained on the British National Corpus (Burnard, 1995) having ~ 122 million words. The language-model-integrated A^* search provided a negligible 0.21% improvement in WER over the A^* -15-t system on average. The task of combining captions does not require recognizing words; it only requires aligning them in the correct order. This could explain why language model did not improve accuracy, as it does for speech recognition. Since the standard MSA- A^* algorithm (without language model) produced comparable accuracy and faster running time, we used that version in the rest of the

(a) Varying heuristic weights for fixed chunk sizes (c)

(b) Varying chunk size for fixed heuristic weight (w)

Figure 5: The trade-off between speed and accuracy for different heuristic weights and chunk size parameters.

experiments.

Next, we look at the critical speed versus accuracy trade-off for different values of the heuristic weight (w) and the chunk size (c) parameters. Since WER has been shown to correlate most with human judgment, we show the next results only with respect to WER. First, we fix the chunk size at different values, and then vary the heuristic weight parameter: $w = 1.8, 2, 2.5, 3, 4, 6$, and 8 . The results are shown in Figure 5(a), where each curve represents how time and accuracy changed over the range of values of w and a fixed value of c . We observe that for smaller values of w , the algorithm is more accurate, but comparatively slower. As w increases, the search reaches the goal faster, but the quality of the solution degrades as well. Next, we fix w and vary chunk size $c = 5, 10, 15, 20, 40, 60$ second. We repeat this experiment for a range of values of w and the results are shown in Figure 5(b). We can see that the accuracy improves steeply up to $c = 20$ seconds, and does not improve much beyond $c = 40$ seconds. For all these benchmarks, we set the beam size (b) to 20 seconds and voting threshold (t_v) to 2.

In our tests, the beam size parameter (b) did not play a significant role in performance, and setting it to any reasonably large value (usually ≥ 15 seconds) resulted in similar accuracy and running time. This is because the A^* search with h_{pair} heuristic already reduces the search space significantly, and usually reaches the goal in a number of steps smaller than the state space size after the beam restriction.

Finally, we investigate how the accuracy of our algorithm varies with the number of inputs/workers. We start with a pool of 10 input captions for one of the audio clips. We vary the number of input captions (K) to the MSA- A^* algorithm from 2 up to 10. The quality of input captions differs greatly among the workers. Therefore, for each value of K , we repeat the experiment $\min(20, \binom{10}{K})$ times; each time we randomly select K input captions out of the total pool of 10. Figure 6 shows that accuracy steeply increases as the number of inputs increases to 7, and after that adding more workers does not provide much improvement in accuracy, but increases running time.

5 Discussion and Future Work

In this paper, we show that the A^* search based MSA algorithm performs better than existing algorithms for combining multiple captions. The existing graph-based model has low latency, but it usually can not find a near optimal alignment because of its incremental alignment. Weighted A^* search on the other hand performs joint multiple sequence alignment, and is guaranteed to produce a solution having cost no more than $(1 + \epsilon)$ times the cost of the optimal solution, given a heuristic weight of $(1 + \epsilon)$. Moreover, A^* search allows for straightforward integration of an n-gram language model during the search.

Another key advantage of the proposed algorithm is the ease with which we can trade-off between

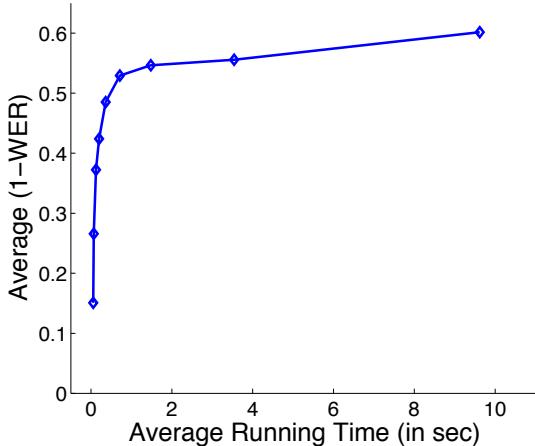

Figure 6: Experiments showing how the accuracy of the final caption by MSA-A* algorithm varies with the number of inputs from 2 to 10.

speed and accuracy. The algorithm can be tailored to real-time by using a larger heuristic weight. On the other hand, we can produce better transcripts for offline tasks by choosing a smaller weight.

It is interesting to compare our results with those achieved using the MUSCLE MSA tool of Edgar (2004). One difference is that our system takes a hierarchical approach in that it aligns at the word level, but also uses string edit distance at the letter level as a substitution cost for words. Thus, it is able to take advantage of the fact that individual transcriptions do not generally contain arbitrary fragments of words. More fundamentally, it is interesting to note that MUSCLE and most other commonly used MSA tools for biological sequences make use of a *guide tree* formed by a hierarchical clustering of the input sequences. The guide tree produced by the algorithms may or may not match the evolutionary tree of the organisms whose genomes are being aligned, but, nevertheless, in the biological application, such an underlying evolutionary tree generally exists. In aligning transcriptions, there is no particular reason to expect individual pairs of transcriptions to be especially similar to one another, which may make the guide tree approach less appropriate.

In order to get competitive results, the A* search based algorithm aligns sequences that are at least 7–10 seconds long. The delay for collecting the captions within a chunk can introduce latency, however,

each alignment usually takes less than 300 milliseconds, allowing us to repeatedly align the stream of words, even before the window is filled. This provides less accurate but immediate response to users. Finally, when we have all the words entered in a chunk, we perform the final alignment and show the caption to users for the entire chunk.

After aligning the input sequences, we obtain the final transcript by majority voting at each alignment position, which treats each worker equally and does not take individual quality into account. Recently, some work has been done for automatically estimating individual worker’s quality for crowd-based data labeling tasks (Karger et al., 2011; Liu et al., 2012). Extending these methods for crowd-based text captioning could be an interesting future direction.

6 Conclusion

In this paper, we have introduced a new A* search based MSA algorithm for aligning partial captions into a final output stream in real-time. This method has advantages over prior approaches both in formal guarantees of optimality and the ability to trade off speed and accuracy. Our experiments on real captioning data show that it outperforms prior approaches based on a dependency graph model and a standard MSA implementation (MUSCLE). An experiment with 50 participants explored whether existing automatic metrics of quality matched human evaluations of readability, showing WER did best.

Abstract

Automatically assessing the fidelity of a retelling to the original narrative – a task of growing clinical importance – is challenging, given extensive paraphrasing during retelling along with cascading automatic speech recognition (ASR) errors. We present a word tagging approach using conditional random fields (CRFs) that allows a diversity of features to be considered during inference, including some capturing acoustic confusions encoded in word confusion networks. We evaluate the approach under several scenarios, including both supervised and unsupervised training, the latter achieved by training on the output of a baseline automatic word-alignment model. We also adapt the ASR models to the domain, and evaluate the impact of error rate on performance. We find strong robustness to ASR errors, even using just the 1-best system output. A hybrid approach making use of both automatic alignment and CRFs trained tagging models achieves the best performance, yielding strong improvements over using either approach alone.

1 Introduction

Narrative production tasks are an essential component of many standard neuropsychological test batteries. For example, narration of a wordless picture book is part of the Autism Diagnostic Observation Schedule (ADOS) (Lord et al., 2002) and retelling of previously narrated stories is part of both the Developmental Neuropsychological Assessment (NEPSY) (Korkman et al., 1998) and the Wechsler Logical Memory (WLM) test (Wechsler, 1997).

Such tests also arise in reading comprehension, second language learning and other computer-based tutoring systems (Xie et al., 2012; Zhang et al., 2008).

The accuracy of automated scoring of a narrative retelling depends on correctly identifying which of the source narrative’s propositions or events (what we will call ‘story elements’) have been included in the retelling. Speakers may choose to relate these elements using diverse words or phrases, and an automated method of identifying these elements needs to model the permissible variants and paraphrasings. In previous work (Lehr et al., 2012; Prud’hommeaux and Roark, 2012; Prud’hommeaux and Roark, 2011), we developed models based on automatic word-alignment methods, as described briefly in Section 3. Such alignments are learned in an unsupervised manner from a parallel corpus of manual or ASR transcripts of retellings and the original source narrative, much as in machine translation training.

Relying on manual transcripts to train the alignment models limits the ability of these methods to handle ASR errors. By instead training on ASR transcripts, these methods can automatically capture some regularities of lexical variants and their common realizations by the recognizer. Additionally, evidence of acoustic confusability is available in word lattice output from the recognizer, which can be exploited to yield more robust automatic scoring, particularly in high error-rate scenarios.

In this paper, we present and evaluate the use of word tagging models for this task, in contrast to just using automatic (unsupervised) word-alignment methods. The approach is general enough to al-

low tagging of word confusion networks derived from lattices, thus allowing us to explore the utility of such representations to achieve robustness. We present results under a range of experimental conditions, including: variously adapting the ASR models to the domain; using maximum entropy models rather than CRFs; differing tagsets (BIO versus IO); and with varying degrees of supervision. Finally, we demonstrate improved utility in terms of using the automatic scores to classify elderly individuals as having Mild Cognitive Impairment. Ultimately we find that hybrid approaches, making use of both word-alignment and tagging models, yield strong improvements over either used independently.

2 Wechsler Logical Memory (WLM) task

The Wechsler Logical Memory (WLM) task (Wechsler, 1997), a widely used subtest of a battery of neuropsychological tests used to assess memory function in adults, has been shown to be a good indicator of Mild Cognitive Impairment (MCI) (Storandt and Hill, 1989; Petersen et al., 1999; Wang and Zhou, 2002; Nordlund et al., 2005), the stage of cognitive decline that is often a precursor to dementia of the Alzheimer’s type. In the WLM, the subject listens to the examiner read a brief narrative and then retells the narrative twice: immediately upon hearing it and after about 20 minutes. The examiner grades the subject’s response by counting how many of the story elements the subject recalled.

An excerpt of the text read by the clinician while administering the WLM task is shown in Figure 1. The story elements in the text are delineated using slashes, 25 elements in all. An example retelling is shown in Figure 2 to illustrate how the retellings are scored. The clinical evaluation guidelines specify what lexical substitutions, if any, are allowed for each element. Some elements, such as *cafeteria* and *Thompson*, must be recalled verbatim. In other cases, subjects are given credit for variants, such as *Annie* for *Anna*, or paraphrasing of concepts such as *sympathetic* for *touched by the woman’s story*. The example retelling received a score of 12, with one point for each of the recalled story elements: *Anna, Boston, employed, as a cook, and robbed of, she had four, small children, reported, station, touched by the woman’s story, took up a collection and for her*.

Anna / Thompson / of South / Boston / employed / as a cook / in a school / cafeteria / reported / at the police / station / that she had been held up / on State Street / the night before / and robbed / ... / police / touched by the woman’s story / took up a collection / for her.

Figure 1: Reference text and the set of story elements.

Ann Taylor worked in Boston as a cook. And she was robbed of sixty-seven dollars. Is that right? And she had four children and reported at the some kind of station. The fellow sympathetic and made a collection for her so that she can feed the children.

Figure 2: An example retelling with 12 recalled story elements.

3 Unsupervised generative automated scoring with word alignment

In previous work (Lehr et al., 2012; Prud’hommeaux and Roark, 2012; Prud’hommeaux and Roark, 2011), we developed a pipeline for automatically scoring narrative retellings for the WLM task. The utterances corresponding to a retelling were recognized using an ASR system. The story elements were identified from the 1-best ASR transcript using word alignments produced by the Berkeley aligner (Liang et al., 2006), an EM-based word alignment package developed to align parallel texts for machine translation. The word alignment model was estimated in an unsupervised manner from a parallel corpus consisting of source narrative and manual transcripts of retellings from a small set of training subjects, and from a pairwise parallel corpus of manual retelling transcripts.

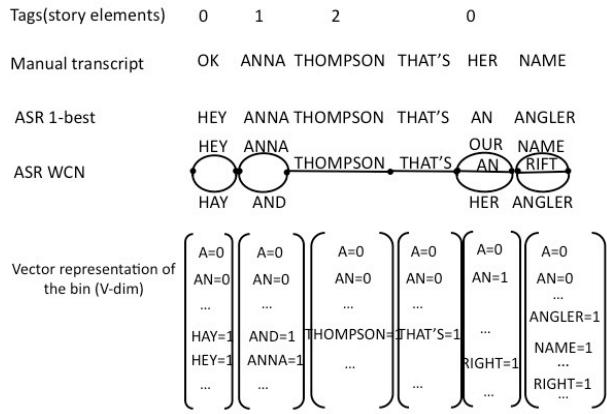

During inference or test, the ASR transcripts of the retellings were aligned using the estimated alignment model to the source narrative text. If a word in the retelling was mapped by the alignment model to a content word in the source narrative, the element associated with that content word was counted as correctly recalled in that retelling. Recall that the models were trained on unsupervised data so the aligned words may not always be permissible variants of the target elements. To alleviate such extraneous as well as unaligned words, the alignments below a threshold of posterior probability are discarded while decoding.

4 Supervised discriminative automated scoring with log-linear models

In this work, we frame the task of detecting story elements as a tagging task. Thus, our problem reduces to assigning a tag to each word position in the retelling, the tag indicating the story element that the word is associated with. In its simplest form, we have 26 tags: one for each of the 25 story elements indicating the word is ‘in’ that element (e.g., I15); and one for ‘outside’ of any story element (‘O’). By tagging word positions, we are framing the problem in a general enough way to allow tagging of word confusion networks (Mangu et al., 2000), which encode word confusions that may provide additional robustness, particularly in high word-error rate scenarios. We make use of log-linear models, which have been used for tagging confusion networks (Kurata et al., 2012), and which allow very flexible feature vector definition and discriminative optimization.

The model allows us to experiment with three types of inputs as illustrated in the Figure 3 – the manual transcript, the 1-best ASR transcript, and the word confusion network. To create supervised training data, we force-align ASR transcripts to manual transcripts and transfer manually annotated story element tags from the reference transcripts to word positions in the confusion network or 1-best ASR output using the word-level time marks. Our unsupervised training scenario instead derives story element tags from a baseline word-alignment based model.

Figure 3: Feature vectors at each word position includes lexical variants and acoustic confusions.

	Markov order 0 (MaxEnt)	Markov order 1 (CRF)
Context independent (CI)	y_i $y_i x_i$	$y_{i-1} y_i$ $y_{i-1} y_i x_i$
Context dependent (CD)	$y_i x_{i-1}$ $y_i x_{i+1}$	$y_{i-1} y_i x_{i-1}$ $y_{i-1} y_i x_{i+1}$

Table 1: Feature templates either using or not using neighboring tag y_{i-1} (MaxEnt vs. CRF); and for using or not using neighboring words x_{i-1}, x_{i+1} (CI vs. CD).

4.1 Features

Given a sequence of word positions $x = x_1 \dots x_n$, the tagger assigns a sequence of labels $y = y_1 \dots y_n$ from a tag lexicon. For each word x_i in the sequence, we can define features in the log-linear model based on word and tag identities. Table 1 presents several sets of features, defined over words and tags at various positions relative to the current word x_i and tag y_i and compound features are denoted as concatenated symbols.

Features that rely only on the current tag y_i are used in a Markov order 0 model, i.e., one for which each tag is labeled independently. A maximum entropy classifier (see Section 4.2) is used with these feature sets. Features that include prior tags encode dependencies between adjacent tags, and are used within conditional random fields models (see Section 4.3). To examine the utility of surrounding words x_{i-1} and x_{i+1} , we distinguish between models trained with context independent features (just x_i) and context dependent features. Note that models including context dependent feature sets also include the context independent features, and Markov order 1 models also include Markov order 0 features.

Two other details about our use of the feature templates are worth noting. First, when tagging confusion networks, each word in the network at position i results in a feature instance. Thus, if there are five confusable words at position i , then there will be five different x_i values being used to instantiate the features in Table 1. Second, following Kurata et al. (2012), we multiply the feature counts for the context dependent features by a weight to control their influence on the model. In this paper, the scaling weight of the context-dependent features was 0.3.

We investigate two different tagsets for this task, as presented in Table 2. The simpler tagset (IO) simply identifies words that are in a story element; the

Tagging	<i>anna</i>	<i>rent was due</i>
IO-tags	I1	I19 I19 I19
BIO-tags	B1	B19 I19 I19

Table 2: Two possible tagsets for labeling.

larger tagset (BIO) differentiates among positions in a story element chunk. The latter tagset is only of utility for models with Markov order greater than zero, and hence are only used with CRF models.

4.2 MaxEnt-based multiclass classifier

Our baseline model is a Maximum Entropy (MaxEnt) classifier where each position i from the retelling x gets assigned one of the IO output tags y_i corresponding to the set of 25 story elements and a null ('O') symbol. The output tag is modeled as the conditional probability $p(y_i | x_i)$ given the word x_i at position i in the retelling.

$$p(y_i | x_i) = \frac{\exp\left(\sum_{k=1}^d \lambda_k \phi_k(x_i, y_i)\right)}{Z(x_i)}$$

where $Z(x_i)$ is a normalization factor. The feature functions $\phi(x_i, y_i)$ are the Markov order 0 features as defined as in the previous section. The parameters $\lambda \in \Re^d$ are estimated by optimizing the above conditional probability, with L2 regularization. We use the Mallet Toolkit (McCallum, 2002) with default regularization parameters.

4.3 CRF-based sequence labeling model

The MaxEnt models assign a tag to each position from the input retelling independently. However, there are a few reasons why reframing the task as a sequence modeling problem may improve tagging performance. First, some of the story elements are multiword sequences, such as *she had been held up* or *on State Street*. Second, even if a retelling orders recalled elements differently than the original narrative, there is a tendency for story elements to occur in certain orders.

The parameters of the CRF model, $\lambda \in \Re^d$ are estimated by optimizing the following conditional probability:

$$P(y | x) = \frac{\exp\left(\sum_{k=1}^d \lambda_k \phi_k(x, y)\right)}{Z(x)}$$

where $\Phi(x, y)$ aggregates features across the entire sequence, and $Z(x)$ is a global normalization constant over the sequence, rather than local for a particular position as with MaxEnt. Features for the CRF model are Markov order 1 features, and as with the MaxEnt training, we use default (L2) regularization parameters within the Mallet toolkit.

5 Combining tagging and alignment

This paper contrasts a discriminatively trained tagging approach with an unsupervised alignment-based approach, but there are several ways in which the two approaches can be combined. First, the alignment model is unsupervised and can provide its output as training data to the tagging approach, resulting in an unsupervised discriminative model. Second, the alignment model can provide features to the log-linear tagging model in the supervised condition. We explore both methods of combination here.

5.1 Unsupervised discriminative tagger

The tagging task based on log-linear models provides an appropriate framework to easily incorporate diverse features and discriminatively estimate the parameters of the model. However, this approach requires supervised tagged training data, in this case manual labels indicating the correspondence of phrases in the retellings with story elements in the original narrative. These manual annotations are used to derive sequences of story element tags labeling the words of the retelling. Manually labeling the retellings is costly, and the scoring (thus labeling) scheme is very specific to the test being analyzed. To avoid manual labeling and provide a general framework that can easily be adopted in any retelling based assessment task, we experiment here with an unsupervised discriminative approach.

In this unsupervised approach, the labeled training data required by the log-linear model is provided by the automatic word alignments trained without supervision. The resulting tag sequences replace the manual tag sequences used in the standard supervised approach.

5.2 Word-alignment derived features

When training discriminative models it is a common practice to incorporate into the feature space the output from a generative model, since it is a good esti-

mator. Here we augment the feature space of the log-linear models with the tags generated by the automatic word alignments. In addition to the features defined in Section 4.1, we include new features that match predicted labels z_i from the word-alignment model with possible labels in the tagger y_i . Our features include the current tagger label with (1) the current predicted word-alignment label; (2) the previous predicted label; and (3) the next predicted label. Thus, the new features were $y_i z_i$, $y_i z_{i-1}$ and $y_i z_{i+1}$.

6 Experimental evaluations

Corpus: Our models were trained on immediate and delayed retellings from 144 subjects with a mean age of 85.4, of whom 36 were clinically diagnosed with MCI (training set). We evaluated our models on a set of retellings from 70 non-overlapping subjects with a mean age of 88.5, half of whom had received a diagnosis of MCI (test set). In contrast to the unsupervised word-alignment based method, the method outlined here required manual story element labels of the retellings. The training and test sets from this paper are therefore different from the sets used in previous work (Lehr et al., 2012; Prud’hommeaux and Roark, 2012; Prud’hommeaux and Roark, 2011), and the results are not directly comparable.

The recordings were sometimes made in an informal setting, such as the subject’s home or a senior center. For this reason, there are often extraneous noises in the recordings such as music, footsteps, and clocks striking the hour. Although this presents a challenge for ASR, part of the goal of our work is to demonstrate the robustness of our methods to noisy audio.

6.1 Automatic transcription

The baseline ASR system used in the current work is a Broadcast News system which is modeled after Kingsbury et al. (2011). Briefly, the acoustics of speech are modeled by 4000 clustered allophone states defined over a pentaphone context, where states are represented by Gaussian mixture models with a total of 150K mixture components. The observation vectors consist of PLP features, stacked from 10 neighboring frames and projected to a 50-

System	1-best (%)	oracle WCN(%)	oracle lat(%)
Baseline	47.2	39.7	27.7
AM adaptation	38.2	35.5	21.2
LM adaptation	28.3	30.7	19.9
AM+LM adaptation	25.6	26.5	16.5

Table 3: Improvement in ASR word error-rate by adapting the Broadcast News models to the domain of narrative retelling.

dimension space using linear discriminant analysis (LDA). The acoustic models were trained on 430 hours of transcribed speech from Broadcast News corpus (LDC97S44, LDC98S71). The language model is defined over an 84K vocabulary and consists of about 1.8M, 1M and 331K bigrams, trigrams and 4-grams, estimated from standard Broadcast news corpus. The decoding is performed in several stages using successively refined acoustic models – a context-dependent model, a vocal-tract normalized model, a speaker-adapted maximum likelihood linear regression (MLLR) model, and finally a discriminatively trained model with the boosted MMI criteria (Povey et al., 2008). The system gives a word error rate of 13.1% on the 2004 Rich Transcription benchmark by NIST (Fiscus et al., 2007), which is comparable to state-of-the-art for equivalent amounts of acoustic training data. On the WLM corpus, the recognition word error rate was significantly higher at 47.2% due to a mismatch in domain and the skewed demographics (age) of the speakers.

We improved the performance of the above Broadcast News models by adapting to the domain of the WLM retellings. The acoustic models were adapted using standard MLLR, where linear transforms were estimated in an unsupervised manner to maximize the likelihood over the transcripts of the retellings. The transcripts were generated from the baseline system after the final stage of decoding with the discriminative model. The language models were adapted by interpolating the in-domain model (weight=0.7) with the out-of-domain model. The gains from these adaptations are reported in the Table 3. As expected, we find substantial gains from both acoustic model (AM) and language model (LM) adaptation. Furthermore, we find benefit in employing them simultaneously. We also include the oracle word error rate (WER) of the WCNs and lattices for each ASR configuration.

One thing to note is that the oracle WER of the WCNs is worse than the 1-best WER when adapting the language models. We speculate that this is due to bias introduced by the language model adapted to the story retellings, resulting in word candidates in the bins that are not truly acoustically confusable candidates. This is one potential reason for the lack of utility of WCNs in low WER conditions.

6.2 Evaluating retelling scoring

We analyzed the performance of the retelling scoring methods under five different input conditions for producing transcripts: (1) the out-of-domain Broadcast News recognizer with no adaptation; (2) domain adapted acoustic model; (3) domain adapted language model; (4) domain adapted acoustic and language models; and (5) manual (reference) transcripts. Each story element is automatically labeled by the systems as either having been recalled or not, and this is compared with manual scores to derive an F-score accuracy, by calculating precision and recall of recalled story elements. Derived word alignments or tag sequences are converted to binary story element indicators by simply setting the element to 1 if any open-class word is tagged for (or aligned to) that story element.

6.2.1 Word alignment based scoring

We evaluate the word alignment approach only on 1-best ASR transcripts and manual transcripts, not WCNs. The first row of Table 4 reports the story element F-scores for a range of ASR adaptation scenarios. The performance of the model improves significantly as the WER reduces with adaptation. With the fully adapted ASR the F-score improves more than 13%, and it is only 3.4% worse than with the man-

ual transcripts. The alignments produced in each of these scenarios are used as training data in the unsupervised condition evaluated below.

6.2.2 Log-linear based automated scoring

Context-independent features Table 4 summarizes the performance of the log-linear models using context independent features (CI) in supervised (section 4), unsupervised (section 5.1) and hybrid (section 5.2) training scenarios for different inputs (reference transcript, ASR 1-best, and word confusion network ASR output) and four different ASR configurations.

The results show a few clear trends. Both in the supervised and unsupervised training scenarios the CRF model provides substantial improvements over the MaxEnt classifier. The F-scores obtained in the unsupervised training scenario are slightly worse than with supervision, though they are comparable to supervised results and an improvement over just using the word alignment approach, particularly in high WER scenarios. The hybrid training scenario – supervised learning with word alignment derived features – leads to reduced differences between MaxEnt and CRF training compared to the other two training scenarios. In fact, in high WER scenarios, the MaxEnt slightly outperforms the CRF.

As expected the best performance is obtained with manual transcripts and the worst with 1-best transcripts generated by the out-of-domain ASR with relatively high word error rate. For this ASR configuration, using WCNs provide some gain, though the gain is insignificant for the hybrid approach. In the hybrid approach, the output labels of the word alignment are already good indicators of the output tag and incorporating the confusable words from the

Table 4: Story element F-score achieved by baseline word-alignment model and log-linear models (MaxEnt and CRF) using **context independent** features (CI) under 3 different scenarios, with 3 different inputs (1-best ASR, word confusion network, and manual transcripts) and different ASR models (baseline out-of-domain, AM adapted, LM adapted and AM+LM adapted).

Table 5: Story element F-score achieved by log-linear models (MaxEnt and CRF) when adding **context dependent** features (CD) and **BIO tags** for the CRF models, under 3 different scenarios, with 3 different inputs (1-best ASR, word confusion network, and manual transcripts) and different ASR models (baseline out-of-domain, AM adapted, LM adapted and AM+LM adapted).

WCN into the feature vector apparently mainly adds noise.

When the transcripts are generated with the adapted models, the word confidence score of the 1-best is higher and the WCN bins have fewer acoustically confusable words. Still, the WCN input is helpful in the AM-adapted ASR system. When the transcripts are generated with LM adapted models, the performance is better with 1-best than with WCNs. As mentioned earlier, adapting the language models may introduce a bias due to the relatively low LM perplexity for this domain. In the lowest WER scenarios, the best performing systems achieve over 90% F-score, within two percent of the performance achieved with manual transcripts.

Context-dependent features Exercising the flexibility of log-linear models, we investigated the impact of using context-dependent (CD) features instead of the CI features used in the previous experiments. Our CD features take into account the two immediately neighboring word positions. As mentioned earlier, following Kurata et al. (2012), the counts from the neighboring word positions were weighted ($\alpha = 0.3$) to avoid data sparsity. This reduces the sensitivity of the model to time alignment errors between the tag and feature vector sequences without increasing the dimensions. In Table 5, we report the F-scores for the different ASR configurations, inputs, and log-linear models with context dependent features, using the standard IO tagset as in Table 4.

Although there are some exceptions, adding context information from the input features improves

the performance of the models. In particular, the MaxEnt models benefit from incorporating this extra information. The MaxEnt models improve their performance substantially for all three training scenarios, while the gains for the CRF models are more modest, especially for the unsupervised approach where the performance degrades or does not change much, since some context information is already captured by the Markov order 1 features.

BIO tagset As detailed in Section 4.1, story elements sometimes span multiple words, so for the CRF models we investigated two different schemes for tagging, following typical practice in named entity extraction (Ratinov and Roth, 2009) and syntactic chunking (Sha and Pereira, 2003). The BIO tagging scheme makes the distinction between the tokens from the story elements that are in the beginning from the ones that are not. The O tag is assigned to the tokens that do not belong to any of the story elements. The IO tagging uses a single tag for the tokens that fall in the same story element, which is the approach we have followed so far. In addition to presenting results using context dependent features, Table 5 presents results with the BIO tagset.

For the supervised and hybrid approaches, the BIO tagging provides insignificant but consistent gains for most of the scenarios. The unsupervised approach provides mixed results. This may be due to the way in which the word alignment model scores the retellings. It tags only those words from the retelling that are aligned with a content word in the source narrative, which may result in the loss of the

Training Scenario	Transcripts: ASR:	1-best				WCN				manual N/A

structure of some multiwords story elements that we are trying to capture with the BIO scheme.

6.3 Evaluating MCI classification

Each of the individuals producing retellings in our corpus underwent a battery of neuropsychological tests, and were assigned a Clinical Dementia Rating (CDR) (Morris, 1993), which is a composite score derived from measures of cognitive function in six domains, including memory. Importantly, it is assigned independently of the Wechsler Logical Memory test we are analyzing in this paper, which allows us to evaluate the utility of our WLM analyses in an unbiased manner. MCI is defined as a CDR of 0.5 (Ritchie and Touchon, 2000), and subjects in this study have either a CDR of 0 (no impairment) or 0.5 (MCI).

In previous work, we found that the features extracted from the retellings are useful in distinguishing subjects with MCI from neurotypical age-matched controls (Lehr et al., 2012; Prud’hommeaux and Roark, 2012; Prud’hommeaux and Roark, 2011). From each retellings, we extract Boolean features for each story element, for a total of 50 features for classification. Each feature indicates whether the retelling contained that story element.

In this paper, we carry out similar classification experiments to investigate the impact of using log-linear models on the extraction of features for classification. We build a support vector machine (SVM) using the LibSVM (Chang and Lin, 2011) extension to the WEKA data mining Java API (Hall et al., 2009). This allows recollection of different elements to be weighted differently. This is unlike the manual scoring of WLM based on clinical guidelines where all elements are weighted equally irrespective of the

difficulty. The SVM was trained on manually extracted story element feature vectors. We compared the performance of the MCI classification for three types of input and four ASR configurations under the supervised, unsupervised, and hybrid scenarios. For each scenario we chose the best scoring system from among the automated systems reported in Tables 4 and 5. Classification results, evaluated as area under the curve (AUC), are reported in Table 6, both for the log-linear trained tagging models and for the baseline word-alignment based method. For reference (not shown in the table), the SVM classifier performed at 0.83 when features values are manually populated.

The results show that the AUC improves steadily as the quality of the transcription is improved, going from the baseline system to the adapted models. This is consistent with the improvements seen in the F-score for detecting story elements. The different approaches for detecting the story elements from the transcriptions did not ultimately show significant differences in MCI classification results. Overall, the best classification values are given by the hybrid approach, which performs slightly better than the other two approaches. The best AUC in the hybrid scenario (0.79, very close to the AUC=0.81 achieved with manual transcripts) is obtained with a CRF trained with WCNs from the fully adapted ASR model and with context dependent features and BIO tags.

Comparing WCN versus 1-best as inputs, using WCN as input improves classification performance when the 1-best transcripts are poor, as in the case of out-of-domain ASR. The adapted recognizer improves the performance of the 1-best significantly making it unnecessary to resort to WCN as inputs.

Comparing the MaxEnt model with CRF model

for extracting story elements, we see that the average F-scores for the MaxEnt models trained on CD features are nearly as good as and sometimes slightly better than those produced using the CRF models. The CRF extracted story elements, however, tend to yield classifiers that perform slightly better, especially in the unsupervised approach with 1-best inputs.

7 Summary and discussion

This paper examines the task of automatically scoring narrative retellings in terms of their fidelity to the original narrative content, using discriminatively trained log-linear tagging models. Fully automatic scoring must account for both lexical variation and acoustic confusion from ASR errors. Lexical variation – due to extensive paraphrasing on the part of the individuals retelling the narrative – can be modeled effectively using word-alignment models such as those employed in machine translation systems (Lehr et al., 2012; Prud'hommeaux and Roark, 2011). This paper focuses on an alternative approach, where both lexical variation and ASR confusions are modeled using log-linear models. In addition to very flexible feature definitions, the log-linear models bring the advantage of a discriminative model to the task. We see improvements in story element F-score using these models over unsupervised word-alignment models. Further, the feature definition flexibility allows us to incorporate the unsupervised word-alignment labels into these models, resulting either in fully unsupervised approaches that perform competitively with the supervised models or in hybrid (supervised) approaches that provide the best performing systems in this study.

Our tagging models are able to process word confusion networks as inputs and thus improve performance over using 1-best ASR transcripts in scenarios where the speech recognition error rate is high. These improvements carry through to the MCI classification task, making use of features computed from the automatic scoring of narrative retelling.

One advantage of the word-alignment model is that such approaches do not require manual annotation of the story elements, which is more labor intensive than typical manual transcription of speech. Thus, the word-alignment model can exploit large

numbers of retellings in an unsupervised manner when trained on ASR transcripts of the retellings. Controlled experiments here with relatively limited training sets demonstrate that semi-supervised approaches on larger untranscribed sets are likely to be successful.

Finally, experiments with different amounts of ASR adaptation show that both acoustic and language model adaptations in this domain are effective, yielding scenarios that are competitive with manual transcription both for detecting story elements as well as for subsequent classification. With full model adaptation to the domain, the 1-best transcripts improved significantly, and their performance was found to be at par with WCNs.

In future work, we would like to investigate two questions left open by these results. First, word-alignment models can be extended to process ASR lattices or word confusion networks as part of the unsupervised alignment learning algorithm, and incorporated into our approach. Second, the contextual features can be refined (e.g., concatenated features instead of smoothed features) when large amounts of training data is available.

It is noteworthy to mention that the lexical variants and paraphrasing learned from the data using automated method may be useful in refining the clinical guidelines for scoring (e.g., allowing additional lexical variants and paraphrasings, or assigning unequal credits for different story elements to reflect the difficulty of recollecting them) or to create the guidelines for new languages or stories.

Acknowledgments

Abstract

Addressee detection (AD) is an important problem for dialog systems in human-human-computer scenarios (contexts involving multiple people and a system) because system-directed speech must be distinguished from human-directed speech. Recent work on AD (Shriberg et al., 2012) showed good results using prosodic and lexical features trained on in-domain data. In-domain data, however, is expensive to collect for each new domain. In this study we focus on lexical models and investigate how well out-of-domain data (either outside the domain, or from single-user scenarios) can fill in for matched in-domain data. We find that human-addressed speech can be modeled using out-of-domain conversational speech transcripts, and that human-computer utterances can be modeled using single-user data: the resulting AD system outperforms a system trained only on matched in-domain data. Further gains (up to a 4% reduction in equal error rate) are obtained when in-domain and out-of-domain models are interpolated. Finally, we examine which parts of an utterance are most useful. We find that the first 1.5 seconds of an utterance contain most of the lexical information for AD, and analyze which lexical items convey this. Overall, we conclude that the H-H-C scenario can be approximated by combining data from H-C and H-H scenarios only.

1 Introduction

Before a spoken dialog system can recognize and interpret a user’s speech, it should ideally determine if speech was even meant to be interpreted by the system. We refer to this task as addressee detection (AD). AD is often overlooked, especially in traditional single-user scenarios, because with the exception of self-talk, side-talk or background speech, the majority of speech is usually system-directed. As dialog systems expand to more natural contexts and multiperson environments, however, AD can become a crucial part of the system’s operational requirements. This is particularly true for systems in which explicit system addressing (e.g., push-to-talk or required keyword addressing) is undesirable.

Past research on addressee detection has focused on human-human (H-H) settings, such as meetings, sometimes with multimodal cues (op den Akker and Traum, 2009). Early systems relied primarily on rejection of H-H utterances either because they could not be interpreted (Paek et al., 2000), or because they yielded low speech recognition confidence (Dowding et al., 2006). Some systems combine gaze with lexical and syntactic cues to detect H-H speech (Katzenmaier et al., 2004). Others use relatively simple prosodic features based on pitch and energy in addition to those derived from automatic speech recognition (ASR) (Reich et al., 2011).

With some exceptions (Bohus and Horvitz, 2011; Shriberg et al., 2012), relatively little work has looked at the human-human-computer (H-H-C) scenario, i.e. at contexts involving two or more people who interact both with a system and with each other.

*Work done while first author was an intern with Microsoft.

Shriberg et al. (2012) found that novel prosodic features were more accurate than lexical or semantic features based on speech recognition for the addressee task. The corpus, also used herein, is comprised of H-H-C dialog in which roughly half of the computer-addressed speech consisted of a small set of fixed commands. While the word-based features map directly to the commands, they had trouble distinguishing all other (noncommand) computer-directed speech from human-directed speech. This is because addressee detection in the H-H-C scenario becomes even more challenging when the system is designed for natural speech, i.e., utterances that are conversational in form and not limited to command phrases with restricted syntax. Furthermore, H-H utterances can be about the domain of the system (e.g., discussing the dialog task), making AD based on language content more difficult. The prosodic features were good at both types of distinctions—even improving performance significantly when combined with true-word (cheating) lexical features that have 100% accuracy on the commands. Nevertheless, the prior work showed that lexical n-grams are useful for addressee detection in the H-H-C scenario.

A problem with lexical features is that they are highly task- and domain-dependent. As with other language modeling tasks, one usually has to collect matched training data in significant quantities. Data collection is made more cumbersome and expensive by the multi-user aspect of the scenario. Thus, for practical reasons alone, it would be much better if the language models for AD could be trained on out-of-domain data, and if whatever in-domain data is needed could be limited to single-user interaction. We show in this paper that precisely this training scenario is feasible and achieves results that are comparable or better than using completely matched H-H-C training data.

In addition to studying the role of out-of-domain data for lexical AD models, we also examine which words are useful, and how soon in elapsed time they are available. Whereas most prior work in AD has looked at processing of entire utterances, we consider an online processing version where AD decisions are to be made as soon as possible after an utterance was initiated. We find that most of the addressee-relevant lexical information can be found

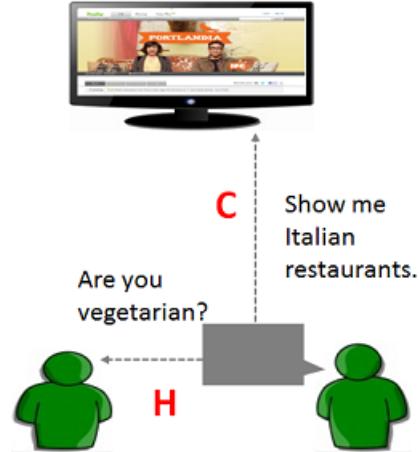

Figure 1: Conversational Browser dialog system environment with multi-human scenario

in the first 1.5 seconds, and analyze which words convey this information.

2 Data

We use in-domain and out-of-domain data from various sources. The corpora used in this work differ in size, domain, and scenario.

2.1 In-domain data

In-domain data is collected from interactions between two users and a “Conversational Browser” (CB) spoken dialog system. We used the same methodology as Shriberg et al. (2012), but using additional data. As depicted in Figure 1, the system shows a browser on a large TV screen and users are asked to use natural language for a variety of information-seeking tasks. For more details about the dialog system and language understanding approach, see Hakkani-Tür et al. (2011a; 2011b).

We split the in-domain data into training, development, and test sets, preserving sessions. Each session is about 5 to 40 minutes long. Even though the whole conversation is recorded, only the segments captured by the speech recognition system are used in our experiments. Each utterance segment belongs to one of four types: computer-command (C-command), comprising navigational commands to the system, computer-noncommand (C-noncommand), which are computer-directed utterances other than commands, human-directed (H), and mixed (M) utterances, which contain a combina-

Table 1: In-domain corpus

(a) Sizes, distribution, and ASR word error rates of in-domain utterance types

Data set	Train	Dev	Test	WER
Transcribed words	6,490	11,298	9,486	
ASR words	4,649	6,360	5,514	59.3%
H (%)	19.1	48.6	37.0	87.6%
C-noncomm. (%)	38.3	27.8	32.2	32.6%
C-command (%)	39.9	18.7	27.2	19.7%
M (%)	2.7	4.9	3.6	69.6%

(b) Example utterances by type

Type	Example
H	Do you want to watch a movie?
C-noncommand	How is the weather today?
C-command	Scroll down, Go back.
M	Show me sandwich shops. Oh, are you vegetarian?

tion of human- and computer-directed speech. The sizes and distribution of all utterance types, as well as sample utterances are shown in Table 1.

The ASR system used in the system was based on off-the-shelf acoustic models and had only the language model adapted to the domain, using very limited data. Consequently, as shown in the right-most column of Table 1(a), the word error rates (WERs) are quite high, especially for human-directed utterances. While these could be improved with targeted effort, we consider this a realistic application scenario, where in-domain training data is typically scarce, at least early in the development process. Therefore, any lexically based AD methods need to be robust to poor ASR accuracy.

2.2 Out-of-domain data

To replace the hard-to-obtain in-domain H-H-C data for training, we use the four out-of-domain corpora (two H-C and two H-H) shown in Table 2.

Single-user CB data comes from the same Conversational Browser system as the in-domain data, but with only one user present. This data can therefore be used for modeling H-C speech. Bing anchor text (Huang et al., 2010) is a large n-gram corpus of anchor text associated with links on web pages en-

Table 2: Out-of-domain corpora. “Single-user CB” is a corpus collected in same environment as the H-H-C in-domain data, except that only a single user was present.

Corpus	Addressee	Size
Single-user CB	H-C	21.9k words
Bing anchor text	H-C	1.3B bigrams
Fisher	H-H	21M words
ICSI meetings	H-H	0.7M words

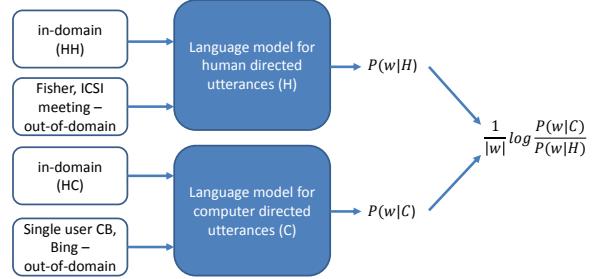

Figure 2: Language model-based score computation for addressee detection

countered by the Bing search engine. When users want to follow a link displayed on screen, they usually speak a variant of the anchor text for the link. We hypothesized that this corpus might aid the modeling of computer-noncommand type utterances in which such “verbal clicks” are frequent. Fisher telephone conversations and ICSI meetings are both corpora of human-directed speech. The Fisher corpus (Cieri et al., 2004) comprises two-person telephone conversations between strangers on prescribed topics. The ICSI meeting corpus (Janin et al., 2003) contains multiparty face-to-face technical discussions among colleagues.

3 Method

3.1 Language modeling for addressee detection

We use a lexical AD system that is based on modeling word n-grams in the two addressee-based utterance classes, H (for H-H) and C (for H-C utterances). This approach is similar to language model-based approaches to speaker and language recognition, and was shown to be quite effective for this task (Shriberg et al., 2012). Instead of making hard decisions, the system outputs a score that is

the length-normalized likelihood ratio of the two classes:

$$\frac{1}{|w|} \log \frac{P(w|C)}{P(w|H)}, \quad (1)$$

where $|w|$ is the number of words in the recognition output w for an utterance. $P(w|C)$ and $P(w|H)$ are obtained from class-specific language models. Figure 2 gives a flow-chart of the score computation.

Class likelihoods are obtained from standard trigram backoff language models, using Witten-Bell discounting for smoothing (Witten and Bell, 1991). For combining various training data sources, we use language model adaptation by interpolation (Bellegarda, 2004). First, a separate model is trained from each source. The probability estimates from in-domain and out-of-domain models are then averaged in a weighted fashion:

$$P(w_k|h_k) = \lambda P_{in}(w_k|h_k) + (1 - \lambda) P_{out}(w_k|h_k) \quad (2)$$

where w_k is the k -th word, h_k is the $(n - 1)$ -gram history for the word w_k . λ is the interpolation weight and is obtained by tuning a task-related metric on the development set. We investigated optimizing λ for either model perplexity or classification accuracy, as discussed below.

3.2 Part-of-speech-based modeling

So far we have only been modeling the lexical forms of words in utterances. If we encounter a word never before seen, it would appear as an out-of-vocabulary item in all class-specific language models, and not contribute much to the decision. More generally, if a word is rare, its n-gram statistics will be unreliable and poorly modeled by the system. (The sparseness issue is exacerbated by small amounts of training data as in our scenario.)

One common approach to deal with data sparseness in language modeling is to model n-grams over word classes rather than raw words (Brown et al., 1992). For example, if we have an utterance *How is the weather in Paris?*, the addressee probabilities are likely to be similar had we seen *London* instead of *Paris*. Therefore, replacing words with properly chosen word class labels can give better generalization from the observed training data. Among the many methods proposed to class words for language modeling purposes we chose part-of-speech (POS)

tagging over other, purely data-derived classing algorithms (Brown et al., 1992), for two reasons. First, our goal here is not to minimize the perplexity of the data, but to enhance discrimination among utterance classes. Second, a data-driven class inference algorithm would suffer from the same sparseness issues when it comes to unseen and rare words (as no robust statistics are available to infer an unseen word's best class in the class induction step). A POS tagger, on the other hand, can do quite well on unseen words, using context and morphological cues.

A hidden Markov model tagger using POS-trigram statistics and context-independent class membership probabilities was used for tagging all LM training data. The tagger itself had been trained on the Switchboard (conversational telephone speech) transcripts of the Penn Treebank-3 corpus (Marcus et al., 1999), and used the 39 Treebank POS labels. To strike a compromise between generalization and discriminative power in the language model, we retained the top N most frequent word types from the in-domain training data as distinct tokens, and varied N as a metaparameter. Barzilay and Lee (2003) used a similar idea to generalize patterns by substituting words with slots. This strategy will tend to preserve words that are either generally frequent function and domain-independent words, capturing stylistic and syntactic patterns, or which are frequent domain-specific words, and can thus help characterize computer-directed utterances.

Here is a sample sentence and its transformed version:

Original: *Let's find an Italian restaurant around this area.*

POS-tagged: *Let's find an JJ NN around this area.*

The words except *Italian* and *restaurant* are unchanged because they are in the list of N most frequent words. We transformed all training and test data in this fashion and then modeled n-gram statistics as before. The one exception was the Bing anchor-text data, which was only available in the form of word n-grams (the sentence context required for accurate POS tagging was missing).

Table 3: Addressee detection performance (EER) with different training sets

	ASR	Transcript
Baseline (in-domain only)	31.1	17.3
Fisher+ICSI, Single-user CB+Bing (out-of-domain only)	27.8	14.2
Baseline + Fisher+ICSI, Single CB + Bing (both-all)	26.9	14.0
Baseline + ICSI, Single-user CB (both-small)	26.6	13.0

3.3 Evaluation metrics

Typically, an application-dependent threshold would be applied to the decision score to convert it into a binary decision. The optimal threshold is a function of prior class probabilities and error costs. As in Shriberg et al. (2012), we used equal error rate (EER) to compare systems, since we are interested in the discriminative power of the decision score independent of priors and costs. EER is the probability of false detections and misses at the operating point at which the two types of errors are equally probable. A prior-free metric such as EER is more meaningful than classification accuracy because the utterance type distribution is heavily skewed (Table 1), and because the rate of human- versus computer-directed speech can vary widely depending on the particular people, domain, and context. We also use classification accuracy (based on data priors) in one analysis below, because EERs are not comparable for different test data subdivisions.

3.4 Online model

The actual dialog system used in this work processes utterances after receiving an entire segment of speech from the recognition subsystem. However, we envision that a future version of the system would perform addressee detection in an online manner, making a decision as soon as enough evidence is gathered. This raises the question how soon the addressee can be detected once the user starts speaking. We simulate this processing mode using a windowed AD model.

As shown in Figure 3, we define windows starting at the beginning of the utterance and investigate how AD performance changes as a function of window size. We use only the words and n-grams falling completely within a given window. For example, the word *find* would be excluded from Window 1 in Fig-

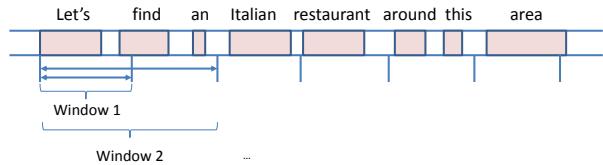

Figure 3: The window model

ure 3.

The benefit of early detection in this case is that once speech is classified as human-directed, it does not need to be sent to the speech recognizer and subsequent semantic processing. This saves processing time, especially if processing happens on a server. Based on the window model performance, we can assess the feasibility of an online AD model, which can be approached by shifting the detection window through time and finding addressee changes.

4 Results and Discussion

Table 3 compares the performance of our system using various training data sources. For diagnostic purposes we also compare performance based on recognized words (the realistic scenario) to that based on human transcripts (idealized, best-case word recognition).

Somewhat surprisingly, the system trained on out-of-domain data alone performs better by 3.3 EER points on ASR output and 3.1 points on transcripts compared to the in-domain baseline. Combining in-domain and out-of-domain data (both-all, both-small) gives about 1 point additional EER gain. Note that training on in-domain data plus the smaller-size out-of-domain corpora (both-small) is better than using all available data (both-all).

Figure 4 shows the detection error trade-off (DET) between false alarm and miss errors for the

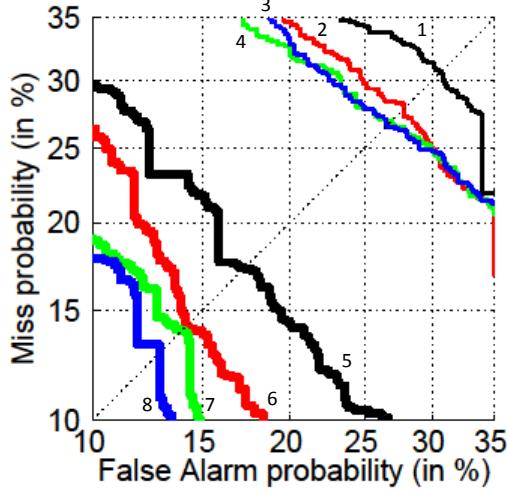

Figure 4: Detection error trade-off (DET) curves for the systems in Table 3. Thin lines at the top right corner use ASR output (1-4); thick lines at the bottom left corner use reference transcripts (5-8). Each line number represents one of the systems in Table 3: 1,5 = in-domain only, 2,6 = out-of-domain only, 4,7 = both-all, 3,8 = both-small.

systems in Table 3. The DET plot depicts performance not only at the EER operating point (which lies on the diagonal), but over the range of possible trade-offs between false alarm and miss error rates. As can be seen, replacing or combining in-domain data with out-of-domain data gives clear performance gains, regardless of operating point (score threshold), and for both reference and recognized words.

Figure 5 shows H-H vs. H-C classification accuracies on each of the four utterance subtypes listed in Table 1. It is clear that computer-command utterances are the easiest to classify; the accuracy is more than 90% using transcripts, and more than 85% using ASR output. This is not surprising, since commands are from a fixed small set of phrases. The biggest gain from use of out-of-domain data is found for computer-directed noncommand utterances. This is helpful, since in general it is the noncommand computer-directed utterances (rather than the commands) that are highly confusable with human-directed utterances: both use unconstrained natural language. We note that H-H utterance are very poorly recognized in the ASR condition when only out-of-domain data is used. This may be be-

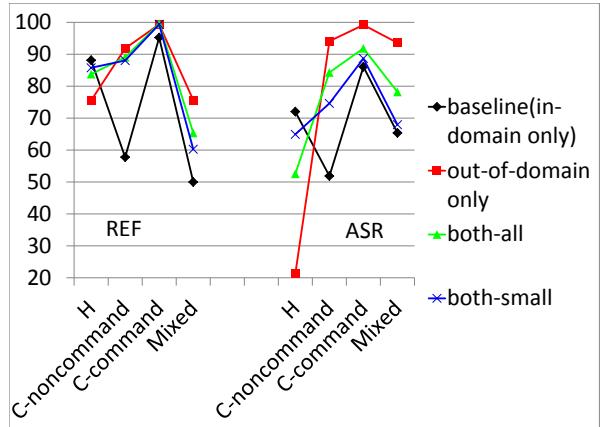

Figure 5: AD accuracies by utterance type

Table 4: Perplexities (computed on dev set ASR words) by utterance type, for different training corpora. Interpolation refers to the combination of the three models listed in each case.

Training set	Test class	
	H-C	H-H
In-domain H-C (ASR)	257	1856
Single-user CB	104	1237
Bing anchor text	356	789
Interpolation	58	370
In-domain H-H (ASR)	887	1483
Fisher	995	795
ICSI meeting	2007	1583
Interpolation	355	442

cause the human-human corpora used in training consist of transcripts, whereas the ASR output for human-directed utterances is very errorful, creating a severe train-test mismatch.

As for the optimization of the mixing weight λ , we found that minimizing perplexity on the development set of each class is effective. This is a standard optimization approach for interpolated language models, and can be carried out efficiently using an expectation maximization algorithm. We also tried search-based optimization using the classification metric (EER) as the criterion. While this approach could theoretically give better results (since perplexity is not a discriminative criterion) we found no significant improvement in our experiments.

Table 4 shows the perplexities by class of language models trained on different corpora. We can take these as an indication of training/test mismatch (lower perplexity indicating better match). We also find substantial perplexity reductions from interpolating models. In order to make perplexities comparable, we trained all models using the union of the vocabularies from the different sources.

In spite of perplexity being a good way to optimize the *weighting* of sources, it is not clear that it is a good criterion for *selecting* data sources. For example, we see that the Fisher model has a much lower perplexity on H-H utterances than the ICSI meeting model. However, as reflected in Table 3, the H language model that leaves out the Fisher data actually performed better. The most likely explanation is that the Fisher corpus is an order of magnitude larger than the ICSI corpus, and that sheer data size, not stylistic similarity, may account for the lower perplexity of the Fisher model. Further investigation is needed regarding good criteria for corpus selection for classification tasks such as AD.

Table 5 shows the EER performance of the POS-based model, for various sizes N of the most-frequent word list. We observe that the partial replacement of words with POS tags indeed improves over the baseline model performance, by 1.5 points on ASR output and by 1.1 points on transcripts. We also see that the gain over the corresponding word-only model is largest for the in-domain baseline model, and less or non-existent for the out-of-domain model. This is consistent with the notion that the in-domain model suffers the most from data sparseness, and therefore has the most to gain from better generalization.

Interpolating with out-of-domain data still helps here. The optimal N differs for ASR output versus transcripts. The POS-based model with $N = 300$ improves the EER by 0.5 points on ASR output, and $N = 1000$ improves the EER by 0.8 points on transcripts. Here we use relatively large amounts of training data, thus the performance gain is smaller, though still meaningful.

Figure 6 shows the performance of the system using time windows anchored at the beginnings of utterances. We incrementally increase the window width from 0.5 seconds to 3 seconds and compare results to using full utterances. The leveling off of

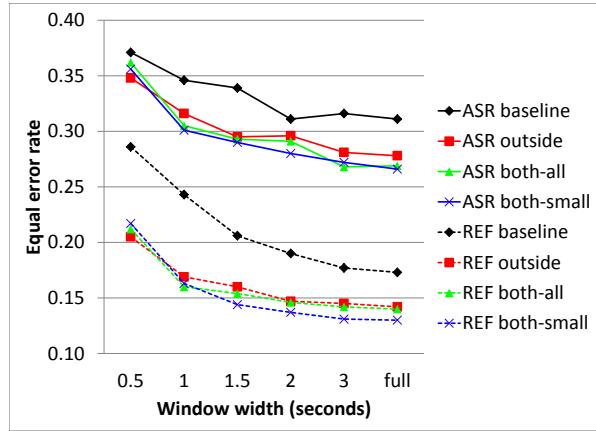

Figure 6: Simulated online performance on incremental windows

the error plots indicates that most addressee information is contained in the first 1 to 1.5 seconds, although some additional information is found in the later part of utterances (the plots never level off completely). This pattern holds for both in-domain and out-of-domain training, as well as for combined models.

To give an intuitive understanding of where this early addressee-relevant information comes from, we tabulated the top 15 word unigrams in each utterance class, are shown in Table 6. Note that the substantial differences between the third and fourth columns in the table reflect the high ASR error rate for human-directed utterances, whereas

for computer-directed utterances, the frequent first words are mostly recognized correctly.

In computer-directed utterances we see mostly command verbs, which, due to the imperative syntax of these commands occur in utterance-initial position. Human-directed utterances are characterized by subject pronouns such as *I* and *it*, or answer particles such as *yeah* and *okay*, which likewise occur in initial position. Based on word frequency and syntax alone it is thus clear why the beginnings of utterances contain strong lexical cues.

5 Conclusion

We explored the use of outside data for training lexical addressee detection systems for the human-human-computer scenario. Advantages include saving the time and expense of an in-domain data collection, as well as performance gains even when some in-domain data is available. We show that H-C training data can be obtained from a single-user H-C collection, and that H-H speech can be modeled using general conversational speech. Using the outside training data, we obtain results that are even better than results using matched (but smaller) H-H-C training data. Results can be improved considerably by adapting H-C and H-H language models with small amounts of matched H-H-C data, via interpolation. The main reason for the improvement is better detection of computer-directed noncommand utterances, which tend to be confusable with human-directed utterances. Another effective way to overcome scarce training data is to replace the less frequent words with part-of-speech labels. In both baseline and interpolated model, we found that POS-

based models that keep an appropriate number of the top N most frequent word types can further improve the system's performance.

In a second study we found that the most salient phrases for lexical addressee detection occur within the first 1 to 1.5 seconds of speech in each utterance. It reflects a syntactic tendency of class-specific words to occur utterance-initially, which shows the feasibility of the online AD system.

Acknowledgments

We thank our Microsoft colleagues Madhu Chinthakunta, Dilek Hakkani-Tür, Larry Heck, Lisa Stiefelman, and Gokhan Tür for developing the dialog system used in this work, as well as for many valuable discussions. Ashley Fidler was in charge of much of the data collection and annotation required for this study. We also thank Dan Jurafsky for useful feedback.

Abstract

The study presented in this work is a first effort at real-time speech translation of TED talks, a compendium of public talks with different speakers addressing a variety of topics. We address the goal of achieving a system that balances translation accuracy and latency. In order to improve ASR performance for our diverse data set, adaptation techniques such as constrained model adaptation and vocal tract length normalization are found to be useful. In order to improve machine translation (MT) performance, techniques that could be employed in real-time such as monotonic and partial translation retention are found to be of use. We also experiment with inserting text segmenters of various types between ASR and MT in a series of real-time translation experiments. Among other results, our experiments demonstrate that a good segmentation is useful, and a novel conjunction-based segmentation strategy improves translation quality nearly as much as other strategies such as comma-based segmentation. It was also found to be important to synchronize various pipeline components in order to minimize latency.

1 Introduction

The quality of automatic speech-to-text and speech-to-speech (S2S) translation has improved so significantly over the last several decades that such systems are now widely deployed and used by an increasing number of consumers. Under the hood, the individual components such as automatic speech recognition (ASR), machine translation (MT) and text-to-speech synthesis (TTS) that constitute a S2S system are still loosely coupled and typically trained on disparate data and domains. Nevertheless, the

models as well as the pipeline have been optimized in several ways to achieve tasks such as high quality offline speech translation (Cohen, 2007; Kingsbury et al., 2011; Federico et al., 2011), on-demand web based speech and text translation, low-latency real-time translation (Wahlster, 2000; Hamon et al., 2009; Bangalore et al., 2012), etc. The design of a S2S translation system is highly dependent on the nature of the audio stimuli. For example, talks, lectures and audio broadcasts are typically long and require appropriate segmentation strategies to chunk the input signal to ensure high quality translation. In contrast, single utterance translation in several consumer applications (apps) are typically short and can be processed without the need for additional chunking. Another key parameter in designing a S2S translation system for any task is latency. In offline scenarios where high latencies are permitted, several adaptation strategies (speaker, language model, translation model), denser data structures (N-best lists, word sausages, lattices) and rescoring procedures can be utilized to improve the quality of end-to-end translation. On the other hand, real-time speech-to-text or speech-to-speech translation demand the best possible accuracy at low latencies such that communication is not hindered due to potential delay in processing.

In this work, we focus on the speech translation of talks. We investigate the tradeoff between accuracy and latency for both offline and real-time translation of talks. In both these scenarios, appropriate segmentation of the audio signal as well as the ASR hypothesis that is fed into machine translation is critical for maximizing the overall translation quality of the talk. Ideally, one would like to train the models on entire talks. However, such corpora are not available in large amounts. Hence, it is necessary to con-

form to appropriately sized segments that are similar to the sentence units used in training the language and translation models. We propose several non-linguistic and linguistic segmentation strategies for the segmentation of text (reference or ASR hypotheses) for machine translation. We address the problem of latency in real-time translation as a function of the segmentation strategy; i.e., we ask the question “what is the segmentation strategy that maximizes the number of segments while still maximizing translation accuracy?”.

2 Related Work

Speech translation of European Parliamentary speeches has been addressed as part of the TCSR project (Vilar et al., 2005; Fügen et al., 2006). The project focused primarily on offline translation of speeches. Simultaneous translation of lectures and speeches has been addressed in (Hamon et al., 2009; Fügen et al., 2007). However, the work focused on a single speaker in a limited domain. Offline speech translation of TED¹ talks has been addressed through the IWSLT 2011 and 2012 evaluation tracks. The talks are from a variety of speakers with varying dialects and cover a range of topics. The study presented in this work is the first effort on real-time speech translation of TED talks. In comparison with previous work, we also present a systematic study of the accuracy versus latency tradeoff for both offline and real-time translation on the same dataset.

Various utterance segmentation strategies for offline machine translation of text and ASR output have been presented in (Cettolo and Federico, 2006; Rao et al., 2007; Matusov et al., 2007). The work in (Fügen et al., 2007; Fügen and Kolss, 2007) also examines the impact of segmentation on offline speech translation of talks. However, the real-time analysis in that work is presented only for speech recognition. In contrast with previous work, we tackle the latency issue in simultaneous translation of talks as a function of segmentation strategy and present some new linguistic and non-linguistic methodologies. We investigate the accuracy versus latency tradeoff across translation of reference text, utterance segmented speech recognition output and

partial speech recognition hypotheses.

3 Problem Formulation

The basic problem of text translation can be formulated as follows. Given a source (French) sentence $\mathbf{f} = f_1^J = f_1, \dots, f_J$, we aim to translate it into target (English) sentence $\hat{\mathbf{e}} = \hat{e}_1^I = \hat{e}_1, \dots, \hat{e}_I$.

$$\hat{\mathbf{e}}(\mathbf{f}) = \arg \max_{\mathbf{e}} \Pr(\mathbf{e}|\mathbf{f}) \quad (1)$$

If, as in talks, the source text (reference or ASR hypothesis) is very long, i.e., J is large, we attempt to break down the source string into shorter sequences, $\mathbf{S} = s_1 \dots s_k \dots s_{Q_s}$, where each sequence $s_k = [f_{j_k} f_{j_k+1} \dots f_{j_{(k+1)}-1}]$, $j_1 = 1, j_{Q_s+1} = J + 1$. Let the translation of each foreign sequence s_k be denoted by $t_k = [e_{i_k} e_{i_k+1} \dots e_{i_{(k+1)}-1}]$, $i_1 = 1, i_{Q_s+1} = I' + 1^2$. The segmented sequences can be translated using a variety of techniques such as independent chunk-wise translation or chunk-wise translation conditioned on history as shown in Eqs. 2 and 3, respectively. In Eq. 3, t_i^* denotes the best translation for source sequence s_i .

$$\hat{\mathbf{e}}(\mathbf{f}) = \arg \max_{t_1} \Pr(t_1|s_1) \dots \arg \max_{t_k} \Pr(t_k|s_k) \quad (2)$$

$$\begin{aligned} \hat{\mathbf{e}}(\mathbf{f}) = & \arg \max_{t_1} \Pr(t_1|s_1) \arg \max_{t_2} \Pr(t_2|s_2, s_1, t_1^*) \\ & \dots \arg \max_{t_k} \Pr(t_k|s_1, \dots, s_k, t_1^*, \dots, t_{k-1}^*) \end{aligned} \quad (3)$$

Typically, the hypothesis $\hat{\mathbf{e}}$ will be more accurate than $\hat{\mathbf{e}}$ for long texts as the models approximating $\Pr(\mathbf{e}|\mathbf{f})$ are conventionally trained on short text segments. In Eqs. 2 and 3, the number of sequences Q_s is inversely proportional to the time it takes to generate partial target hypotheses. Our main focus in this work is to obtain a segmentation \mathbf{S} such that the quality of translation is maximized with minimal latency. The above formulation for automatic speech recognition is very similar except that the foreign string $\check{\mathbf{f}} = \check{f}_1^J = \check{f}_1, \dots, \check{f}_J$ is obtained by decoding the input speech signal.

4 Data

In this work, we focus on the speech translation of TED talks, a compendium of public talks from several speakers covering a variety of topics. Over the past couple of years, the International Workshop on Spoken Language Translation (IWSLT) has been conducting the evaluation of speech translation on TED talks for English-French. We leverage the IWSLT TED campaign by using identical development (dev2010) and test data (tst2010). However, English-Spanish is our target language pair as our internal projects are cater mostly to this pair. As a result, we created parallel text for English-Spanish based on the reference English segments released as part of the evaluation (Cettolo et al., 2012).

We also harvested the audio data from the TED website for building an acoustic model. A total of 1308 talks in English were downloaded, out of which we used 1119 talks recorded prior to December 2011. We split the stereo audio file and duplicated the data to account for any variations in the channels. The data for the language models was also restricted to that permitted in the IWSLT 2011 evaluation. The parallel text for building the English-Spanish translation model was obtained from several corpora: Europarl (Koehn, 2005), JRC-Acquis corpus (Steinberger et al., 2006), Openseg subtitle corpus (Tiedemann and Lars Nygaard, 2004), Web crawling (Rangarajan Sridhar et al., 2011) as well as human translation of proprietary data. Table 1 summarizes the data used in building the models. It is important to note that the IWSLT evaluation on TED talks is completely offline. In this work, we perform the first investigation into the real-time translation of these talks.

5 Speech Translation Models

In this section, we describe the acoustic, language and translation models used in our experiments.

5.1 Acoustic and Language Model

We use the AT&T WATSONSM speech recognizer (Goffin et al., 2004). The speech recognition component consisted of a three-pass decoding approach utilizing two acoustic models. The models used three-state left-to-right HMMs representing just over 100 phonemes. The phonemes represented general English, spelled letters and head-body-tail representation for the eleven digits (with "zero" and "oh"). The pronunciation dictionary used the appropriate phoneme subset, depending on the type of the word. The models had 10.5k states and 27k HMMs, trained on just over 300k utterances, using both of the stereo channels. The baseline model training was initialized with several iterations of ML training, including two builds of context dependency trees, followed by three iterations of Minimum Phone Error (MPE) training.

The Vocal Tract Length Normalization (VTLN) was applied in two different ways. One was estimated on an utterance level, and the other at the talk level. No speaker clustering was attempted in training. The performance at test time was comparable for both approaches on the development set. Once the warps were estimated, after five iterations, the ML trained model was updated using MPE training. Constrained model adaptation (CMA) was applied to the warped features and the adapted features were recognized in the final pass with the VTLN model. All the passes used the same LM. For offline recognition the warps, and the CMA adaptation, are performed at the talk level. For the real-time speech translation experiments, we used the VTLN model.

The English language model was built using the permissible data in the IWSLT 2011 evaluation. The texts were normalized using a variety of cleanup, number and spelling normalization techniques and filtered by restricting the vocabulary to the top 375000 types; i.e., any sentence containing a token outside the vocabulary was discarded. First, we removed extraneous characters beyond the ASCII range followed by removal of punctuations. Subsequently, we normalized hyphenated words and removed words with more than 25 characters. The resultant text was normalized using a variety of number conversion routines and each corpus was filtered by restricting the vocabulary to the top 150000 types; i.e., any sentence containing a token outside the vocabulary was discarded. The vocabulary from all the corpora was then consolidated and another round of filtering to the top 375000 most frequent types was performed. The OOV rate on the TED dev2010 set is 1.1%. We used the AT&T FSM toolkit (Mohri et al., 1997) to train a trigram language model (LM) for each component (corpus). Finally, the component language models were interpolated by minimizing the perplexity on the dev2010 set. The results are shown in Table 2.

Model	Accuracy (%)	
	dev2010	test2010
Baseline MPE	75.5	73.8
VTLN	78.8	77.4
CMA	80.5	80.0

Table 2: ASR word accuracies on the IWSLT data sets.³

5.2 Translation Model

We used the Moses toolkit (Koehn et al., 2007) for performing statistical machine translation. Minimum error rate training (MERT) was performed on the development set (dev2010) to optimize the feature weights of the log-linear model used in translation. During decoding, the unknown words were preserved in the hypotheses. The data used to train the model is summarized in Table 1.

³We used the standard NIST scoring package as we did not have access to the IWSLT evaluation server that may normalize and score differently

We also used a finite-state implementation of translation without reordering. Reordering can pose a challenge in real-time S2S translation as the text-to-speech synthesis is monotonic and cannot retract already synthesized speech. While we do not address the text-to-speech synthesis of target text in this work, we perform this analysis as a precursor to future work. We represent the phrase translation table as a weighted finite state transducer (FST) and the language model as a finite state acceptor (FSA). The weight on the arcs of the FST is the dot product of the MERT weights with the translation scores. In addition, a word insertion penalty was also applied to each word to penalize short hypotheses. The decoding process consists of composing all possible segmentations of an input sentence with the phrase table FST and language model, followed by searching for the best path. Our FST-based translation is the equivalent of phrase-based translation in Moses without reordering. We present results using the independent chunk-wise strategy and chunk-wise translation conditioned on history in Table 3. The chunk-wise translation conditioned on history was performed using the *continue-partial-translation* option in Moses.

6 Segmentation Strategies

The output of ASR for talks is a long string of words with no punctuation, capitalization or segmentation markers. In most offline ASR systems, the talk is first segmented into short utterance-like audio segments before passing them to the decoder. Prior work has shown that additional segmentation of ASR hypotheses of these segments may be necessary to improve translation quality (Rao et al., 2007; Matusov et al., 2007). In a simultaneous speech translation system, one can neither find the optimal segmentation of the entire talk nor tolerate high latencies associated with long segments. Consequently, it is necessary to decode the incoming audio incrementally as well as segment the ASR hypotheses appropriately to maximize MT quality. We present a variety of linguistic and non-linguistic segmentation strategies for segmenting the source text input into MT. In our experiments, they are applied to different inputs including reference text, ASR 1-best hypothesis for manually segmented audio and

incremental ASR hypotheses from entire talks.

6.1 Non-linguistic segmentation

The simplest method is to segment the incoming text according to length in number of words. Such a procedure can destroy semantic context but has little to no overhead in additional processing. We experiment with segmenting the text according to word window sizes of length 4, 8, 11, and 15 (denoted as data sets *win4*, *win8*, *win11*, *win15*, respectively in Table 3). We also experiment with concatenating all of the text from one TED talk into a single chunk (*complete talk*).

A novel hold-output model was also developed in order to segment the input text. Given a pair of parallel sentences, the model segments the source sentence into minimally sized chunks such that crossing links and links of one target word to many source words in an optimal GIZA++ alignment (Och and Ney, 2003) occur only within individual chunks. The motivation behind this model is that if a segment s_0 is input at time t_0 to an incremental MT system, it can be translated right away without waiting for a segment s_i that is input at a later time t_i , $t_i > 0$. The hold-output model detects these kinds of segments given a sequence of English words that are input from left to right. A kernel-based SVM was used to develop this model. It tags a token t in the input with either the label HOLD, meaning to chunk it with the next token, or the label OUTPUT, meaning to output the chunk constructed from the maximal consecutive sequence of tokens preceding t that were all tagged as HOLD. The model considers a five word and POS window around the target token t . Unigram, bigram, and trigram word and POS features based upon this window are used for classification. Training and development data for the model was derived from the English-Spanish TED data (see Table 1) after running it through GIZA++. Accuracy of the model on the development set was 66.62% F-measure for the HOLD label and 82.75% for the OUTPUT label.

6.2 Linguistic segmentation

Since MT models are trained on parallel text sentences, we investigate segmenting the source text into sentences. We also investigate segmenting the text further by predicting comma separated chunks within sentences. These tasks are performed by

training a kernel-based SVM (Haffner et al., 2003) on a subset of English TED data. This dataset contained 1029 human-transcribed talks consisting of about 103,000 sentences containing about 1.6 million words. Punctuation in this dataset was normalized as follows. Different kinds of sentence ending punctuations were transformed into a uniform end of sentence marker. Double-hyphens were transformed into commas. Commas already existing in the input were kept while all other kinds of punctuation symbols were deleted. A part of speech (POS) tagger was applied to this input. For speed, a unigram POS tagger was implemented which was trained on the Penn Treebank (Marcus et al., 1993) and used orthographic features to predict the POS of unknown words. The SVM-based punctuation classifier relies on a five word and POS window in order to classify the target word. Specifically, token t_0 is classified given as input the window $t_{-2}t_{-1}t_0t_1t_2$. Unigram, bigram, and trigram word and POS features based on this window were used for classification. Accuracy of the classifier on the development set was 60.51% F-measure for sentence end detection and 43.43% F-measure for comma detection. Subsequently, data sets *pred-sent* (sentences) and *pred-punct* (comma-separated chunks) were obtained. Corresponding to these, two other data sets *ref-sent* and *ref-punct* were obtained based upon gold-standard punctuations in the reference.

Besides investigating the use of comma-separated segments, we investigated other linguistically motivated segments. These included conjunction-word based segments. These segments are separated at either conjunction (e.g. “and,” “or”) or sentence-ending word boundaries. Conjunctions were identified using the unigram POS tagger. F-measure performance for detecting conjunctions by the tagger on the development set was quite high, 99.35%. As an alternative, text chunking was performed within each sentence, with each chunk corresponding to one segment. Text chunks are non-recursive syntactic phrases in the input text. We investigated segmenting the source into text chunks using TreeTagger, a decision-tree based text chunker (Schmid, 1994). Initial sets of text chunks were created by using either gold-standard sentence boundaries or boundaries detected using the punctuation classifier, yielding the data sets *chunk-ref-*

punct and *chunk-pred-punct*. Chunk types included NC (noun chunk), VC (verb chunk), PRT (particle), and ADVC (adverbial chunk).

Because these chunks may not provide sufficient context for translation, we also experimented with concatenating neighboring chunks of certain types to form larger chunks. Data sets *lgchunk1* concatenate together neighboring chunk sequences of the form NC, VC or NC, ADVC, VC, intended to capture as single chunks instances of subject and verb. In addition to this, data sets *lgchunk2* capture chunks such as PC (prepositional phrase) and VC followed by VC (control and raising verbs). Finally, data sets *lgchunk3* capture as single chunks VC followed by NC and optionally followed by PRT (verb and its direct object).

Applying the conjunction segmenter after the aforementioned punctuation classifier in order to detect the ends of sentences yields the data set *conj-pred-eos*. Applying it on sentences derived from the gold-standard punctuations yields the data set *conj-ref-eos*. Finally, applying the hold-output model to sentences derived using the punctuation classifier produces the data set *pred-hold*. Obtaining English sentences tagged with HOLD and OUTPUT directly

from the output of GIZA++ on English-Spanish sentences in the reference produces the data set *ref-hold*. The strategies containing the keyword *ref* for ASR simply means that the ASR hypotheses are used in place of the gold reference text.

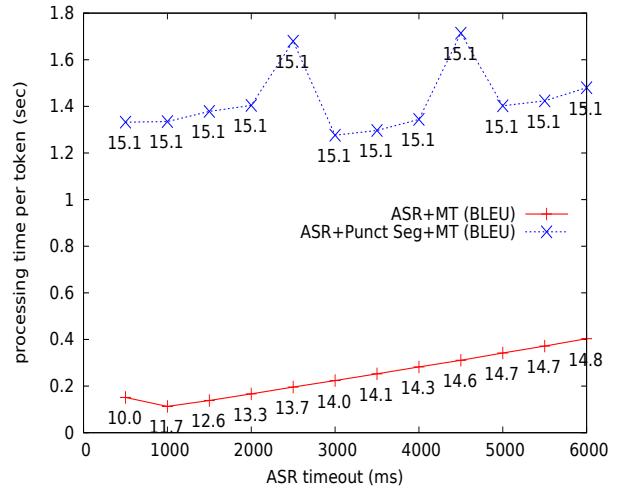

Figure 1: Latencies and BLEU scores for *tst2010* set using incremental ASR decoding and translation

We also performed real-time speech translation by using incremental speech recognition, i.e., the decoder returns partial hypotheses that, independent of

the pruning during search, will not change in the future. Figure 1 shows the plot for two scenarios: one in which the partial hypotheses are sent directly to machine translation and another where the best segmentation strategy *pred-punct* is used to segment the partial output before sending it to MT. The plot shows the BLEU scores as a function of ASR timeouts used to generate the partial hypotheses. Figure 1 also shows the average latency involved in incremental speech translation.

7 Discussion

The BLEU scores for the segmentation strategies over ASR hypotheses was computed at the talk level. Since the ASR hypotheses do not align with the reference source text, it is not feasible to evaluate the translation performance using the gold reference. While other studies have used an approximate edit distance algorithm for resegmentation of the hypotheses (Matusov et al., 2005), we simply concatenate all the segments and perform the evaluation at the talk level.

The *hold* segmentation strategy yields the poorest translation performance. The significant drop in BLEU score can be attributed to relatively short segments (2-4 words) that was generated by the model. The scheme oversegments the text and since the translation and language models are trained on sentence like chunks, the performance is poor. For example, the input text *the sea* should be translated as *el mar*, but instead the *hold* segmenter chunks it as *the·sea* which MT’s chunk translation renders as *el·el mar*. It will be interesting to increase the span of the *hold* strategy to subsume more contiguous sequences and we plan to investigate this as part of future work.

The *chunk* segmentation strategy yields quite poor translation performance. In general, it does not make the same kinds of errors that the *hold* strategy makes; for example, the input text *the sea* will be treated as one NC chunk by the *chunk* segmentation strategy, leading MT to translate it correctly as *el mar*. The short chunk sizes of *chunk* lead to other kinds of errors. For example, the input text *we use* will be chunked into the NC *we* and the VC *use*, which will be translated incorrectly as *nosotros·usar*; the infinitive *usar* is se-

lected rather than the properly conjugated form *usamos*. However, there is a marked improvement in translation accuracy with increasingly larger chunk sizes (*lgchunk1*, *lgchunk2*, and *lgchunk3*). Notably, *lgchunk3* yields performance that approaches that of *win8* with a chunk size that is one third of *win8*’s.

The *conj-pred-eos* and *pred-punct* strategies work the best, and it can be seen that the average segment length (8-12 words) generated in both these schemes is very similar to that used for training the models. It is also about the average latency (4-5 seconds) that can be tolerated in cross-lingual communication, also known as ear-voice span (Lederer, 1978). The non-linguistic segmentation using fixed word length windows also performs well, especially for the longer length windows. However, longer windows (*win15*) increase the latency and any fixed length window typically destroys the semantic context. It can also be seen from Table 3 that translating the complete talk is suboptimal in comparison with segmenting the text. This is primarily due to bias on sentence length distributions in the training data. Training models on complete talks is likely to resolve this issue. Contrasting the use of reference segments as input to MT (*ref-sent*, *ref-punct*, *conj-ref-eos*) versus the use of predicted segments (*pred-sent*, *pred-punct*, *conj-pred-eos*, respectively), it is interesting to note that the MT accuracies never differed greatly between the two, despite the noise in the set of predicted segments.

The performance of the real-time speech translation of TED talks is much lower than the offline scenario. First, we use only a VTLN model as performing CMA adaptation in a real-time scenario typically increases latency. Second, the ASR language model is trained on sentence-like units and decoding the entire talk with this LM is not optimal. A language model trained on complete talks will be more appropriate for such a framework and we are investigating this as part of current work.

Comparing the accuracies of different speech translation strategies, Table 3 shows that *pred-punct* performs the best. When embedded in an incremental MT speech recognition system, Figure 1 shows that it is more accurate than the system that sends partial ASR hypotheses directly to MT. This advantage decreases, however, when the ASR timeout parameter is increased to more than five or six sec-

onds. In terms of latency, Figure 1 shows that the addition of the *pred-punct* segmenter into the incremental system introduces a significant delay. About one third of the increase in delay can be attributed to merely maintaining the two word lookahead window that the segmenter’s classifier needs to make decisions. This is significant because this kind of window has been used quite frequently in previous work on simultaneous translation (cf. (Fügen et al., 2007)), and yet to our knowledge this penalty associated with this configuration was never mentioned. The remaining delay can be attributed to the long chunk sizes that the segmenter produces. An interesting aspect of the latency curve associated with the segmenter in Figure 1 is that there are two peaks at ASR timeouts of 2,500 and 4,500 ms, and that the lowest latency is achieved at 3,000 ms rather than at a smaller value. This may be attributed to the fact that the system is a pipeline consisting of ASR, segmenter, and MT, and that 3,000 ms is roughly the length of time to recite comma-separated chunks. Consequently, the two latency peaks appear to correspond with ASR producing segments that are most divergent with segments that the segmenter produces, leading to the most pipeline “stalls.” Conversely, the lowest latency occurs when the timeout is set so that ASR’s segments most resemble the segmenter’s output to MT.

8 Conclusion

We investigated various approaches for incremental speech translation of TED talks, with the aim of producing a system with high MT accuracy and low latency. For acoustic modeling, we found that VTLN and CMA adaptation were useful for increasing the accuracy of ASR, leading to a word accuracy of 80% on TED talks used in the IWSLT evaluation track. In our offline MT experiments retention of partial translations was found useful for increasing MT accuracy, with the latter being slightly more helpful. We experimented with several linguistic and non-linguistic strategies for text segmentation before translation. Our experiments indicate that a novel segmentation into conjunction-separated sentence chunks resulted in accuracies almost as high and latencies almost as short as comma-separated sentence chunks. They also indicated that signifi-

cant noise in the detection of sentences and punctuation did not seriously impact the resulting MT accuracy. Experiments on real-time simultaneous speech translation using partial recognition hypotheses demonstrate that introduction of a segmenter increases MT accuracy. They also showed that in order to reduce latency it is important for buffers in different pipeline components to be synchronized so as to minimize pipeline stalls. As part of future work, we plan to extend the framework presented in this work for performing speech-to-speech translation. We also plan to address the challenges involved in S2S translation across languages with very different word order.

Acknowledgments

We would like to thank Simon Byers for his help with organizing the TED talks data.

Abstract

Treebanks are not large enough to adequately model subcategorization frames of predicative lexemes, which is an important source of lexico-syntactic constraints for parsing. As a consequence, parsers trained on such treebanks usually make mistakes when selecting the arguments of predicative lexemes. In this paper, we propose an original way to correct subcategorization errors by combining subparses of a sentence S that appear in the list of the n -best parses of S . The subcategorization information comes from three different resources, the first one is extracted from a treebank, the second one is computed on a large corpora and the third one is an existing syntactic lexicon. Experiments on the French Treebank showed a 15.24% reduction of erroneous subcategorization frames (SF) selections for verbs as well as a relative decrease of the error rate of 4% Labeled Accuracy Score on the state of the art parser on this treebank.

1 Introduction

Automatic syntactic parsing of natural languages has witnessed many important changes in the last fifteen years. Among these changes, two have modified the nature of the task itself. The first one is the availability of treebanks such as the Penn Treebank (Marcus et al., 1993) or the French Treebank (Abeillé et al., 2003), which have been used in the parsing community to train stochastic parsers, such as (Collins, 1997; Petrov and Klein, 2008). Such work remained rooted in the classical language theoretic tradition of parsing, generally based on vari-

ants of generative context free grammars. The second change occurred with the use of discriminative machine learning techniques, first to rerank the output of a stochastic parser (Collins, 2000; Charniak and Johnson, 2005) and then in the parser itself (Ratnaparkhi, 1999; Nivre et al., 2007; McDonald et al., 2005a). Such parsers clearly depart from classical parsers in the sense that they do not rely anymore on a generative grammar: given a sentence S , all possible parses for S^1 are considered as possible parses of S . A parse tree is seen as a set of lexico-syntactic features which are associated to weights. The score of a parse is computed as the sum of the weights of its features.

This new generation of parsers allows to reach high accuracy but possess their own limitations. We will focus in this paper on one kind of weakness of such parser which is their inability to properly take into account subcategorization frames (SF) of predicative lexemes², an important source of lexico-syntactic constraints. The proper treatment of SF is actually confronted to two kinds of problems: (1) the acquisition of correct SF for verbs and (2) the integration of such constraints in the parser.

The first problem is a consequence of the use of treebanks for training parsers. Such treebanks are composed of a few thousands sentences and only a small subpart of acceptable SF for a verb actually

¹Another important aspect of the new parsing paradigm is the use of dependency trees as a means to represent syntactic structure. In dependency syntax, the number of possible syntactic trees associated to a sentence is bounded, and only depends on the length of the sentence, which is not the case with syntagmatic derivation trees.

²We will concentrate in this paper on verbal SF.

occur in the treebank.

The second problem is a consequence of the parsing models. For algorithmic complexity as well as data sparseness reasons, the parser only considers lexico-syntactic configurations of limited domain of locality (in the parser used in the current work, this domain of locality is limited to configurations made of one or two dependencies). As described in more details in section 2, SF often exceed in scope such domains of locality and are therefore not easy to integrate in the parser. A popular method for introducing higher order constraints in a parser consist in reranking the n best output of a parser as in (Collins, 2000; Charniak and Johnson, 2005). The reranker search space is restricted by the output of the parser and high order features can be used. One drawback of the reranking approach is that correct SF for the predicates of a sentence can actually appear in different parse trees. Selecting complete trees can therefore lead to sub-optimal solutions. The method proposed in this paper merges parts of different trees that appear in an n best list in order to build a new parse.

Taking into account SF in a parser has been a major issue in the design of syntactic formalisms in the eighties and nineties. Unification grammars, such as Lexical Functional Grammars (Bresnan, 1982), Generalized Phrase Structure Grammars (Gazdar et al., 1985) and Head-driven Phrase Structure Grammars (Pollard and Sag, 1994), made SF part of the grammar. Tree Adjoining Grammars (Joshi et al., 1975) proposed to extend the domain of locality of Context Free Grammars partly in order to be able to represent SF in a generative grammar. More recently, (Collins, 1997) proposed a way to introduce SF in a probabilistic context free grammar and (Arun and Keller, 2005) used the same technique for French. (Carroll et al., 1998), used subcategorization probabilities for ranking trees generated by unification-based phrasal grammar and (Zeman, 2002) showed that using frame frequency in a dependency parser can lead to a significant improvement of the performance of the parser.

The main novelties of the work presented here is (1) the way a new parse is built by combining subparses that appear in the n best parse list and (2) the use of three very different resources that list the possible SF for verbs.

The organization of the paper is the following: in section 2, we will briefly describe the parsing model that we will be using for this work and give accuracy results on a French corpus. Section 3 will describe three different resources that we have been using to correct SF errors made by the parser and give coverage results for these resources on a development corpus. Section 4 will propose three different ways to take into account, in the parser, the resources described in section 3 and give accuracy results. Section 5 concludes the paper.

2 The Parser

The parser used in this work is the second order graph based parser (McDonald et al., 2005b) implementation of (Bohnet, 2010). The parser was trained on the French Treebank (Abeillé et al., 2003) which was transformed into dependency trees by (Candito et al., 2009). The size of the treebank and its decomposition into train, development and test sets are represented in table 1.

	nb of sentences	nb of tokens
TRAIN	9 881	278 083
DEV	1 239	36 508
TEST	1 235	36 340

Table 1: Size and decomposition of the French Treebank

The parser gave state of the art results for parsing of French, reported in table 2. Table 2 reports the standard Labeled Accuracy Score (LAS) and Unlabeled Accuracy Score (UAS) which is the ratio of correct labeled (for LAS) or unlabeled (for UAS) dependencies in a sentence. We also defined a more specific measure: the SF Accuracy Score (SAS) which is the ratio of verb occurrences that have been paired with the correct SF by the parser. We have introduced this quantity in order to measure more accurately the impact of the methods described in this paper on the selection of a SF for the verbs of a sentence.

	TEST	DEV
SAS	80.84	79.88
LAS	88.88	88.53
UAS	90.71	90.37

Table 2: Subcategorization Frame Accuracy, Labeled and Unlabeled Accuracy Score on TEST and DEV.

We have chosen a second order graph parser in this work for two reasons. The first is that it is the parsing model that obtained the best results on the French Treebank. The second is that it allows us to impose structural constraints in the solution of the parser, as described in (Mirroshandel and Nasr, 2011), a feature that will reveal itself precious when enforcing SF in the parser output.

3 The Resources

Three resources have been used in this work in order to correct SF errors. The first one has been extracted from a treebank, the second has been extracted from an automatically parsed corpus that is several order of magnitude bigger than the treebank. The third one has been extracted from an existing lexico-syntactic resource. The three resources are respectively described in sections 3.2, 3.3 and 3.4. Before describing the resources, we describe in details, in section 3.1 our definition of SF. In section 3.5, we evaluate the coverage of these resources on the DEV corpus. Coverage is an important characteristic of a resource: in case of an SF error made by the parser, if the correct SF that should be associated to a verb, in a sentence, does not appear in the resource, it will be impossible to correct the error.

3.1 Subcat Frames Description

In this work, a SF is defined as a couple (G, L) where G is the part of speech tag of the element that licenses the SF. This part of speech tag can either be a verb in infinitive form (VINF), a past participle (VPP), a finite tense verb (V) or a present participle (VPR). L is a set of couples (f, c) where f is a syntactic function tag chosen among a set \mathcal{F} and c is a part of speech tag chosen among the set \mathcal{C} . Couple (f, c) indicates that function f can be realized as part of speech tag c . Sets \mathcal{F} and \mathcal{C} are respectively displayed in top and bottom tables of figure 1. An anchored SF (ASF) is a couple (v, S) where v is a verb lemma and S is a SF, as described above.

A resource is defined as a collection of ASF (v, S) , each associated to a count c , to represent the fact that verb v has been seen with SF S c times. In the case of the resource extracted from an existing lexicon (section 3.4), the notion of count is not applicable and we will consider that it is always equal

SUJ	subject
OBJ	object
A_OBJ	indirect object introduced by the preposition à
DE_OBJ	indirect object introduced by the preposition de
P_OBJ	indirect object introduced by another preposition
ATS	attribute of the subject
ATO	attribute of the direct object
ADJ	adjective
CS	subordinating conjunction
N	noun
V	verb finite tense
VINF	verb infinitive form
VPP	verb past participle
VPR	verb present participle

Figure 1: Syntactic functions of the arguments of the SF (top table). Part of speech tags of the arguments of the SF (bottom table)

to one.

Below is an example of three ASF for the french verb *donner* (*to give*). The first one is a transitive SF where both the subject and the object are realized as nouns as in *Jean donne un livre* (*Jean gives a book*.). The second one is ditransitive, it has both a direct object and an indirect one introduced by the preposition à as in *Jean donne un livre à Marie*. (*Jean gives a book to Marie*). The third one corresponds to a passive form as in *le livre est donné à Marie par Jean* (*The book is given to Marie by Jean*).

```
(donner, (V, (suj, N), (obj, N)))
(donner, (V, (suj, N), (obj, N), (a_obj, N)))
(donner, (VPP, (suj, N), (aux_pass, V),
          (a_obj, N), (p_obj, N)))
```

One can note that when an argument corresponds to an indirect dependent of the verb (introduced either by a preposition or a subordinating conjunction), we do not represent in the SF, the category of the element that introduces the argument, but the category of the argument itself, a noun or a verb.

Two important choices have to be made when defining SF. The first one concerns the dependents of the predicative element that are in the SF (argument/adjunct distinction) and the second is the level of abstraction at which SF are defined.

In our case, the first choice is constrained by the treebank annotation guidelines. The FTB distinguishes seven syntactic functions which can be considered as arguments of a verb. They are listed in the top table of figure 1. Most of them are straight-

forward and do not deserve an explanation. Something has to be said though on the syntactic function P_OBJ which is used to model arguments of the verb introduced by a preposition that is neither *à* nor *de*, such as the agent in passive form, which is introduced by the preposition *par*.

We have added in the SF two elements that do not correspond to arguments of the verb: the reflexive pronoun, and the passive auxiliary. The reason for adding these elements to the SF is that their presence influences the presence or absence of some arguments of the verb, and therefore the SF.

The second important choice that must be made when defining SF is the *level of abstraction*, or, in other words, how much the SF abstracts away from its realization in the sentence. In our case, we have used two ways to abstract away from the surface realization of the SF. The first one is factoring several part of speech tags. We have factored pronouns, common nouns and proper nouns into a single category N. We have not gathered verbs in different modes into one category since the mode of the verb influences its syntactic behavior and hence its SF. The second means of abstraction we have used is the absence of linear order between the arguments. Taking into account argument order increases the number of SF and, hence, data sparseness, without adding much information for selecting the correct SF, this is why we have decided to ignore it. In our second example above, each of the three arguments can be realized as one out of eight parts of speech that correspond to the part of speech tag N and the 24 possible orderings are represented as one canonical ordering. This SF therefore corresponds to 12 288 possible realizations.

3.2 Treebank Extracted Subcat Frames

This resource has been extracted from the TRAIN corpus. At a first glance, it may seem strange to extract data from the corpus that have been used for training our parser. The reason is that, as seen in section 1, SF are not directly modeled by the parser, which only takes into account subtrees made of, at most, two dependencies.

The extraction procedure of SF from the treebank is straightforward : the tree of every sentence is visited and, for every verb of the sentence, its daughters are visited, and, depending whether they are consid-

ered as arguments of the verb (with respect to the conventions or section 3.1), they are added to the SF. The number of different verbs extracted, as well as the number of different SF and the average number of SF per verb are displayed in table 3. Column T (for Train) is the one that we are interested in here.

	T	L	A_0	A_5	A_{10}
nb of verbs	2058	7824	23915	4871	3923
nb of diff SF	666	1469	12122	2064	1355
avg. nb of SF	4.83	52.09	14.26	16.16	13.45

Table 3: Resources statistics

The extracted resource can directly be compared with the TREELEX resource (Kupsc and Abeillé, 2008), which has been extracted from the same treebank. The result that we obtain is different, due to the fact that (Kupsc and Abeillé, 2008) have a more abstract definition of SF. As a consequence, they define a smaller number of SF: 58 instead of 666 in our case. The smaller number of SF yields a smaller average number of SF per verb: 1.72 instead of 4.83 in our case.

3.3 Automatically computed Subcat Frames

The extraction procedure described above has been used to extract ASF from an automatically parsed corpus. The corpus is actually a collection of three corpora of slightly different genres. The first one is a collection of news reports of the French press agency *Agence France Presse*, the second is a collection of newspaper articles from a local French newspaper : *l'Est Républicain*. The third one is a collection of articles from the French Wikipedia. The size of the different corpora are detailed in table 4.

The corpus was first POS tagged with the MELT tagger (Denis and Sagot, 2010), lemmatized with the MACAON tool suite (Nasr et al., 2011) and parsed in order to get the best parse for every sentence. Then the ASF have been extracted.

The number of verbs, number of SF and average number of SF per verb are represented in table 3, in column A_0 (A stands for Automatic). As one can see, the number of verbs and SF are unrealistic. This is due to the fact that the data that we extract SF from is noisy: it consists of automatically produced syntactic trees which contain errors (recall

CORPUS	Sent. nb.	Tokens nb.
AFP	2 041 146	59 914 238
EST REP	2 998 261	53 913 288
WIKI	1 592 035	33 821 460
TOTAL	5 198 642	147 648 986

Table 4: sizes of the corpora used to collect SF

that the LAS on the DEV corpus is 88,02%). There are two main sources of errors in the parsed data: the pre-processing chain (tokenization, part of speech tagging and lemmatization) which can consider as a verb a word that is not, and, of course, parsing errors, which tend to create crazy SF. In order to fight against noise, we have used a simple thresholding: we only collect ASF that occur more than a threshold i . The result of the thresholding appears in columns A_5 and A_{10} , where the subscript is the value of the threshold. As expected both the number of verbs and SF decrease sharply when increasing the value of the threshold.

Extracting SF for verbs from raw data has been an active direction of research for a long time, dating back at least to the work of (Brent, 1991) and (Manning, 1993). More recently (Messiant et al., 2008) proposed such a system for French verbs. The method we use for extracting SF is not novel with respect to such work. Our aim was not to devise new extraction techniques but merely to evaluate the resource produced by such techniques for statistical parsing.

3.4 Using an existing resource

The third resource that we have used is the *Lefff* (Lexique des formes fléchies du français — *Lexicon of French inflected form*), a large-coverage syntactic lexicon for French (Sagot, 2010). The *Lefff* was developed in a semi-automatic way: automatic tools were used together with manual work. The latest version of the *Lefff* contains 10,618 verbal entries for 7,835 distinct verbal lemmas (the *Lefff* covers all categories, but only verbal entries are used in this work).

A sub-categorization frame consists in a list of syntactic functions, using an inventory slightly more fine-grained than in the French Treebank, and for each of them a list of possible realizations (e.g., noun phrase, infinitive clause, or null-realization if

the syntactic function is optional).

For each verbal lemma, we extracted all sub-categorization frames for each of the four verbal part-of-speech tags (V, VINF, VPR, VPP), thus creating an inventory of SFs in the same sense and format as described in Section 3.1. Note that such SFs do not contain alternatives concerning the way each syntactic argument is realized or not: this extraction process includes a de-factorization step. Its output, hereafter L , contains 801,246 distinct (lemma, SF) pairs.

3.5 Coverage

In order to be able to correct SF errors, the three resources described above must possess two important characteristics: high coverage and high accuracy. Coverage measures the presence, in the resource, of the correct SF of a verb, in a given sentence. Accuracy measures the ability of a resource to select the correct SF for a verb in a given context when several ones are possible.

We will give in this section coverage result, computed on the DEV corpus. Accuracy will be described and computed in section 4. The reason why the two measures are not described together is due to the fact that coverage can be computed on a reference corpus while accuracy must be computed on the output of a parser, since it is the parser that will propose different SF for a verb in a given context.

Given a reference corpus C and a resource R , two coverage measures have been computed, lexical coverage, which measures the ratio of verbs of C that appear in R and syntactic coverage, which measures the ratio of ASF of C that appear in R . Two variants of each measures are computed: on types and on occurrences. The values of these measures computed on the DEV corpus are summarized in table 5.

		T	L	A_0	A_5	A_{10}
Lex.	types	89.56	99.52	99.52	98.56	98.08
	occ	96.98	99.85	99.85	99.62	99.50
Synt.	types	62.24	78.15	95.78	91.08	88.84
	occ	73.54	80.35	97.13	93.96	92.39

Table 5: Lexical and syntactic coverage of the three resources on DEV

The figures of table 5 show that lexical coverage of the three resources is quite high, ranging

from 89.56 to 99.52 when computed on types and from 96.98 to 99.85 when computed on occurrences. The lowest coverage is obtained by the T resource, which does not come as a surprise since it is computed on a rather small number of sentences. It is also interesting to note that lexical coverage of A does not decrease much when augmenting the threshold, while the size of the resource decreases dramatically (as shown in table 3). This validates the hypothesis that the resource is very noisy and that a simple threshold on the occurrences of ASF is a reasonable means to fight against noise.

Syntactic coverage is, as expected, lower than lexical coverage. The best results are obtained by A_0 : 95.78 on types and 97.13 on occurrences. Thresholding on the occurrences of anchored SF has a bigger impact on syntactic coverage than it had on lexical coverage. A threshold of 10 yields a coverage of 88.84 on types and 92.39 on occurrences.

4 Integrating Subcat Frames in the Parser

As already mentioned in section 1, SF usually exceed the domain of locality of the structures that are directly modeled by the parser. It is therefore difficult to integrate directly SF in the model of the parser. In order to circumvent the problem, we have decided to work on the n-best output of the parser: we consider that a verb v , in a given sentence S , can be associated to any of the SF that v licenses in one of the n-best trees. The main weakness of this method is that an SF error can be corrected only if the right SF appears at least in one of the n-best parse trees.

In order to estimate an upper bound of the SAS that such methods can reach (how many SF errors can actually be corrected), we have computed the oracle SAS on the 100 best trees of the DEV corpus DEV (for how many verbs the correct SF appears in at least one of the n-best parse trees). The oracle score is equal to 95.16, which means that for 95.16% of the verb occurrences of the DEV, the correct SF appears somewhere in the 100-best trees. 95.16 is therefore the best SAS that we can reach. Recall that the baseline SAS is equal to 79.88% the room for progress is therefore equal to 15.28% absolute.

Three experiments are described below. In the first one, section 4.1, a simple technique, called Post

Processing is used. Section 4.2 describes a second technique, called Double Parsing, which is a refinement of Post Processing. Both sections 4.1 and 4.2 are based on single resources. Section 4.3 proposes a simple way to combine the different resources.

4.1 Post Processing

The post processing method (PP) is the simplest one that we have tested. It takes as input the different ASF that occur in the n-best output of the parser as well as a resource R . Given a sentence, let's note $T_1 \dots T_n$ the trees that appear in the n-best output of the parser, in decreasing order of their score. For every verb v of the sentence, we note $\mathcal{S}(v)$ the set of all the SF associated to v that appear in the trees $T_1 \dots T_n$.

Given a verb v and a SF s , we define the following functions:

$\mathcal{C}(v, s)$ is the number of occurrences of the ASF (v, s) in the trees $T_1 \dots T_n$.

$\mathcal{F}(v)$ is the SF associated to v in T_1

$\mathcal{C}_R(v, s)$ the number of occurrences of the ASF (v, s) in the resource R .

We define a selection function as a function that selects a SF for a given verb in a given sentence. A selection function has to take into account the information given by the resource (whether an SF is acceptable/frequent for a given verb) as well as the information given by the parser (whether the parser has a strong preference to associate a given SF to a given verb).

In our experiments, we have tested two simple selection functions. φ_R which selects the first SF $s \in \mathcal{S}(v)$, such that $\mathcal{C}_R(v, s) > 0$ when traversing the trees $T_1 \dots T_n$ in the decreasing order of score (best tree first).

The second function, $\psi_R(v)$ compares the most frequent SF for v in the resource R with the SF of the first parse. If the ratio of the number of occurrences in the n-best of the former and the latter is above a threshold α , the former is selected. More formally:

$$\psi_R(v) = \begin{cases} \hat{s} = \arg \max_{s \in \mathcal{S}(v)} \mathcal{C}_R(v, s) & \text{if } \frac{\mathcal{C}(v, \hat{s})}{\mathcal{C}(v, \mathcal{F}(v))} > \alpha \\ \mathcal{F}(v) & \text{otherwise} \end{cases}$$

The coefficient α has been optimized on DEV corpus. Its value is equal to 2.5 for the Automatic resource, 2 for the Train resource and 1.5 for the Lefff.

The construction of the new solution proceeds as follows: for every verb v of the sentence, a SF is selected with the selection function. It is important to note, at this point, that the SF selected for different verbs of the sentence can pertain to different parse trees. The new solution is built based on tree T_1 . For every verb v , its arguments are potentially modified in agreement with the SF selected by the selection function. There is no guarantee at this point that the solution is well formed. We will return to this problem in section 4.2.

We have evaluated the PP method with different selection functions on the TEST corpus. The results of applying function ψ_R were more successful. As a result we just report the results of this function in table 6. Different levels of thresholding for resource A gave almost the same results, we therefore used A_{10} which is the smallest one.

	B	T	L	A
SAS	80.84	83.11	82.14	82.17
LAS	88.88	89.14	89.03	89.03
UAS	90.71	90.91	90.81	90.82

Table 6: LAS and UAS on TEST using PP

The results of table 6 show two interesting facts. First, the SAS is improved, it jumps from 80.84 to 83.11. PP therefore corrects some SF errors made by the parser. It must be noted however that this improvement is much lower than the oracle score. The second interesting fact is the very moderate increase of both LAS and UAS. This is due to the fact that the number of dependencies modified is small with respect to the total number of dependencies. The impact on LAS and UAS is therefore weak.

The best results are obtained with resource T . Although the coverage of T is low, the resource is very close to the train data, this fact probably explains the good results obtained with this resource.

It is interesting, at this point, to compare our method with a reranking approach. In order to do so, we have compared the upper bound of the number of SF errors that can be corrected when using reranking and our approach. The results of the comparison computed on a list of 100 best trees is reported in

table 7 which shows the ratio of subcat frame errors that could be corrected with a reranking approach and the ratio of errors sub-parse recombining could reach.

	DEV	TEST
reranking	53.9%	58.5%
sub-parse recombining	75.5%	76%

Table 7: Correction rate for subcat frames errors with different methods

Table 7 shows that combining sub Parses can, in theory, correct a much larger number of wrong SF assignments than reranking.

4.2 Double Parsing

The post processing method shows some improvement over the baseline. But it has an important drawback: it can create inconsistent parses. Recall that the parser we are using is based on a second order model. In other words, the score of a dependency depends on some neighboring dependencies. When building a new solution, the post processing method modifies some dependencies independently of their context, which may give birth to very unlikely configurations.

In order to compute a new optimal parse tree that preserves the modified dependencies, we have used a technique proposed in (Mirroshandel and Nasr, 2011) that modifies the scoring function of the parser in such a way that the dependencies that we want to keep in the parser output get better scores than all competing dependencies. The new solution is therefore the optimal solution that preserves the dependencies modified by the PP method.

The double parsing (DP) method is therefore a three stage method. First, sentence S is parsed, producing the n -best parses. Then, the post processing method is used, modifying the first best parse. Let's note \mathcal{D} the set of dependencies that were changed in this process. In the last stage, a new parse is produced, that preserves \mathcal{D} .

	B	T	L	A
SAS	80.84	83.11	82.14	82.17
LAS	88.88	89.30	89.25	89.31
UAS	90.71	91.07	91.05	91.08

Table 8: LAS and UAS on TEST using DP

The results of DP on TEST are reported in table 8. SAS did not change with respect to PP, because DP keeps the SF selected by PP. As expected DP does increase LAS and UAS. Recomputing an optimal solution therefore increases the quality of the parses. Table 8 also shows that the three resources get almost the same LAS and UAS although SAS is better for resource T.

4.3 Combining Resources

Due to the different generation techniques of our three resources, another direction of research is combining them. We did different experiments concerning all possible combination of resources: A and L (AL), T and L (TL), T and A (TA), and all tree (TAL) resources. The results of these combinations for PP and DP methods are shown in tables 9 and 10, respectively.

The resource are combined in a back-off schema: we search for a candidate ASF in a first resource. If it is found, the search stops. Otherwise, the next resource(s) are probed. One question that arises is: which sequence is the optimal one for combining the resources. To answer this question, we did several experiments on DEV set. Our experiments have shown that it is better to search T resource, then A, and, eventually, L. The results of this combining method, using PP are reported in table 9. The best results are obtained for the TL combination. The SAS jumps from 83.11 to 83.76. As it was the case with single resources, the LAS and UAS increase is moderate.

	B	AL	TL	TA	TAL
SAS	80.84	82.12	83.76	83.50	83.50
LAS	88.88	89.03	89.22	89.19	89.19
UAS	90.71	90.79	90.98	90.95	90.95

Table 9: LAS and UAS on TEST using PP with resource combination

With DP (table 9), the order of resource combination is exactly the same as with PP. As was the case with single resources, DP has a positive, but moderate, impact on LAS and UAS.

The results of tables 9 and 10 do not show considerable improvement over single resources. This might be due to the large intersection between our resources. In other words, they do not have complementary information, and their combination will not

	B	AL	TL	TA	TAL
SAS	80.84	82.12	83.76	83.50	83.50
LAS	88.88	89.22	89.31	89.34	89.34
UAS	90.71	91.02	91.05	91.08	91.09

Table 10: LAS and UAS on TEST using DP with resource combination

introduce much information. Another possible reason for this result is the combination technique used. More sophisticated techniques might yield better results.

5 Conclusions

Subcategorization frames for verbs constitute a rich source of lexico-syntactic information which is hard to integrate in graph based parsers. In this paper, we have used three different resources for subcategorization frames. These resources are from different origins with various characteristics. We have proposed two different methods to introduce the useful information from these resources in a second order model parser. We have conducted different experiments on French Treebank that showed a 15.24% reduction of erroneous SF selections for verbs. Although encouraging, there is still plenty of room for better results since the oracle score for 100 best parses is equal to 95.16% SAS and we reached 83.76%. Future work will concentrate on more elaborate selection functions as well as more sophisticated ways to combine the different resources.

Large-Scale Discriminative Training for Statistical Machine Translation Using Held-Out Line Search

Jeffrey Flanigan Chris Dyer Jaime Carbonell

Abstract

We introduce a new large-scale discriminative learning algorithm for machine translation that is capable of learning parameters in models with extremely sparse features. To ensure their reliable estimation and to prevent overfitting, we use a two-phase learning algorithm. First, the contribution of individual sparse features is estimated using large amounts of parallel data. Second, a small development corpus is used to determine the relative contributions of the sparse features and standard dense features. Not only does this two-phase learning approach prevent overfitting, the second pass optimizes corpus-level BLEU of the Viterbi translation of the decoder. We demonstrate significant improvements using sparse rule indicator features in three different translation tasks. To our knowledge, this is the first large-scale discriminative training algorithm capable of showing improvements over the MERT baseline with only rule indicator features in addition to the standard MERT features.

1 Introduction

This paper is about large scale discriminative training of machine translation systems. Like MERT (Och, 2003), our procedure directly optimizes the cost of the Viterbi output on corpus-level metrics, but does so while scaling to millions of features. The training procedure, which we call the **Held-Out Line Search** algorithm (HOLS), is a two-phase iterative batch optimization procedure consisting of (1) a gradient calculation on a differentiable approximation to the loss on a large amount of parallel training

data and (2) a line search (using the standard MERT algorithm) to search in a subspace defined by the gradient for the weights that minimize the true cost.

While sparse features are successfully used in many NLP systems, such parameterizations pose a number of learning challenges. First, since any one feature is likely to occur infrequently, a large amount of training data is necessary to reliably estimate their weights. Therefore, we use the full parallel training data (rather than a small development set) to estimate the contribution of the sparse features in phase 1. Second, sparse features can lead to overfitting. To prevent this from hurting our model’s ability to generalize to new data, we do two things. First, we use “grammar and language model folds” (translation grammars and language models built from other portions of the training data than are being used for discriminative training), and second, we run the phase 2 line search on a held-out development set. Finally, since our algorithm requires decoding the entire training corpus, it is desirable (on computational grounds) to only require one or two passes through the training data. To get the most out of these passes, we rescale features by their inverse frequency which improves the scaling of the optimization problem. In addition to learning with few passes through the training data, the HOLS algorithm has the advantage that it is easily parallelizable.

After reviewing related work in the next section, we analyze two obstacles to effective discriminative learning for machine translation: overfitting (since both rules and their weights must be learned, if they are learned together degenerate solutions that fail to generalize are possible) and poor scaling (since MT

decoding is so expensive, it is not feasible to make many passes through large amounts of training data, so optimization must be efficient). We then present the details of our algorithm that addresses these issues, give results on three language pairs, and conclude.

2 Related Work

Discriminative training of machine translation systems has been a widely studied problem for the last ten years. The pattern of using small, high-quality development sets to tune a relatively small number of weights was established early (Och and Ney, 2002; Och, 2003). More recently, standard structured prediction algorithms that target linearly decomposable approximations of translation quality metrics have been thoroughly explored (Liang et al., 2006; Smith and Eisner, 2006; Watanabe et al., 2007; Rosti et al., 2010; Hopkins and May, 2011; Chiang, 2012; Gimpel and Smith, 2012; Cherry and Foster, 2012; Saluja et al., 2012). These have without exception used sentence-level approximations of BLEU to determine oracles and update weights using a variety of criteria and with a variety of different theoretical justifications.

Despite advancements in discriminative training for machine translation, large-scale discriminative training with rule indicator features has remained notoriously difficult. **Rule indicator features** are an extremely sparse and expressive parameterization of the translation model: every rule has a feature, each of which has its own separately tuned weight, which count how often a specific rule is used in a translation. Early experiments (Liang et al., 2006) used the structured perceptron to tune a phrase-based system on a large subset of the training data, showing improvements when using rule indicator features, word alignment features, and POS tag features. Another early attempt (Tillmann and Zhang, 2006) used phrase pair and word features in a block SMT system trained using stochastic gradient descent for a convex loss function, but did not compare to MERT. Problems of overfitting and degenerate derivations were tackled with a probabilistic latent variable model (Blunsom et al., 2008) which used rule indicator features yet failed to improve upon the MERT baseline for the standard Hiero features.

Techniques for distributed learning and feature selection for the perceptron loss using rule indicator, rule shape, and source side-bigram features have recently been proposed (Simianer et al., 2012), but no comparison to MERT was made.

3 Difficulties in Large-Scale Training

Discriminative training for machine translation is complicated by several factors. First, both translation rules and feature weights are learned from parallel data. If the same data is used for both tasks, overfitting of the weights is very possible.¹ Second, the standard MT cost function, BLEU (Papineni et al., 2002), does not decompose additively over training instances (because of the “brevity penalty”) and so approximations are used—these often have problems with the length (Nakov et al., 2012). Finally, state-of-the-art MT systems make extensive good use of “dense” features, such as the log probability of translation decisions under a simpler generative translation model. Our goal is to begin to use much sparser features without abandoning the proven dense features; however, extremely sparse features leads to problems of scaling in the optimization problem as we will show.

3.1 Training Data and Overfitting

One of the big questions in discriminative training of machine translation systems is why standard machine learning techniques can perform so poorly when applied to large-scale learning on the training data. Figure 1 shows a good example of this. The structured SVM (Tsouchantidis et al., 2004; Cherry and Foster, 2012) was used to learn the weights for a Chinese-English Hiero system (Chiang, 2005) with just eight features, using stochastic gradient descent (SGD) for online learning (Bottou, 1998; Bottou, 2010). The weights were initialized from MERT values tuned on a 2k-sentence dev set (MT06), and the figure shows the progress of the online method during a single pass through the 300k-sentence Chinese-English FBIS training set.

As the training progresses in Figure 1, BLEU scores on the training data go up, but scores on the

¹Previous work has attempted to mitigate the risk of overfitting through careful regularization (Blunsom et al., 2008; Simianer et al., 2012).

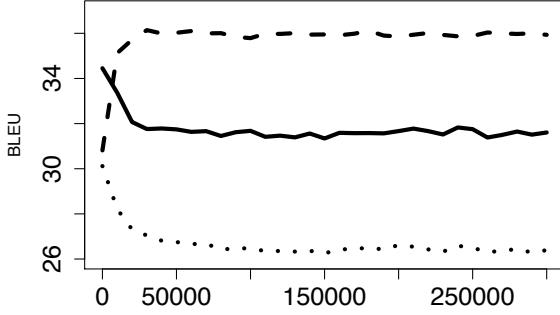

Figure 1: Progress of the online SVM training method after each training instance on FBIS dataset. The solid line is BLEU on the test set, training set is the dashed line, and the dev set is dotted.

dev and test sets go down. If we hope to apply discriminative training techniques for not eight but millions of features on the training data, we must find a way to prevent this overfitting.

We suggest that an important reason why overfitting occurs is that the training data is used not only to tune the system but also to extract the grammar, and the target side is included in the data used to build the language model. To test this hypothesis, we compare tuning using three different dev sets: 1000 sentences from the standard 4-reference MT06 dev set (Dev1000), a random selection of 1000 sentences that overlap with the corpus used to extract translation rules (In1000), and 1000 sentences that came from the training data but were then excluded from rule extraction (Out1000). We run MERT on each of these and evaluate. For evaluation we compare three different sets: a random 1000 sentences from the training corpus that was used to create the grammars but which do not overlap with In1000 (Train1000), the 1000 sentence dev set (Dev1000), and the standard 4-reference MT02-03 test set (Test). The entire experiment (including selection of the 1000 sentences) was replicated 5 times.

Table 1 shows the results, averaging over replications. Out1000 gives much higher scores on the testing data, validating our hypothesis that tuning on data used to build the LM and grammar can lead to overfitting. However, the results also show that tuning on the training data, even when it is held-out, can still lead to a small reduction in translation quality. One possible reason is that, unlike the training data

which may come from various domains, the dev data is in the same domain as the test data and is typically of higher quality (e.g., it has multiple references).

Table 1: MERT on Zh-En FBIS

Tuning Set	Train1000	Dev1000	Test
Dev1000	32.2 ± 1.1	30.2 ± 1.1	34.1 ± 3.3
In1000	37.0 ± 1.2	25.7 ± 0.7	30.1 ± 0.6
Out1000	34.9 ± 0.8	29.0 ± 0.4	33.6 ± 0.5

3.2 Poor Scaling

When features occur with different frequencies, changing the weights of more frequent features has a larger effect than changing the weights of less frequent features.² An example of frequent features that have a large impact on the translation quality are the language model and translation model features. These features are non-zero for every sentence, and changing their weights slightly has a large impact on translation output. In contrast, changing the weight drastically for a feature that is non-zero for only one out of a million sentences has very little effect on translation metrics. The sensitivity of the translation output to some feature weights over others was also pointed out in a recent paper (Chiang, 2012).

When the objective function is more sensitive in some dimensions than others, the optimization problem is said to be **poorly scaled** (Nocedal and Wright, 2000), and can slow down the convergence rate for some optimizers. A typical fix is to rescale the dimensions, as we will do in Section 5.2.

To verify that BLEU is poorly scaled with respect to weights of rule indicator features, we look at the effect of changing the weights for individual rules. We vary the feature weights for four randomly chosen frequent rules and four randomly chosen infrequent rules on our FBIS dev set (Figure 2). One can think of this plot as a “cross-section” of the BLEU score in the direction of the feature weight. The dense features are set to MERT-tuned values which are normalized to one. All other rule indicator features are set to zero, except the rule feature weight that is varied. The frequent features

²By the “frequency of a feature” we mean this: given a set of input instances, how many input instances the feature is nonzero in the space of possible outputs for that input.

were selected randomly from the 20 most common rule indicator features in the n-best lists on the dev set, and the infrequent features were selected from the features that only occurred once in these n-best lists. The plots indicate that the BLEU score is

poorly scaled for rule feature weights. Changing the weights for one of the common features changes the BLEU score by almost 2.5 BLEU points, while for the infrequent features the BLEU score changes by at most .02 BLEU points. We take this as a sign that gradient descent based optimizers for machine translation with rule features could be slow to converge due to poor scaling, and that rescaling will improve convergence.

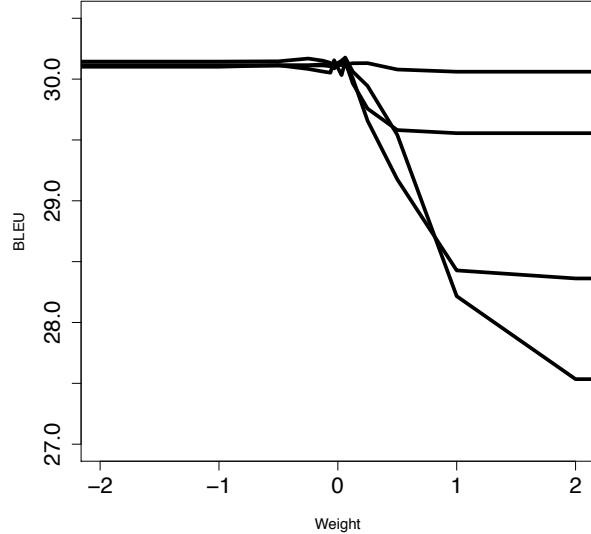

3.3 Sentence Level Approximations to BLEU

Finally, we note that discriminative training methods often use a sentence level approximation to BLEU. It has been shown that optimizing corpus level BLEU versus sentence level BLEU can lead to improvements of up to nearly .4 BLEU points on the test set (Nakov et al., 2012). Possible fixes to this problem include using a proper sentence level metric such as METEOR (Denkowski and Lavie, 2011) or a pseudo-corpus from the last few updates (Chiang et al., 2008). However, in light of the result from section 3.1 that tuning on the dev set is still better than tuning on a held-out portion of the training data, we observe that tuning a corpus level metric on a high-quality dev set from the same domain as the test set probably leads to the best translation quality. Attempts to improve upon this strong baseline lead us to the development of the HOLS algorithm which we describe next.

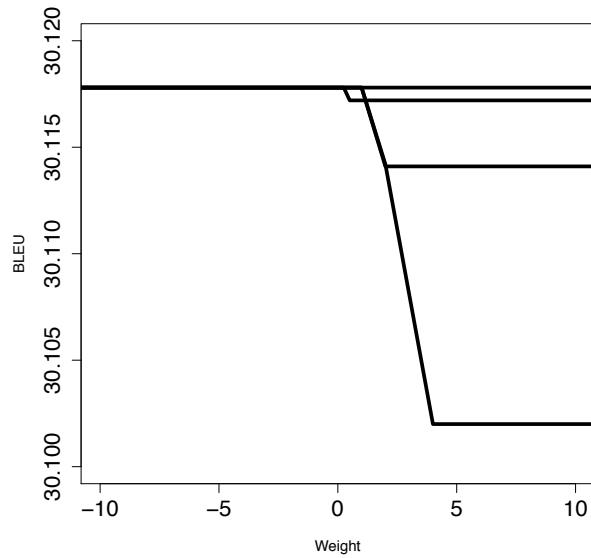

4 Held-Out Line Search Algorithm

In this section we give the details of the learning algorithm that we developed for use in large-scale discriminative training for machine translation, which we call the Held-Out Line Search algorithm (abbreviated HOLS). It optimizes millions of features using evidence from the full set of parallel training data to obtain optimal predictive performance on a secondary development set.

The learning algorithm is a batch optimizer where each iteration has two phases: a gradient calculation phase and a line search phase. In the gradient calculation phase, a surrogate loss function is used to compute a gradient for the feature weights. The gradient is computed over a subset of the training data. In the line search phase, a separate optimizer (MERT) is used to search along this gradient to opti-

(a) Four representative *frequent* sparse features.

(b) Four representative *infrequent* sparse features

mize the evaluation score of the one-best prediction of a translation system on a secondary development set.³ The secondary dev set is a crucial aspect of the algorithm that helps reduce overfitting (we will demonstrate this in the experiments section).

During the line search phase we allow some of the feature weights to be adjusted independently of the line search. We will call the features we optimize independently the dense features, and the features we include in the line search the sparse features.⁴ The feature vector space V is the direct sum $V = V_d \oplus V_s$, where V_d is the vector space of the dense features and V_s is the vector space of the sparse features. The feature and weight vectors decompose as $\vec{f} = \vec{f}_d + \vec{f}_s$ and $\vec{w} = \vec{w}_d + \vec{w}_s$. \vec{f}_d and \vec{w}_d are in the dense vector space, and the \vec{f}_s and \vec{w}_s are in the sparse vector space.

In the gradient phase, we calculate a gradient of the surrogate loss function and project it onto the subspace of the sparse features. Let P_s be the projection operator onto V_s . Then the gradient projected onto the sparse feature space is

$$\vec{g} = P_s \nabla_{\vec{w}} \tilde{L}(\vec{w}, \mathcal{D}_g)$$

where \mathcal{D}_g is the subset of the training data used to calculate this gradient, and \tilde{L} is the surrogate loss function. This just sets the dense components of the gradient of \tilde{L} to zero.

In the line search phase, we use a separate optimizer to optimize the weights for the dense features and the stepsize α . Let L be the loss function we wish to minimize, then

$$(\vec{w}_d^*, \alpha^*) = \arg \min_{\vec{w}_d, \alpha} L(\vec{w}_d + \vec{w}_s + \alpha \vec{g}, \mathcal{D}_l)$$

Note \vec{w}_s is held fixed from the previous iteration. \mathcal{D}_l is the portion of the training data which is used in the line search phase, and must not overlap with \mathcal{D}_g used in the gradient calculation phase.⁵

After the line search, the dense weights are updated to \vec{w}_d^* , and the sparse weights are updated with $\vec{w}_s \leftarrow \vec{w}_s + \alpha^* \vec{g}$. The process repeats for another iteration as desired (or until convergence).

³While we use BLEU any loss function whose sufficient statistics decompose over training instances could be used.

⁴The split over the features does not have to be done this way in practice.

⁵ $L(\vec{w}_d^*, \alpha^*, \mathcal{D}_l)$ can be thought of as unbiased or more accurately less biased estimator of expected loss when $\mathcal{D}_l \cap \mathcal{D}_g = \emptyset$.

5 Procedure for Large-Scale Training

Now that we have described the HOLS algorithm in general, we next describe how to apply it to large-scale training of machine translation systems with millions of features. We find that it is necessary to use disjoint sets of training instances for grammar extraction and gradient estimation (§5.1) and to deal with the poor scaling of the optimization problem (§5.2).

5.1 Grammar and Language Model Folds

To address the problem of overfitting on the training data, we split the training data into n -folds, and extract grammars for each fold using the data from the other $n - 1$ folds. Similarly, we build a language model for each fold using a target language monolingual corpus and the target side of the training data from the other $n - 1$ folds. Whenever we decode a sentence from the training data, we use the grammar and language model for the appropriate fold. This ensures that a sentence is never decoded using a grammar or language model it helped build, thereby reducing the overfitting effect demonstrated in §3.1.

To perform the training, the HOLS algorithm is used on the training data. In our experiments, only 1-2 passes over the training data are necessary for significant gains. Data from one of the grammar folds is used for the line search, and the rest of the training data is used to calculate the gradient.

The procedure is iterative, first decoding training data to obtain a gradient, and then performing a line search with data from a held-out grammar fold. Instead of decoding the whole set of sentences used for the gradient updates at once, one can also decode a portion of the data, do a gradient update, and then continue the next iteration of HOLS on the remaining data before repeating.

The last line search of the HOLS algorithm is done using dev data, rather than training data. This is because the dev data is higher quality, and from Table 1 we can see that tuning on dev data produces better results than tuning on training data (even if the training data has been held out from the grammar process). The initial weights are obtained by running MERT on a subset of the one of the grammar folds.

If one has an existing implementation of an op-

timer for the loss function used during the line search (in our case MERT), it can be used to perform the line search. This is done simply by calling MERT with two extra features in addition to the dense features and omitting the sparse features.

To see how, notice that the feature weights during the line search are decomposed as $\vec{w} = \vec{w}_{dense} + \vec{w}_{sparse} + \alpha\vec{g}$ where \vec{g} is in the sparse feature subspace, so the model score decomposes as $score(x, y) = \vec{w}_d \cdot \vec{f}_d(x, y) + \vec{w}_s \cdot \vec{f}_s(x, y) + \alpha\vec{g} \cdot \vec{f}_s(x, y)$ where x is the input translation, y is the output translation and derivation. If we create two new features $f_1(x, y) = \vec{w}_s \cdot \vec{f}_s(x, y)$ and $f_2(x, y) = \vec{g} \cdot \vec{f}_s(x, y)$ then the score can be written

$$\begin{aligned} score(x, y) &= \vec{w}_d \cdot \vec{f}_d(x, y) \\ &\quad + f_1(x, y) + \alpha f_2(x, y) \\ &= (\vec{w}_d, 1, \alpha) \cdot (\vec{f}_d, f_1, f_2) \end{aligned}$$

Thus we can do the line search simply by calling MERT with the features (\vec{f}_d, f_1, f_2) .⁶

In summary our training algorithm is as follows: 1) split the training data into n -folds (we use $n = 5$), 2) initialize the dense weights to MERT values, 3) decode some or all the data in 4 of the 5 folds to get a gradient, 4) condition as in §5.2 (see below), 5) run MERT on a 10k subset of the remaining fold to do the line search, 6) repeat steps 3-4 until convergence or stop as desired, and 7) run MERT on the normal dev set as a final step. We only run MERT on a 10k subset of one of the folds so it does not require running MERT on an entire fold.

In the special case where just one iteration of HOLS is performed, the procedure is very simple: decode the training data to get a gradient, include the components of the gradient as an extra feature f_2 in addition to the dense features, and tune on a dev set using MERT.

5.2 Conditioning

To address the problem of poor scaling, we use a simple strategy of rescaling each component of the gradient based on how frequent the feature is. We call this process “conditioning.” For each feature, we simply divide the corresponding dimension of

⁶We could constrain the weight for f_1 to be 1, but this is not necessary since MERT is invariant to the overall scale of the weights.

the gradient by the number of n-best lists in which the feature was non-zero in.

The necessity for conditioning is evident when we run the HOLS algorithm as detailed so far on the training data without conditioning. On subsequent iterations, we observe that the features with the highest component of the gradient oscillate between iterations, but the rest of the feature gradients stay the same.

Based on our knowledge that the optimization problem was poorly scaled, we divided by the frequency of the feature. We can give the following heuristic justification for our method of conditioning. For the i th feature weight, we will take a step Δw_i . Assume that we want to take the step Δw_i proportional to the average gradient \hat{g}_i calculated from n -best lists in which the feature is non-zero. In other words, we want $\Delta w_i = \alpha \hat{g}_i$. Let g_i be the total gradient calculated by adding the gradients over all n -best lists (i.e. summing over training examples in the corpus). For a feature that is nonzero in exactly n_i n -best lists, the gradient from each example will have been added up n_i times, so the total gradient $g_i = n_i \hat{g}_i$. Therefore we should take the step $\Delta w_i = \alpha g_i / n_i$. In other words, we rescale each component g_i of the gradient by $1/n_i$ before taking the gradient step.

We can relate this argument back to the oscillation we observed of the rule feature weights. For rules that are used a thousand times more often than the average rule, the corresponding component of the gradient is roughly a thousand times larger. But that does not indicate that the adjustment Δw_i to the rule weight should be a thousand times larger in each iteration.

6 Experiments

We evaluate and analyze the performance of our training method with three sets of experiments. The first set of experiments compares HOLS to other tuning algorithms used in machine translation in a medium-scale discriminative setting. The second set looks in detail at HOLS for large scale discriminative training for a Chinese-English task. The third set looks at two other languages.

All the experiments use a Hiero MT system with rule indicator features for the sparse features and the

Table 2: Corpora

Language	Corpus	Sentences	Tokens	
			Source	Target
En	Gigaword	24M		594M
Ar-En	Train	1M	7M	31M
	Dev (MT06)	1797	13K	236K
	MT05	1,056	7K	144K
	MT08nw	813	5K	116K
	MT05wb	547	5K	89K
Mg-En	Train	89K	2.1M	1.7M
	Dev	1,359	34K	28K
	Test	1,133	29K	24K
Zh-En	Train (FBIS)	302K	1M	9.3M
	Dev (MT06)	1,664	4K	192K
	Test (MT02-03)	1,797	5K	223K
	MT08	1,357	4K	167K

following 8 dense features: LM, phrasal and lexical $p(e|f)$ and $p(f|e)$, phrase and word penalties, and glue rule. The total number of features is 2.2M (Mg-En), 28.8M (Ar-En), and 10.8M (Zh-En). The same features are used for all tuning methods, except MERT baseline which uses only dense features. Although we extract different grammars from various subsets of the training corpus, word alignments were done using the entire training corpus. We use GIZA++ for word alignments (Och and Ney, 2003), Thrax (Weese et al., 2011) to extract the grammars, our decoder is cdec (Dyer et al., 2010) which uses KenLM (Heafield, 2011), and we used a 4-gram LM built using SRILM (Stolcke, 2002). Our optimizer uses code implemented in the pycdec python interface to cdec (Chahuneau et al., 2012). To speed up decoding, for each source RHS we filtered the grammars to the top 15 rules ranked by $p(e | f)$. Statistics about the datasets we used are listed in Table 2.

We use the “soft ramp 3” loss function (Gimpel, 2012; Gimpel and Smith, 2012) as the surrogate loss function for calculating the gradient in HOLS. It is defined as

$$\tilde{L} = \sum_{i=1}^n \left[-\log \sum_{y \in \text{Gen}(x_i)} e^{\vec{w} \cdot \vec{f}(x_i, y) - \text{cost}(y_i, y)} + \log \sum_{y \in \text{Gen}(x_i)} e^{\vec{w} \cdot \vec{f}(x_i, y) + \text{cost}(y_i, y)} \right]$$

where the sum over i ranges over training examples, $\text{Gen}(x)$ is the space of possible outputs and

derivations for the input x , and $\text{cost}(y_i, y)$ is add one smoothing sentence level BLEU.⁷

Except where noted, all experiments are repeated 5 times and results are averaged, initial weights for the dense features are drawn from a standard normal, and initial weights for the sparse features are set to zero. We evaluate using MultEval (Clark et al., 2011) and report standard deviations across optimizer runs and significance at $p = .05$ using MultEval’s built-in permutation test. In the large-scale experiments for HOLS, we only run the full optimizer once, and report standard deviations using multiple runs of the last MERT run (i.e. the last line search on the dev data).

6.1 Comparison Experiments for ZH-EN

Our first set of experiments compares the performance of the proposed HOLS algorithm to learning algorithms popularly used in machine translation on a Chinese-English task. We also compare to a close relative of the HOLS algorithm: optimizing the soft ramp 3 loss directly with online stochastic gradient descent and with conditioning. As we will see, SGD SOFTRAMP3 performs significantly worse than HOLS, despite both algorithms optimizing similar loss functions.

In the experiments in this section, we do not use the full version of the training setup described in §5 since we wish to compare to algorithms that do not necessarily scale to large amounts of training data. We therefore use only one fifth of the training data for learning the weights for both the dense and sparse features.

In this section we refer to the subset of the training data used to learn the weights as the **tuning set** (Tune). The grammar and LM are built using the training data that is not in the tuning set (the LM also includes the English monolingual corpus), and the weights for the features are tuned using the tuning set. This is similar to the typical train-dev-test split commonly used to tune machine translation systems, except that the tuning set is much larger (60k sentence pairs versus the usual 1k-2k) and comes from a random subset of the training data rather than a

⁷We found this loss function to work well, but other “soft” loss functions (Gimpel, 2012; Gimpel and Smith, 2012) also work. $\text{Gen}(x)$ is restricted to a k-best size of 1000. Following (Gimpel, 2012) $\text{cost}(y_i, y)$ is multiplied by a factor of 20.

Table 3: Comparison Experiments for Zh-En

Algorithm	Tune	MT08	Runtime
MERT	22.1 \pm .1	23.1 \pm .1	6 hours
PRO	23.8 \pm .05	23.6\pm.1	2 weeks
MIRA	21.7 \pm .1	22.5 \pm .1	19 hours
SOFTRAMP3	21.5 \pm .3	22.3 \pm .3	29 hours
HOLS	22.3 \pm .1	23.4 \pm .1	10 hours
HILS	24.3\pm.2	22.4 \pm .1	10 hours

specialized development set.

We compare MERT, PRO (Hopkins and May, 2011), MIRA (Chiang, 2012), SOFTRAMP3, HOLS, and a variant of HOLS which we call HILS (discussed below). For HOLS, we used 10k of the 60k tuning set for the line search, and the rest of the tuning set was used for calculating the gradient. For HILS (“Held-In” Line Search), the full 60k tuning set was used to calculate the gradient, but the line search was on a 10k subset of that set. For MERT, we used a 10k subset of the tuning data because it takes a long time to run on large datasets, and it only has the eight dense features and so does not need the entire 60k tuning set. All the subsets are drawn randomly. Conditioning was performed only for HOLS, HILS, and SOFTRAMP3 because conditioning would affect the regularizer for PRO and require modifications to the MIRA algorithm. To do the conditioning for SOFTRAMP3 we used rule count during extraction of the grammar and not the frequency in the n-best lists because the online nature of SOFTRAMP3 prevents us from knowing how frequent a rule will be (and the dense features are conditioned using the corpus size). We chose MIRA’s best learning rate ($\eta = .001$) from $\{.1, .01, .001\}$, used default settings for PRO in cdec, and for SOFTRAMP3 we used the same loss function as HOLS but included an L_2 regularizer of strength .001 and used a step-size of 1 (which was scaled because of conditioning). To remedy problems of length bias for sentence level BLEU, we used brevity penalty smoothed and grounded BLEU+1 for sentence level scores (Nakov et al., 2012). Tuning was repeated four times with different initial weights, except for PRO which we only ran three times (due to training costs). The initial weights for MERT were drawn from a standard normal distribution, and final MERT weights were

used as the initial weights for the dense features for the other algorithms. Initial weights for the sparse features were set to zero. For HOLS, and HILS, tuning set BLEU scores were evaluated on the set that the line search was run on. We also report run times for 8 threads on an Opteron 6220 processor.⁸

The results are shown in Table 3. PRO and HOLS are a statistically significant improvement upon the MERT baseline on the MT08 test data, but MIRA, SOFTRAMP3, and HILS are not.

HILS dramatically overfits the tuning set, while HOLS does not, justifying the use of a held-out dataset for the line search. SOFTRAMP3 performs significantly worse than HOLS on the test set. PRO is a promising training algorithm, but does not scale to the full FBIS corpus because it requires many iterations.

6.2 Full ZH-EN and Ablation Experiments

This set of experiments evaluates the performance of the full HOLS algorithm described in §5 for large-scale discriminative training on the full FBIS Chinese-English dataset. Since this is a relatively small and widely studied dataset, we also investigate what happens if different aspects of the procedure are omitted.

Table 4 gives the results. The number of updates is the number of times the HOLS line search optimizer is run (gradient updates). For 2 passes, 4 updates, a line search is performed after a half pass through the training data, which is repeated four times for a total of two passes.

Using just one pass through the training data and

⁸Standard MIRA and SGD SOFTRAMP3 are not parallelizable and only use a single thread. All of these algorithms were run for one iteration, except for MERT which ran for at least seven iterations, and PRO which we stopped after 20 iterations.

Table 4: Full-scale Chinese-English and Ablation Experiments

Configuration	Dev	Test
MERT Baseline	29.9 \pm .3	34.0 \pm .8
2 Pass, 4 updates	31.1\pm.2	35.1\pm.4
1 Pass, 1 update	30.7 \pm .1	34.6 \pm .5
–Folds	30.0 \pm .2	34.0 \pm .4
–Conditioning	30.1 \pm .1	34.2 \pm .2

Table 5: Arabic-English

System	Dev (MT06)	MT05	MT08(nw)	MT08(wb)
MERT Baseline	39.2±.4	50.3±.4	45.2±.2	29.4±.14
HOLS 1 Pass, 2 updates	39.9±.9	51.2±.4	45.8±.4	30.0±.4
ΔBLEU	+.7	+.9	+.6	+.6

Table 6: Malagasy-English

System	Dev	Test
MERT Baseline	19.8±.3	17.7±.2
HOLS 1 Pass, 1 update	20.5±.1	18.4±.2
ΔBLEU	+.7	+.7

one gradient update, HOLS improves upon the MERT baseline by .6 BLEU points, which is a statistically significant improvement. With 2 passes through the training data and 4 gradient updates, HOLS performs even better, obtaining a 1.1 BLEU point improvement over the baseline and is also statistically significant. With 16 threads, 1 pass, 1 update completed in 9 hours, and 2 pass, 4 updates, completed in 40 hours. The medium-scale PRO setup in §6.1 obtains a result of $34.4 \pm .1$ on this test set, which is a statistically significant improvement of .4 BLEU points over the MERT baseline but does not beat the large-scale HOLS results.

Is folding and conditioning necessary? We experiment with what happens if grammar and LM folds are not used and if conditioning is not done. –Folds denotes 1 pass 1 update without folds, and –Conditioning denotes 1 pass 1 update without conditioning. We can see that both these steps are important for the training procedure to work well.

The decrease in performance of the training procedure without folds or conditioning is dramatic but not too surprising. With just one gradient update, one would expect conditioning to be very important. And from the lessons learned in section 3.1, one would also expect the procedure to perform poorly or even worse than the MERT baseline without grammar or LM folds. But because HOLS runs MERT on the dev data for the last line search, it is almost impossible for HOLS to be worse than the MERT baseline. (This, in fact, was part of our motivation when we originally attempted the HOLS algorithm.)

6.3 Other Language Pairs

The last set of experiments looks at the performance of the learning algorithm for two other languages and data scenarios for one pass through the training data. Using the same setup for large-scale discriminative training as before, we apply the training procedure to a large data scenario Arabic-English task and a small data scenario Malagasy-English task (Tables 5 and 6). The training procedure gives statistically significant improvements over the baseline by .6 to .9 BLEU for Arabic, and a statistically significant improvement of .7 BLEU for Malagasy. With 16 threads, the runtime was 44 hours for Arabic and 5 hours for Malagasy.

7 Conclusion

We have explored the difficulties encountered in large-scale discriminative training for machine translation, and introduced a learning procedure designed to overcome them and scale to large corpora. We leave to future work to experiment with feature sets designed for the large-scale discriminative setting. In particular, we hope this framework will facilitate incorporation of richer linguistic knowledge into machine translation.

Abstract

Measuring term informativeness is a fundamental NLP task. Existing methods, mostly based on statistical information in corpora, do not actually measure informativeness of a term with regard to its semantic context. This paper proposes a new lightweight feature-free approach to encode term informativeness in context by leveraging web knowledge. Given a term and its context, we model context-aware term informativeness based on semantic similarity between the context and the term’s most featured context in a knowledge base, Wikipedia. We apply our method to three applications: core term extraction from snippets (text segment), scientific keywords extraction (paper), and back-of-the-book index generation (book). The performance is state-of-the-art or close to it for each application, demonstrating its effectiveness and generality.

1 Introduction

Computationally measuring importance of a word in text, or “term informativeness” (Kireyev, 2009; Rennie and Jaakkola, 2005), is fundamental to many NLP tasks such as keyword extraction, text categorization, clustering, and summarization, etc. Various features derived from statistical and linguistic information can be helpful in encoding term informativeness, whereas practical feature definition and selection are usually ad hoc, data-driven and application dependent. Statistical information based on term frequency (TF) and document frequency (DF) tend to be more effective in finding keywords in large corpora, but can have issues with small amounts of

text or small corpora. Linguistic information such as POS tag patterns often require manual selection based on prior applications. We contend that few methods actually measure the informativeness of a term to the discourse unit it contains. For example, given a context such as “*A graph comprises nodes (also called vertices) connected by links (also known as edges or arcs)*”, it is difficult to measure the term informativeness of “graph”, “nodes”, or “links” based on any statistical or linguistic information.

This raises many issues. Is there a fundamental and less ad hoc way to measure the term informativeness of a word within a discourse unit? Can we actually find a general approach based on comprehensive and high-level “knowledge” and not have to nitpick over features? Can this new metric be effectively applied to real world applications? To answer these questions, we develop a new term informativeness metric, motivated by query-document relevance in information retrieval. The higher the relevance score a query-document pair is, the more informative the query is to the document. If a similar principle also exists between word and context and there is an effective search engine returning ranked contexts for a given word, then we contend that word is more informative in the higher rank contexts. To see the term informativeness of three words “graph”, “nodes” and “links” in context, we manually check the search results from Wikipedia, Google, and Bing. We found that very similar contexts are among the top 5 ranked results of “graph” while no such contexts appear in that of the other two words. Thus, we define a context-aware term informativeness based on the semantic relatedness

between the context and the term's featured contexts (or the top important contexts that cover most of a term's semantics).

We apply the context-aware term informativeness (CTI) to three typical NLP applications: core term extraction in snippets, keyword extraction and back-of-the-book index generation. Experiments show that the method is effective and efficient. Moreover, the metric can be easily combined with other methods, or as a feature for learning algorithms.

The remainder of this paper is organized as follows. Section 2 reviews the literature of term informativeness measurements. Section 3 proposes the formal definition of the context-aware term informativeness as well as its practical implementation using Web knowledge. Section 4 studies the three applications. Finally, we conclude with discussion and future work.

2 Related Work

Most known approaches to measure term informativeness fall into basically two categories: statistics-based and semantic-based.

Statistics-based methods, such as *TFIDF* (Salton and Buckley, 1988), *ResidualIDF(RIDF)*, *Variance*, *Burstiness* and *Gain*, are based on derivations from term frequency (TF) and document frequency (DF). Sprck Jones defines *IDF* or *inverse document frequency* as:

$$IDF(w) = -\log_2(df_w/D) \quad (1)$$

where D is the size of the corpus (Jones, 1972; Jones, 1973). Based on a finding that informative words tend to have large deviation between *IDF* and collection frequency f_w (the total number of occurrence of a word), many other informativeness scores have been proposed. Bookstein and Swanson (Bookstein and Swanson, 1974) introduced the x^I as:

$$X^I = f_w - df_w$$

Church and Gale (1995) introduced

$$variance(w) = \frac{1}{D-1} \sum_{d=1}^D (t_{dw} - \bar{t}_w)^2 \quad (2)$$

where t_{dw} denotes w 's TF in d and $\bar{t}_w = f_w/D$ indicates its mean expected word rate. Another measure

suggested by them is

$$burstiness(w) = \frac{f_w}{df_w} \quad (3)$$

which tends to compare collection frequency and document frequency directly. Informative words were found to have *IDF* scores that are larger than what would be expected according to the Poisson model; *residual IDF (RIDF)* was introduced to measure this deviation

$$RIDF(w) = IDF(w) - \widehat{IDF}(w) \quad (4)$$

where $\widehat{IDF}(w) = -\log_2(1 - e^{-\bar{t}_w})$. In addition, Papineni (2001) introduced the notion of *gain* as

$$gain(w) = \frac{df_w}{D} \left(\frac{df_w}{D} - 1 - \log\left(\frac{df_w}{D}\right) \right) \quad (5)$$

More recently, Rennie and Jaakkola (2005) introduced an informativeness score based on the fit of a word's frequency to a mixture of 2 Unigram distribution and applied it to named entity detection. It is worth noting that term necessity, which measures the probability that a term occurs in documents relevant to a given query, has been well studied in Information Retrieval community (Zhao and Callan, 2010; Yang and Callan, 2010). Though our CIT is not designed for probabilistic retrieval models, we may apply it to measure the term necessity in a query by considering it as a context.

Despite extensive research on semantic analysis and understanding of word and text (Deerwester et al., 1990; Budanitsky and Hirst, 2006; Cilibrasi and Vitanyi, 2007; Gabrilovich and Markovitch, 2007; Agirre et al., 2009; Yazdani and Popescu-Belis, 2012), little work studied the measurement of the semantics of term informativeness. An exception is the *LSASpec* from Kireyev (2009), based on latent semantic analysis (Deerwester et al., 1990), which is defined as the ratio of a term's LSA vector length to its document frequency and thus can be interpreted as the rate of vector length growth. However, latent semantic models such as LSA are notoriously hard to interpret since the “latent concepts” cannot be readily mapped to human knowledge (Gabrilovich and Markovitch, 2007). Our approach explicitly leverages the semantics of word and text using existing knowledge bases.

Previous methods, all corpus-based, might be effective in identifying informative words at the document or corpus level, but do not have the ability to capture term informativeness in a particular context due to their absence of semantics and obliviousness of context. Our method measures the term informativeness within a context in a semantic-based approach, regardless of the absence of statistical information.

3 Context-aware Term Informativeness

3.1 Context

A context of a word or phrase may refer to a few words nearby (He et al., 2010), a sentence or paragraph (Soricut and Marcu, 2003), or even a set of documents containing it (Cilibrasi and Vitanyi, 2007). Here we define context as a syntactic unit of discourse such as a sentence or paragraph, for example, “PL/SQL is one of three key programming languages embedded in the Oracle Database”, or “There are two types of functions in PL/SQL”. The universal context set $U(t)$ of a word t is defined as all the contexts containing it in the web. Different contexts vary in their authority just like web pages vary. For the two examples, we could argue that the first context is much more “authoritative” than the second. This can be verified by their popularity on Google; (all results from actual search engines were at the time of this publication) the first retrieves approximately 302,000 exact matching results while the second retrieves only one. We consider this as the number of citations of a context, which, to some extent, indicates its “authority”. We define the *source* of a context as the set of all documents citing it. Here “citing” instead of “containing” is used because some documents may not literally contain an exact copy of the context.

Given a term t , define its universal context set $U(t) = \{c_i\}$ and the source of c_i is $S(c_i) = \{d_{ij}\}$. Ideally, the authority of a context will be contributed by every document citing it. Therefore, we define the authority score of a context as

$$CA(c_i) = \sum_j DA(d_{ij}) \quad (6)$$

where $DA(d_{ij})$ denotes the authority contributed by d_{ij} . It is very difficult to acquire the universal context set of a term. Considering that usually we only

care about the top few results of a query returned by search engines and ignore a large fraction of less important ones, it is reasonable to assume that a term’s semantics will be well covered by a few important contexts. We therefore define the featured context set of term t , or $U_f(t)$, as the top k contexts with the highest authority scores, where k is an application dependent parameter. In our experiments, the default k for the Wikipedia based implementation is 20.

3.2 Term Informativeness

We now consider how to measure the term informativeness in context. Using the context “PL/SQL is one of three key programming languages embedded in the Oracle Database” (denoted by C_p) as an example, for its term “PL/SQL”, the top three contexts returned by Google are

1. PL/SQL (Procedural Language/Structured Query Language) is Oracle Corporation’s procedural extension language for SQL and the Oracle relational database.
2. PL/SQL is Oracle’s procedural extension to industry-standard SQL. PL/SQL naturally, efficiently, and safely extends SQL.
3. This Oracle PL SQL tutorial teaches you the basics of programming in PL/SQL like cursors, stored procedures, PLSQL functions.

Those contexts, though being diverse in actual meaning, all have semantic relatedness to C_p . Even someone who does not completely understand them can gain some meaning by observing common words such as “Oracle”, “database” and “programming”. However, checking the Google results for “Oracle Database” or “programming languages”, we will find little relatedness between them and C_p . This suggests that if term t_a in context c is more informative than t_b , then most likely the contexts from t_a ’s featured context set will be more related to c than will t_b . Thus, given a term t and its featured context set $U_f(t) = \{c_1, \dots, c_k\}$, we define the term informativeness of t in context c_i as

$$I(t, c_i) = \sum_{c_j \in U_f(t)} \kappa(c_i, c_j) \cdot CA(c_j) \quad (7)$$

where $\kappa(c_i, c_j)$ is the semantic relatedness of c_i and c_j , which can be computed by various semantic relatedness metrics such as Wikipedia based (Gabrilovich and Markovitch, 2007; Yazdani

and Popescu-Belis, 2012), Wordnet based (Agirre et al., 2009; Budanitsky and Hirst, 2006), or simple cosine similarity and Jaccard similarity based (Zobel and Moffat, 1998).

The context-aware term informativeness (CTI) introduced above is a formal and general definition. As such the definition in Equation (7) includes several features such as context authority score, featured context set, semantic relatedness, and knowledge base, any or all of which could be flexible for different applications.

3.3 Implementation

Here, we present a simple practical implementation using Wikipedia as the knowledge base and the context authority estimated by the discounted rank of the Wikipedia document. Note that the problem is how to compute $CA(c_j)$ for each context in U_f . We rewrite Equation (6) as

$$CA(c_i) = DA(d_{i0}) + \sum_{j \neq 0} DA(d_{ij}) \quad (8)$$

where d_{i0} is the original document of c_i and all the others are further derivatives of “citing” c_i . For example, the Wikipedia page of “PL/SQL” will be considered as the original document of C_p while all other documents citing C_p are its derivatives. Intuitively, the authority of a context will mainly rely on the authority of its original document. Here, we simply assume that the context authority depends only on its original document, or

$$CA(c_i) \approx DA(d_{i0}) \quad (9)$$

We then take the top ranked document returned by the web knowledge base as the original document. We present a practical implementation of CTI in Algorithm 1. The discounted rank is used to represent the relative context authority score of each context in U_f . We use Wikipedia as our knowledge base to implement the metric since it is currently one of the largest and most readily available knowledge repositories and, more importantly, provides free, unlimited and fast query APIs¹. Given any keyword, the Wikipedia query API will return the ranked Wikipedia entries along with the contexts containing the keyword. We set the default value 20

for k , or $\text{len}(U_f)$. Note that there could be other variations of this implementation. For example, we could rule out duplicate or very similar results in the U_f . Search engines such as Google and Bing are also potential sources since they return high quality web pages along with the contexts containing the query keyword.

In terms of scalability, the proposed method is inherently parallelizable, not only at the document level, but also at the context level, since computing CTI does not depend on any other context in the document. In addition, we do not need to issue the same query more than once. Our strategy is to locally cache the returned results of every seen query. For a new term seen in a previous query, we can directly access the local cached file. If we have built a large local pool, the queries will rarely go to a search engine or other source. Given a corpus size N (words in total), the number of actual issued queries will be at most the number of unique terms, which is far less than O(N). Of course, new terms never seen will have to be processed, but there will be fewer of these over time.

Algorithm 1: Wikipedia-based $I(t, c_i)$

```

1 Input:  $t, c_i$ 
2 Output:  $I(t, c_i)$ 
3 begin
4    $I \leftarrow 0;$ 
5    $U_f \leftarrow \text{queryWikipedia}(t);$ 
6   for  $j \in \text{range}(\text{len}(U_f))$  do
7      $s \leftarrow \kappa(c_i, U_f[j]);$ 
8     if  $j > 0$  then
9        $I \leftarrow I + s / \log(j + 1);$ 
10    else  $I \leftarrow I + s$ 
11   return  $I;$ 

```

4 Applications

4.1 Core Terms Extraction from Snippets

We first investigate CTI in a well defined setting. That is, if we have a collection of terms such that its most important context is a “definition,” e.g. “database” and “A database is a structured collection of data, which are typically organized to model relevant aspects of reality, in a way that supports

Table 1: Term ranked by CTI from exemplary snippets

processes requiring this information”, can CTI identify “database” as the most informative term in this context? To construct the term-context pairs, we could use the Wikipedia title and the top ranked context returned by searching the title using the Wikipedia API. Then we could test our metric based on other search engines such as Google or Bing. Testing manually, we found the results compare well to the search engine results, since both Google and Bing give top ranks to Wikipedia pages if the query keyword is a Wikipedia title. For further analysis, we need a collection of term-context pairs from other sources different from Wikipedia. Fortunately, we found a list of 1255 computer science terms with its definition snippets manually created by Web users ². The snippets are literally different from those contexts in Wikipedia and some of the terms are even not Wikipedia titles, e.g. bBlog, BetBug, etc. These can be part of an “initial” evaluation. The core term extraction algorithm works in the following steps for each term-context pair:

1. Extract all n-grams ($1 \leq n \leq 4$) in the context as candidates
2. For each candidate, calculate its CTI using Wikipedia based implementation
3. Return the top K highest CTI as core terms

We used the top 20 returned Wikipedia contexts as a featured context set U_f and apply the cosine similarity for κ . We show some exemplary snippets

²http://www.labautopedia.org/mw/index.php>List_of_programming_and_computer_science_terms

K	Precision (%)	Recall (%)	F1(%)
1	37.5	37.5	37.5
2	35.1	55.2	42.9
3	32.3	64.7	43.1
4	31.3	72.2	43.7
5	27.6	76.3	40.5
10	20.0	88.1	32.6

Table 2: Results on computer science term extraction from descriptive snippets

with its top 5 core terms and their CTI scores in Table 1. The overall performance is shown in Table 2, in terms of precision, recall and F1 scores based on the only one titled term of each snippet as the ground truth. CTI can correctly find the core term for 37.5% snippets. If we take the top 5 results, then the recall increase to 76.3%.

Though the algorithm can be easily parallelized, sequentially runtime on all snippets took only slightly more than a minute on a 2.35GHz Intel(R) Xeon(R) 4 processors, 23GB of RAM, and Red Hat Enterprise Linux Server(5.7) machine. However, the time could vary due to network conditions.

Though these results look promising, but it could be due to the high lexical similarity between this dataset and Wikipedia content. To test on a more general corpora, we explore more real world tasks.

4.2 Keyword Extraction

There is a rich literature on keyword extraction problem (Frank et al., 1999; Witten et al., 1999; Turney, 2000; Hulth et al., 2003; Tomokiyo and Hurst, 2003;

Method	Wiki20			citeulike180		
	P	R	F	P	R	F
TFIDF	13.7	17.8	15.5	14.4	16.0	15.2
KEA	18.4	21.5	19.8	20.4	22.3	21.3
CTI	19.6	22.7	21.0	18.5	21.4	19.8

Table 3: Results on Wiki20 and citeulike180

Mihalcea and Tarau, 2004; Medelyan and Witten, 2008; Liu, 2010), most of which is treated as a classification or ranking problem with corresponding machine learning algorithms that use statistical and linguistic features in a corpus. Here, we consider the task as finding the most informative keywords in a document. Given a document $d = \{c_i\}$, our keyword extraction algorithm based on CTI works as follows.

1. For each context c_i in a document, compute the semantic relatedness $s(c_i, d)$ between c_i and d
2. For each n-gram ($1 \leq n \leq 4$) t in c_i , calculate $I(t, c_i)$ using Wikipedia based implementation
3. Select the top keywords with the highest $\sum_i I(t, c_i) * s(c_i, d)$

Note that for the last step keywords are selected based on a summarized weighted informativeness score over a document. Obviously, the pure cosine or Jaccard similarity is not a good choice to measure semantic relatedness between two text segments of very low lexical similarity. We thus use the Wikipedia based ESA (Gabrilovich and Markovitch, 2007) to compute the semantic relatedness $s(c_i, d)$ and $\kappa(c_i, c_j)$. To make the calculation more efficient, only the Wikipedia pages whose title is contained in the dataset are used to build the concept space. We ran the algorithm on several datasets including Wiki20 (Medelyan et al., 2008), citeulike180 (Medelyan et al., 2009) and SemEval2010 (Kim et al., 2010)³.

Though keyword extraction as a research topic has a rich literature, to the best of our knowledge there is no large scale datasets publicly available. The Wiki20 dataset contains 20 computer science articles each with around 5 terms labeled by 15 different teams. Every term is a Wikipedia title.

³<http://code.google.com/p/maui-indexer/downloads/list>

Method	Precision (%)	Recall (%)	F1(%)
TFIDF	14.9	15.3	15.1
HUMB	27.2	27.8	27.5
CTI	19.3	20.1	19.7
CTI+	25.3	26.2	25.7

Table 4: Results on SemEval2010

The citeulike180 contains a set of 180 papers each tagged with around three tags by 332 users. For each dataset, the collection of all labeled keywords by different taggers are considered as the gold standard for a document. We use the set of all keywords for evaluation; otherwise a more complicated evaluation metrics for each dataset will be needed. It would be better to investigate other weighting schemes. However, the datasets here are relatively small and the number of tags on which at least two annotators agreed is significantly small; weighting the keywords might not make too much difference. KEA⁴ builds a Naive Bayes model using features TFIDF, first occurrence, length of a phrase, and node degree (number of candidates that are semantically related to this phrase) (Witten et al., 1999). First occurrence is computed as the percentage of the document preceding the first occurrence of the term in the document. We compute the node degree as the textrank (Mihalcea and Tarau, 2004) degree in a document by simply relating two candidate terms with each other if they are in the same context. KEA uses 5 fold cross validation. All precision P, recall R and F1 F results are over the top 10 candidate keywords and the micro-averaged results of the first two datasets are shown in Table 3. The CTI-based algorithm works better than KEA on Wiki20 but slightly worse on citeulike180. We argue that the reason might be two-fold. First, CTI does not use any inter-document or corpus information while KEA learns from the corpus. As such, CTI might not perform as well as supervised learning methods for a domain dependent large corpus. Second, the labeled keywords in Wiki20 are all Wikipedia titles while those in citeulike are general tags labeled by voluntary web users. CTI would give more preference to Wikipedia titles since their featured context set returned from Wikipedia is more semantically representative than other non-Wikipedia title words.

Open Book	213	22,279,530	1,135,919	Computer Science, Engineering, Information Science

Table 5: Datasets for book index generation evaluation

The SemEval2010 dataset contains a set of 284 scientific papers with 15 keyphrases assigned by readers and authors. 144 of them are selected as training set while the other 100 are for testing. A comparison of CTI to the results from TFIDF and the best reported results HUMB (Lopez and Romary, 2010) is shown in Table 4. It achieves 19.8% by micro-averaged F1 score, ranking 11th out of the 19 systems submitted to the competition (Kim et al., 2010). However, by adding the structural features used by HUMB into CTI, we can improve the performance by around 6%, making our results close to that of HUMB. The structural information is encoded as weights for context that is located in title, abstract, section titles and general content. Each weight can be regarded as the prior probability that a keyword will appear in the corresponding location, whose value can be set according to the fraction of the number of keyword occurrences of this type of location with respect to the number of all keyword occurrences in the entire training set. Here they are set to be 0.3, 0.4, 0.25, and 0.05.

4.3 Back-of-the-book Index Generation

A back-of-the-book index (or book index) is a collection of words or phrases, often alphabetically arranged as an index, created to give readers important location of important information in a given book. Usually indexing is done by freelancers hired by authors or publishers, namely professional indexers⁵. Csomai and Mihalcea first evaluated the performance of different informativeness measurements for selecting book index terms (2007) and then investigated automatic book index generation in a supervised learning framework (2008) using syntactic features, linguistical features, encyclopedic features, etc., as a keyword extraction problem rather than building a actual book index.

A set of keywords is not a back-of-the-book index. What really matters for such an index is that

an index term or phrase points to its proper location in the text. For example, in “pattern recognition and machine learning” by Bishop, “hidden Markov model” appears in more than 20 pages while the actual index entry has only 2 pages as its locators. Thus the actual problem is to identify a index term with its context. As such, learning a robust and efficient model for real book indexes is challenging. First, books from different domains vary in vocabulary composition and structure style, requiring various indexing specialties. There are different indexing guides for medicine (Wyman, 1999), psychology (Hornyak, 2002), and law (Kendrick and Zafran, 2001). Second, book indexing is a highly subjective work and indexes of different books are always created by different professional indexers who have their own preferences and background (Diodato and Gandt, 1991; Diodato, 1994). Third, the training set is extremely unbalanced. As we found in our dataset, the index size is only 0.42% of the length of book on average. All these motivate us to explore the automatic creation of index terms that are aware of the context at the term’s locations (locators). To do so we propose the following efficient training-free and domain independent approach:

1. For each context c_i in a book, compute its weight w_i based on structural features
2. For each candidate term t in c_i , calculate $I(t, c_i)$ using Wikipedia based implementation
3. Select term-context pairs with the highest $w_i * I(t, c_i)$ as index entries

The weight in step 1 represents the relative importance of a context in a book. $w(c) = 1 - \frac{cid(c) - cid(title_c)}{N_{title_c}}$ measures the weight based on the normalized distance from the context to its direct chapter or sub-chapter title, where $cid(c)$ denotes the id of context c , $title_c$ the title of context c and N_{title_c} the number of contexts under $title_c$. To select candidate terms, we first filter the improbable index terms

⁵<http://www.asindexing.org/>

based on POS patterns using the Standard POS Tagger (Toutanova et al., 2003). We then select multi-word keyphrases based on Pointwise Mutual Information (PMI) (Church and Hanks, 1990), which was shown to be the best metric to measure word associations (Terra and Clarke, 2003).

To evaluate our back-of-the-book index generation method, we conduct extensive experiments on books in various domains, from the Gutenberg dataset and the open book dataset described in Table 5. The first one was created by (Csomai and Mihalcea, 2006), containing 55 free books collected from Gutenberg⁶. Since the dataset does not provide the locators of index terms, we can only serve the evaluation as a keyword extraction task. The second dataset was collected from CiteSeer repository, most of which are in computer science and engineering. We extracted the paged body text and the back index using Pdfbox⁷. Having each index term associated with its locators (page numbers), we can perform an evaluation for different methods, not based solely on keyword extraction.

We first compare CTI with other metrics on both datasets for keywords extraction since all other metrics are context-oblivious. CTI selects index terms based on the sum of a term’s CTI scores over all its contexts, the same as the algorithm used in Section 4.2. The results are shown in Table 6, where the index size = n indicates the number of output terms is n times of the true book index size for each book. The scores are the average recall over a dataset. The CTI outperforms all other 7 metrics in the two datasets as the output index size increases. Moreover, results show that TF and TFIDF are better than RIDF in identifying book index terms, which seems contradictory to previous findings (Church and Gale, 1995). A possible reason is that a book is much longer than a regular document thus enhancing *TF* as a better indicator of keywords but weakening the role of *IDF*. We believe this is why *Variance*, *Gain*, and *Burstiness*, which relies on *DF*, are less effective here. *Wikipedia keyphraseness* (Csomai and Mihalcea, 2008) can only find a small fraction of index terms because it emphasizes Wikipedia titles that have high in-degree in hyper-link network formed

⁶www.gutenberg.org/

⁷pdfbox.apache.org/

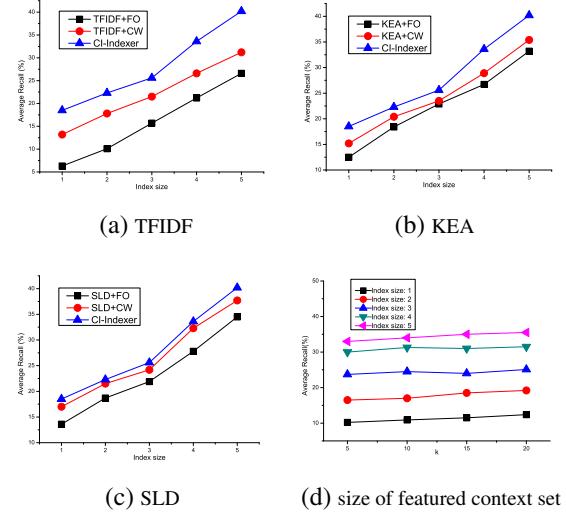

Figure 1: Results for book index generation

by Wikipedia terms. However, a book index covers much broader terms not titled in Wikipedia.

We then compare with three baselines TFIDF, KEA, and SLD (supervised learning using decision tree in Csomai’s (2008)) on the second dataset. For SLD, we use all the features except the discourse comprehension based ones which were too complicate to implement. We choose a decision tree because its training is much faster than the other two models while its performance is quite close to the best. We follow Csomai’s setting to choose 90%(192) books for training and the other 10%(21) for test. We set two strategies to make the baselines context-aware. First, we select the page of a term’s first occurrence as its locator, denoted by “+FO” in Figure 1. Second, we apply the context weight to them, denoted by “+CW”. “CI-Indexer” denotes our method. The results are shown in Figure 1a, 1b and 1c respectively. For all the three baselines, adding context weight gives better performance than using the simple first occurrence guess, especially for TFIDF. KEA benefits least from the context weights, suggesting its first occurrence and node degree features play a similar role as the context weight features. SLD outperforms TFIDF and KEA under both strategies probably because of the new features of POS pattern and Wikipedia keyphraseness. “SLD+CW” is the closest to ours. Finally, we show in Figure 1d that increasing the size of featured context set for CTI from 5 to 20 can slightly improve

4.4 Discussion

The three applications are (incrementally) designed for different goals. The first is a toy application to show the potential capability of this approach, regardless of syntactic or statistical information. Clearly, there are simple heuristics that can work very well for this task, e.g. the first term of the context. TF or TFIDF also performs quite well. We can rewrite each context (by reordering the terms, changing sentence structures, or substituting the core terms with pronouns) to make them ineffective. However, this will not effect our method, because what it essentially measures is a term’s informativeness among a list of terms appearing in the same context. However, for keyword extraction, a topic with a rich literature, to the best of our knowledge, has no publicly available large scale datasets, which makes SemEval2010 the best available. We believe our application on back-of-the-book index generation showed how CTI can scale real world large corpora and will scale to millions of books since each book can be processed separately.

Based on the applications we explored, we can see that the practical utility of CTI used alone could be limited, especially for context-oblivious tasks. It seems reasonable that this method does not outperform supervised learning methods designed for keyword extraction. However, our method shows what simple but elegant methods can achieve without the overhead of machine learning, especially for context-aware scenarios such as finding book index terms.

5 Conclusion and Future Work

We developed a new web knowledge based method for encoding informativeness of terms within a unit of discourse. It is totally feature-free, corpus-free, easy to implement, and inherently parallelizable. Three typical applications on text snippets, scientific papers and non-fiction books show its effectiveness. The segmentation of context, the size of featured context set, the semantic relatedness metric κ , and the knowledge base might more or less affect the final performance of CTI in terms of accuracy or efficiency. For all applications, we treat a paragraph as an individual context, which is not necessarily a complete discourse unit. However, it may not be fair to set the same number for all context terms. In addition, selection of semantic relatedness and knowledge bases need further investigation. The Wikipedia-based implementation might be a good choice for the definitional snippets, scientific articles and text books since they are all “educational” resources sharing a similar concept space. However, it is an open question as whether it works for corpora such as tweets, online reviews, and forum posts.

Based on the proposed methods and encouraging results, it would be interesting to build an online indexing tool which automatically finds informative terms in generic text and generates a back-of-the-book index for a sets of papers, books, theses and other collections.

Abstract

We here present and compare two unsupervised approaches for inducing the main conceptual information in rather stereotypical summaries in two different languages. We evaluate the two approaches in two different information extraction settings: monolingual and cross-lingual information extraction. The extraction systems are trained on auto-annotated summaries (containing the induced concepts) and evaluated on human-annotated documents. Extraction results are promising, being close in performance to those achieved when the system is trained on human-annotated summaries.

1 Introduction

Information Extraction (Piskorski and Yangarber, 2013) and Automatic Text Summarization (Saggion and Poibeau, 2013) are two Natural Language Processing tasks which require domain and language adaptation. For over two decades (Riloff, 1993; Riloff, 1996) the natural language processing community has been interested in automatic or semi-automatic methods which could be used to port systems from one domain or task to another, aiming at reducing at least in part the cost associated with the creation of human annotated datasets. Automatic system adaptation can take different forms: if high

This work is partially supported by Ministerio de Economía y Competitividad, Secretaría de Estado de Investigación, Desarrollo e Innovación, Spain under project number TIN2012-38584-C06-03 and Advanced Research Fellowship RYC-2009-04291. We thank Biljana Drndarević for proofreading the paper.

quality human annotated data is available, then rule-based or statistical systems can be trained on this data (Brill, 1994), reducing the efforts of writing rules and handcrafting dictionaries. If high quality human annotated data is unavailable, a large non-annotated corpus and a bootstrapping procedure can be used to produce annotated data (Ciravegna and Wilks, 2003; Yangarber, 2003). Here, we concentrate on developing and evaluating automatic procedures to learn the *main concepts of a domain* and at the same time *auto-annotate texts* so that they become available for training information extraction or text summarization applications. However, it would be naive to think that in the current state of the art we would be able to learn all knowledge from text automatically (Poon and Domingos, 2010; Biemann, 2005; Buitelaar and Magnini, 2005). We therefore here concentrate on learning template-like representations from concise event summaries which should contain the key information of an event.

18 de julio de 1994*DateOfAttack* . Un atentado contra la **sede de la Asociación Mutual Israelita Argentina***Target* de **Buenos Aires***PlaceOfAttack* causa la muerte de **86***NumberOfVictims* personas.

(*18th July 1994. An attack against the headquarters of the Jewish Mutual Association in Buenos Aires, Argentina, kills 86 people.*)

Figure 1: Sample of Human Annotated Summary in Spanish

An example of the summaries we want to learn from is presented in Figure 1. It is a summary in the terrorist attack domain in Spanish. It has been

manually annotated with concepts such as DateOfAttack, Target, PlaceOfAttack, and NumberOfVictims, which are key in the domain. Our task is to discover from this kind of summary what the concepts are and how to recognise them automatically. As will be shown in this paper and unlike current approaches (Chambers and Jurafsky, 2011; Leung et al., 2011), the methods to be presented here do not require parsing or semantic dictionaries to work or specification of the underlying number of concepts in the domain to be learned. The approach we take learns concepts in the set of domain summaries, relying on noun phrase contextual information. They are able to generate reasonable domain conceptualizations from relatively small datasets and in different languages.

The rest of the paper is structured as follows: In Section 2 we overview related work in the area of concept induction from text. Next, in Section 3 we describe the dataset used and how we have processed it while in Section 4 we outline the two unsupervised learning algorithms we compare in this paper for template induction from text. Then, in Section 5, we describe the experiments on template induction indicating how we have instantiated the algorithms and in Section 6 we explain how we have extrinsically evaluated the induction process. In Section 7 we discuss the obtained results and in Section 8 we summarize our findings and close the paper.

2 Related Work

A long standing issue in natural language processing is how to learn conceptualizations from text in automatic or semi-automatic ways. The availability of redundant data has been used, for example, to discover template-like representations (Barzilay and Lee, 2003) or sentence-level paraphrases which could be used for extraction or generation. Various approaches to concept learning use clustering techniques. (Leung et al., 2011) apply various clustering procedures to learn a small number of slots in three typical information extraction domains, using manually annotated data and fixing the number of concepts to be learnt. (Li et al., 2010) generate templates and extraction patterns for specific entity types (actors, companies, etc.). (Chambers and Jurafsky, 2011) learn the structure of MUC tem-

plates from raw data in English, an approach that needs both full parsing and semantic interpretation using WordNet (Fellbaum, 1998) in order to extract verb arguments and measure the similarity between verbs. In (Saggion, 2012) an iterative learning procedure is used to discover core domain conceptual information from short summaries in two languages. However, the obtained results were not assessed in a real information extraction scenario. There are approaches which do not need any human intervention or sophisticated text processing, but learn based on redundancy of the input dataset and some well grounded linguistic intuitions (Banko and Etzioni, 2008; Etzioni et al., 2004). Related to the work presented here are approaches that aim at generating short stereotypical summaries (DeJong, 1982; Paice and Jones, 1993; Ratnaparkhi, 2000; Saggion and Lapalme, 2002; Konstas and Lapata, 2012).

3 Dataset and Text Processing Steps

For the experiments reported here we rely on the CONCISUS corpus¹ (Saggion and Szasz, 2012) which is distributed free of charge. It is a corpus of Web summaries in Spanish and English in four different application domains: Aviation Accidents (32 English, 32 Spanish), Earthquakes (44 English, 56 Spanish), Train Accidents (36 English, 43 Spanish), and Terrorist Attacks (42 English, 53 Spanish). The dataset contains original and comparable summary pairs, automatic translations of Spanish summaries into English, automatic translation of English summaries into Spanish, and associated original full documents in Spanish and English for two of the domains (Aviation Accidents and Earthquakes). The dataset comes with human annotations representing the key information in each domain. In Table 1 we detail the concepts used in each of the domains. Note that not all concepts are represented in each of the summaries. Creation of such a dataset can take up to 500 hours for a human annotator, considering data collection, cleansing, and annotation proper. Only one human annotator and one curator were responsible for the annotation process.

Table 1: Conceptual Information in Summaries

3.1 Text Processing

In order to carry out experimentation we adopt the GATE infrastructure for document representation and annotation (Maynard et al., 2002). All documents in the dataset are processed with available natural language processors to compute shallow linguistic information. Documents in English are processed with the ANNIE system, a morphological analyzer, and a noun chunker, all three from GATE. The documents in Spanish are analyzed with Tree-Tagger (Schmid, 1995), a rule-base noun chunker, and an SVM-based named entity recognition and classification system.

4 Concept Induction Algorithms

Two algorithms are used to induce conceptual information in a domain from a set of textual summaries. The algorithms form concepts based on target strings (or chunks) in the set of summaries using token-level linguistic information. The chunks are represented with different features which are explained later in Section 5.1. One algorithm we use is based on *clustering*, while the other is based on *iterative learning*.

4.1 Clustering-based Induction

The procedure for learning conceptual information by clustering is straightforward: the chunks in the set of summaries are represented as instances considering both internal and surrounding linguistic information. These instances are the input to a clustering procedure which returns a list of clusters each containing a set of chunks. We consider each cluster as a key concept in the set of domain summaries and the chunks in each cluster as the concept extension.

4.2 Iterative Induction

We use the iterative learning algorithm described in (Saggion, 2012) which learns from a set of sum-

maries S , also annotated with target strings (e.g. chunks) and shallow linguistic information. In a nutshell the algorithm is as follows:

- (1) Choose a document D from the set of summaries S and add it to a training set TRAIN. Set REST to $S - \text{TRAIN}$.
- (2) Choose an available target concept T from D , i.e. a target concept not tried before by the algorithm.
- (3) Train a classifier on TRAIN to learn instances of the target concept using the available linguistic features; the classifier uses the linguistic information provided.
- (4) Apply the classifier to REST (all summaries minus those in TRAIN) to annotate all instances of the target concept T .
- (5) Select a document BEST in REST, where there is an instance of the concept recognised with the highest probability in the REST set.
- (6) Remove BEST from REST and add BEST to the training set, remove all identified instances of T from REST, and go to step 3.

The algorithm is executed a number of times (see Section 5.1 for parametrization of the algorithms) to learn all concepts in the set of summaries, and at each iteration a single concept is formed. There are two circumstances when a concept being formed is discarded and their associated initial target concept removed from the learning process: one case is when there are not enough occurrences of the concept across a set of summaries; another case is when too many identical strings are proposed as instances for the concept in the set of summaries. This latter restriction is only valid if we consider sets of non-redundant documents, which is the case to which we restrict our experiments.

4.3 Text Chunks

Given that the algorithms presented above try to induce a concept from the chunks in the summaries,

we are interested in assessing how the type of chunk influences the learning process. Also, given that our objective is to test methods which learn with minimal human intervention, we are interested in investigating differences between the use of manual and automatic chunks. We therefore use the following chunk types in this work: *gold chunks* (*gold*) are the human produced annotations (as in Figure 1); *named entity chunks* (*ne*) are named entities computed by an off-the-shelf named entity recognizer; *noun chunks* (*nc*) are text chunks identified by rule-based off-the-shelf NP chunkers and finally, *wiki chunks* (*wiki*) are strings of text in the summaries which happen to be Wikipedia titles.

In order to automatically compute these chunk types, different levels of knowledge are needed. For example, NP chunks require syntactic information, while named entities and wiki chunks require some external form of knowledge, such as precompiled gazetteer lists or access to an encyclopaedia or a semantic dictionary. Named entities and noun chunks are computed as described in Section 3, while wiki chunks are computed as follows: string n-grams $w_1w_2\dots w_n$ are computed in each summary and strings $w_1\dots w_n$ are checked against the Wikipedia on-line encyclopaedia, if a hit occurs (i.e. if for an English n-gram the page en.wikipedia.org/wiki/w_1\dots w_n exists or for a Spanish n-gram the page es.wikipedia.org/wiki/w_1\dots w_n exists), the n-gram is annotated in the summary as a wiki chunk. Wiki chunks are cached to speed up the automatic annotation process.

Table 2: Baseline Induction Performance

4.4 Mapping the Induced Concepts onto Human Concepts

For evaluation purposes, each induced concept is mapped onto one human concept applying the following procedure: let HC_i be the set of summary offsets where human concept i occurs, and let IC_j be the set of summary offsets where automatic concept j occurs, then the induced concept j is mapped onto concept k such that: $k = \arg \max_i (|HC_i \cap IC_j|)$, where $|X|$ is the size of set X . That is, the induced concept is mapped onto the label it gives it a best match. As an example, one induced concept in the terrorist attack domain containing the following string instances: *two bombs, car bomb, pair of bombs, 10 coordinated shooting and bombing, two car bombs, suicide bomb, the attack, guerrilla warfare, the coca-growing regions*, etc. This induced concept is mapped onto the *TypeOfAttack* human concept in that domain.

4.5 Baseline Concept Induction

A baseline induction mechanism is designed for comparison with the two learning procedures proposed here. It is based on the mapping of named entity chunks onto concepts in a straightforward way: each named entity type is considered a different concept and therefore mapped onto human concepts as in Section 4.4. For example, in the terrorist attack domain, *Organization* named entity type is mapped by this procedure onto the human concept *Target* (i.e. churches, government buildings, etc., are common targets in terrorist attacks) while in the Aviation Accident domain the *Organization* named entity type is mapped onto *TypeOfAircraft* (i.e. Boeing, Airbus, etc. are names of organizations).

5 Experimental Setting and Results of the Induction Process

In this section we detail the different parameters used by the algorithms and report the performance of the induction process with different inputs.

5.1 Settings

The features used by the induction procedure are extracted from the text tokens. We extract the POS tag, root, and string of each token. The clustering-based algorithm uses a standard Expectation Maximization

implementation from the Weka machine learning library (Witten and Frank, 1999). We instruct the algorithm to decide on the number of clusters based on the data, instead of setting the number of clusters by hand. The instances to cluster are representations of the input chunks; these representations contain the internal features of the chunks, as well as the information of 5 tokens to the left of the beginning of the chunk and 5 tokens to the right of the end of the chunk. The transformation from GATE documents into arff Weka files and the mapping from Weka onto the GATE documents, is carried out using specific programs. The classification algorithm used for the iterative learning process is an SVM classifier distributed with the GATE system and tuned to perform chunk learning using the same features as the clustering procedure (Li et al., 2004). This classifier outputs a probability which we use for selecting the best document at step (5) of the iterative procedure. The document selected to start the process is the one with more target strings, and the target string chosen is the next available in textual order. The iterative learning procedure is set to stop when the number of concepts induced reaches the average number of chunks in the corpus. Induced concepts not covering at least 10% of the number of documents are discarded, as are concepts with strings repeated at least 10% of the concept extension.

5.2 Experiments and Results

We carry out a number of experiments per domain where we run the algorithms using as input the summaries annotated with a different chunk type each time. After each experiment all concepts induced are

Table 4: Comparison of conceptual induction in Spanish

mapped onto the human concepts (see Section 4.4) producing auto-annotated summaries. The automatic annotations are then compared with the gold annotations, and precision, recall, and f-score figures are computed to observe the performance of the two algorithms, the baseline, and the effect of type of chunk on the learning process.

In Table 2 we report baseline performance on the entire dataset. As can be appreciated by the obtained numbers, directly mapping named entity types onto concepts does not provide a very good performance, especially for Spanish; we expected the learning procedures to produce better results. In Table 3 we present the results of inducing concepts from the gold chunks by the two algorithms. In almost all cases, using gold chunks improves over the baseline procedure, except for the Terrorist Attack domain in English, where the iterative learning procedure underperforms the baseline. In all tested domains, the clustering-based induction procedure has a very competitive performance. A *t*-test is run to verify differences in performance between the two systems in terms of f-score. In all tested domains in Spanish, except the Train Accident domain, there are sta-

ically computed chunks (i.e. **nc**, **ne**, **wiki**). We observe that, in general, when presented with automatic chunks, the iterative learning procedure is able to induce concepts with a better f-score than the clustering-based algorithm. A *t*-test is run to verify differences between the two induction procedures within each chunk condition (differences shown with a [†] in the tables). In 11 out of 16 cases in Spanish and in 12 out of 16 cases in English, statistically significant differences are observed. In three out of four domains the combination of automatic chunks outperforms the use of individual chunk types. Generally, named entity chunks and wiki chunks have the lowest performance. This is

not an unexpected result since named entities, for example, cover much fewer strings which may form part of a concept extension. Additionally, off-the-shelf entity recognizers only identify a limited number of entity types.

6 Information Extraction Evaluation Framework

The numbers above are interesting because they provide intrinsic evaluation of the concept induction procedure, but they do not tell us much about their usability. Therefore, and in order to better assess the value of the discovered concepts, we decided to carry out two extrinsic evaluations using an information extraction task. Once the concepts are induced and, as a result, the summaries are auto-annotated with domain specific concepts, we decide to train an off-the-shelf SVM token classification procedure and apply it to unseen human annotated documents. The SVM classifier uses the same linguistic information as the induction procedures: token level information and a window size of 5 around each token to be classified.

Table 11: Full-text Information Extraction Results in English. System trained with auto-annotated summaries in English.

6.1 Extraction from Automatic Translations

The first task we carry out is cross-lingual information extraction where the input documents are automatic translations of summaries in Spanish and English². Note that the experiment is performed in three domains for which such translations are manually annotated. We first run an experiment to assess the extraction performance of the SVM when trained on human annotated data. Results of the experiment are reported in Table 6 and they should be taken as an upperbound of the performance of a system trained on auto-annotated summaries. We then train the SVM on the different auto-annotated datasets, but note that due to space restrictions, we here only report the three most revealing experiments per language: concepts induced with gold chunks, noun chunks, and all automatic chunks. Results are reported in Table 7 (Spanish) and in Table 8 (English). In most cases the SVM trained with auto-annotated summaries produced by the iterative learning procedure outperforms the clustering-based method with statistically significant differences († shown in the tables) ($p = 0.01$).

6.2 Extraction from Full Documents

The second and the last evaluation consists in the application of the SVM extraction system to full documents. In this case, the experiment can be run only in two domains for which full documents have been provided and manually annotated. We first test the performance of the system when trained on human annotated summaries and present the results in Table 9. Results of the experiments when the system is trained on auto-annotated datasets are shown in

²The translations were produced by Google translator.

Tables 10 (Spanish) and 11 (English). Results are lower than when training on clean human annotated summaries. It is unclear which approach is more competitive when training with auto-annotated summaries. What is clear is that the performance of the iterative learning algorithm when training with concepts induced from gold chunks is not statistically different (according to a *t*-test and $p = 0.01$) from the performance of the algorithm when training with concepts induced from automatically computed chunks. We consider this to be a positive outcome of the experiments.

7 Discussion

The two methods presented here are able to produce partial domain conceptualizations from a relatively small set of domain summaries³. We have found that the clustering-based procedure is very competitive when presented with gold chunks. On the other hand, the iterative learning procedure performs very well when presented with automatic chunks in all tested domains and the two languages. We have also found that the performance of the iterative induction system is not much affected by the use of automatically computed chunks. We have run a *t*-test to verify the differences in induction performance when learning with gold and automatic chunks (*all* condition) and have found statistically significant differences in only one domain out of four in Spanish (Terrorist Attack) and in two domains out of four in English (Aviation Accident and Train Accident) ($p = 0.01$). The applicability of the induction process, that is, if the auto-annotated data could be used for specific tasks, has been tested in two information extraction experiments. In a cross-lingual information extraction setting (Riloff et al., 2002; Saggion and Szasz, 2011) we have observed that a system trained on automatically computed chunks has a performance close to one trained on concepts induced from gold chunks. No statistically significant differences exist ($p = 0.01$) between the use of automatic chunks and gold chunks, except for the Train Accident domain in English, where the system trained on fully automatically annotated summaries has a better performance. In a full document information

extraction task, although the best system trained on auto-annotated summaries in Spanish has a big difference with respect to a system trained on human-annotated summaries, in English the differences are slight. We believe that this is due to the differences in performance between the underlying text processing components. Our methods work by grouping together sets of chunks, unlike (Chambers and Jurafsky, 2011), whose approach is centered around verb arguments and clustering, and relies on the availability of considerable amounts of data. Ontology learning approaches such as OntoUSP (Poon and Domingos, 2010) are also clustering-based but focus on learning is-a relations only. Unlike (Leung et al., 2011) whose approach is based on gold-standard human annotations, we here test the performance of the induction process using automatically computed candidate strings, and we additionally learn the number of concepts automatically.

8 Conclusions and Future Work

In this paper we have concentrated on the problem of knowledge induction from text summaries. The approaches we have presented are fully unsupervised and are able to produce reasonable conceptualizations (close to human concepts) without relying on annotated data. Unlike previous work, our approach does not require full syntactic parsing or a semantic dictionary. In fact, it only requires a process of text chunking and named entity recognition, which we have carefully assessed here. We believe our work contributes with a viable methodology to induce conceptual information from texts, and at the same time with an auto-annotation mechanism which could be used to train information extraction systems. Since our procedure requires very little linguistic information, we believe it can be successfully applied to a number of languages. We also believe that there is much work to be carried out and that induction from summaries should be complemented with a process that explores full event reports, in order to reinforce some induced concepts, discard others, and discover additional ones.

Classification of South African languages using text and acoustic based methods: A case of six selected languages

Peleira Nicholas Zulu

University of KwaZulu-Natal

Abstract

Language variations are generally known to have a severe impact on the performance of Human Language Technology Systems. In order to predict or improve system performance, a thorough investigation into these variations, similarities and dissimilarities, is required. Distance measures have been used in several applications of speech processing to analyze different varying speech attributes. However, not much work has been done on language distance measures, and even less work has been done involving South African languages. This study explores two methods for measuring the linguistic distance of six South African languages. It concerns a text based method, (the Levenshtein Distance), and an acoustic approach using extracted mean pitch values. The Levenshtein distance uses parallel word transcriptions from all six languages with as little as 144 words, whereas the pitch method is text-independent and compares mean language pitch differences. Cluster analysis resulting from the distance matrices from both methods correlates closely with human perceptual distances and existing literature about the six languages.

1 Introduction

The development of objective metrics to assess the distances between different languages is of great theoretical and practical importance. Currently, subjective measures have generally been employed to assess the degree of similarity or dissimilarity between different languages (Gooskens &

Heeringa, 2004; Van-Bezoijen & Heeringa, 2006; Van-Hout & Münstermann, 1981), and those subjective decisions are, for example, the basis for classifying separate languages, and certain groups of language variants as dialects of one another. It is well known that languages are complex; they differ in vocabulary, grammar, writing format, syntax and many other characteristics. This presents levels of difficulty in the construction of objective comparative measures between languages. Even if one intuitively knows, for example, that English is closer to French than it is to Chinese, what are the objective factors that allow one to assess the levels of distance?

This bears substantial similarities to the analogous questions that have been asked about the relationships between different species in the science of cladistics. As in cladistics, the most satisfactory answer would be a direct measure of the amount of time that has elapsed since the languages' first split from their most recent common ancestor. Also, as in cladistics, it is hard to measure this from the available evidence, and various approximate measures have to be employed instead. In the biological case, recent decades have seen tremendous improvements in the accuracy of biological measurements as it has become possible to measure differences between DNA sequences. In linguistics, the analogue of DNA measurements is historical information on the evolution of languages, and the more easily measured—though indirect measurements (akin to the biological phenotype)—are either the *textual* or *acoustic* representations of the languages in question.

In the current article, we focus on language distance measures derived from both text and acoustic formats; we apply two different techniques, namely Levenshtein distance between orthographic word transcriptions, and distances between language pitch means in order to obtain measures of dissimilarity amongst a set of languages. These methods are used to obtain language groupings which are represented graphically using multidimensional scaling and dendrograms—two standard statistical techniques. This allows us to visualize and assess the methods relative to known linguistic facts in order to judge their relative reliability(Zulu, Botha, & Barnard, 2008).

Our evaluation is based on six of the eleven official languages of South Africa.¹ The eleven official languages fall into two distinct groups, namely the Germanic group (represented by English and Afrikaans) and the South African Bantu languages, which belong to the South Eastern Bantu group. The South African Bantu languages can further be classified in terms of different subgroupings: Nguni (consisting of Zulu, Xhosa, Ndebele and Swati), Sotho (consisting of Southern Sotho, Northern Sotho and Tswana), and a pair that falls outside these sub-families (Tsonga and Venda). The six languages chosen for our evaluation are English, Afrikaans, Zulu, Xhosa, Northern Sotho (also known as Sepedi) and Tswana, which equally represent the three groups; Germanic, Nguni and Sotho.

We believe that an understanding of these language distances is not only of inherent interest, but also of great practical importance. For purposes such as language learning, the selection of target languages for various resources and the development of Human Language Technologies, reliable knowledge of language distances would be of great value. Consider, for example, the common situation of an organization that wishes to publish information relevant to all languages in a particular multi-lingual community, but has insufficient funding to do so. Such an organization can be guided by knowledge of language distances and mutual intelligibility between languages to make an appropriate choice of publication languages.

The following sections describe the Levenshtein distance and pitch characteristics in detail. There-

after, the paper will present an evaluation on the six languages of South Africa, highlighting language groupings and proximity patterns. In conclusion, the paper discusses the results.

2 Theoretical Background

Orthographic transcriptions are one of the most basic types of annotation used for speech transcription, and are particularly important in most fields of research concerned with spoken language. The orthography of a language refers to the set symbols used to write a language and includes its writing system. English, for example, has an alphabet of 26 letters which includes both consonants and vowels. However, each English letter may represent more than one phoneme, and each phoneme may be represented by more than one letter. In the current research, we investigate the use of Levenshtein distance on orthographic transcriptions for the assessment of language similarities.

On the other hand, speech has been and still very much is the most natural form of communication. Prosodic characteristics such as rhythm, stress and intonation in speech convey important information regarding the identity of a spoken language. Results of perception studies on spoken language identification confirm that prosodic information, specifically pitch and intensity—which represent intonation and stress respectively—are useful for language identification (Kometsu, Mori, Arai, & Murahara, 2001; Mori et al., 1999). This paper presents a preliminary investigation of pitch and its role in determining acoustic based language distances.

2.1 Levenshtein Distance

There are several ways in which phoneticians have tried to measure the distance between two linguistic entities, most of which are based on the description of sounds via various representations. This section introduces the Levenshtein Distance Measure, one of the more popular sequence-based distance measures. In 1995 Kessler introduced the use of the Levenshtein Distance as a tool for measuring linguistic distances between dialects (Kessler, 1995). The basic idea behind the Levenshtein Distance is to imagine that one is rewriting or transforming one string into another. Kessler successfully applied the Levenshtein Distance

¹ Data for all eleven languages is available on the Lwazi website: (<http://www.meraka.org.za/lwazi/index.php>).

measure to the comparison of Irish dialects. In his work, the strings were transcriptions of word pronunciations. In general, rewriting is effected by basic operations, each of which is associated with a cost, as illustrated in Table 1 in the transformation of the string “mošemane” to the string “umfana”, which are both orthographic translations of the word boy in Northern Sotho and Zulu respectively.

Operation	Cost
mošemane	delete m
ošemane	delete š
oemane	delete e
omane	insert f
omfane	substitute o/u
umfane	substitute e/a
Total cost	8

Table 1. Levenshtein Distance between two strings.

The Levenshtein Distance between two strings can be defined as the least costly sum of costs needed to transform one string into another. In Table 1, the transformations shown are associated with costs derived from operations performed on the strings. The operations used are: (i) the deletion of a single symbol, (ii) the insertion of a single symbol, and (iii) the substitution of one symbol for another (Kruskal, 1999). The edit distance method was also taken up by (Nerbonne et al., 1996) who applied it to Dutch dialects. Whereas Kruskal (1999) and Nerbonne *et al.* (1996) applied this method to phonetic transcriptions in which the symbols represented sounds, here the symbols were associated with alphabetic letters.

Similarly, Gooskens and Heeringa (2004) calculated Levenshtein Distances between 15 Norwegian dialects and compared them to the distances as perceived by Norwegian listeners. This comparison showed a high correlation between the Levenshtein distances and the perceptual distances.

2.2 Language pitch distance

Speech is primarily intended to convey some message through a sequence of legal sound units in a language. However, speech cannot merely be characterized as a sequence of sound units. There are some characteristics that lend naturalness to speech, such as the variation of pitch, which provides some recognizable melodic properties to

spoken language. This controlled modulation of pitch is referred to as *intonation*. The sound units are shortened or lengthened in accordance to some underlying pattern giving rhythmic properties to speech. The information attained from these rhythmic patterns increases the intelligibility of spoken languages, enabling the listener to segment continuous speech into phrases and words with ease (Shriberg, Stolcke, Hakkani-Tur, & Tur, 2000). The characteristics that make us perceive this and other information such as stress, accent and emotion are collectively referred to as prosody. Comparisons have shown that languages differ greatly in their prosodic features (Hirst & Cristo, 1998), therefore providing a basis for objective comparison between languages. Further, pitch is a perceptual attribute of sound, the physical correlate of which is fundamental frequency (F_0), which represents vibration of the vocal folds.

This paper extracts pitch contours from six different languages, and uses the mean fundamental frequency values for each language to calculate the differences in pitch amongst them. From this we derive a distance matrix of F_0 dissimilarities (differences) which in turn is used to obtain language groupings.

2.3 Language Clustering

In using the Levenshtein Distance measure, the distance between two languages is equal to the average of a sample of Levenshtein Distances of corresponding word pairs. With pitch, the distance between two languages is merely the difference between the mean fundamental frequencies of the two languages. When we have n languages, then these distances are calculated for each possible pair of languages. For n languages $n \times n$ distances can be calculated. The corresponding distances are arranged in an $n \times n$ matrix. The distance of each language with respect to itself is found in the distance matrix on the diagonal from the upper left to the lower right. As this is a dissimilarity matrix, these values are always zero and therefore give no real information, so that only $n \times (n - 1)$ distances are relevant. Furthermore, both the Levenshtein and pitch distances are symmetric, implying that the distance between language X and Y is equal to the distance between language Y and X . Therefore, the distance matrix is symmetric. We need to use only one half which contains $(n \times (n - 1))/2$ dis-

tances. Given the distance matrix, groups of larger sizes are investigated. Hierarchical clustering methods are employed to classify the languages into related language groups using the distance matrix.

Data clustering is a common technique for statistical data analysis, which is used in many fields including machine learning, bioinformatics, image analysis, data mining and pattern recognition. Clustering is the classification of similar objects into different groups, or more precisely, the partitioning of a data set into subsets, so that the data in each subset share some common trait according to a defined distance measure. The result of this grouping is usually illustrated as a dendrogram; a tree diagram used to illustrate the arrangement of the groups produced by a clustering algorithm (Heeringa & Gooskens, 2003), whereas multidimensional scaling adds to illustrate the visualization of the language proximities in a 2-dimensional space.

3 Evaluation

This evaluation aims to present language groups of the six chosen languages of South Africa generated from dissimilarity matrices of the languages. These matrices are the results of Levenshtein distance and average pitch distance measurements. The diagrams provide visual representations of the pattern of similarities and dissimilarities between the languages.

3.1 Language grouping using Levenshtein distance

Levenshtein distances were calculated using existing parallel orthographic word transcriptions of 144 words from each of the six languages. The data was manually collected from various multilingual dictionaries and online resources. Initially, 200 common English words, mostly common nouns easily translated into the other five languages, were chosen. From this set, those words having unique translations into each of the other five languages were selected, resulting in 144 words that were used in the evaluations. Examples of four word translations in all six languages are shown in Table 2.

Eng	Afr	Xho	Zul	N.Sot	Tsw
fish	vis	intlanzi	inhlanzi	hlapi	tlhapi
house	huis	indlu	indlu	ntlo	ntlo
mother	ma	uma	umama	mma	mme
school	skool	isikolo	isikole	sekolo	sekole

Table 2. Example translations of four common words.

Distance matrix

Table 3 represents the distance matrix, containing the distances, taken pair-wise, between the different languages as calculated from the summed Levenshtein Distances between the 144 target words. The zero values along the diagonal axis of the matrix indicate no dissimilarity, making it clear that higher values reveal high levels of dissimilarity between the paired languages. The distance matrix contains $n \times (n - 1)/2$ independent elements in light of the symmetry of the distance measure.

Table 3. Distance matrices calculated from Levenshtein Distance between 144 words.

Graphical representation

The confusion matrices provide a clear indication of the ways the languages group into families. These relationships can be represented visually using graphical techniques. Multidimensional scaling (MDS) is a technique used in data visualization for exploring the properties of data in high-dimensional spaces. The algorithm uses a matrix of dissimilarities between items and then assigns each item a location in a low dimensional space to match those distances as closely as possible. The study used the dissimilarity matrix to serve as a measure between languages, and used the statistical package XLSTAT (XLSTAT, 2012). The dissimilarity matrix was input into the multidimensional scaling algorithm which mapped the language dissimilarities in a 2-dimensional space.

Figure 1 shows the mapping that was created using the dissimilarity matrix in Table 3; we can see that the languages from the same subfamilies group together. The mapping using just 144 words shows a definite grouping of the families. In the mapping the Sotho languages are more closely related internally than both the Nguni and Germanic languages as expected — from the historical record (Heine & Nurse, 2000), it is clear that a tighter internal grouping of the Sotho and Nguni languages is accurate.

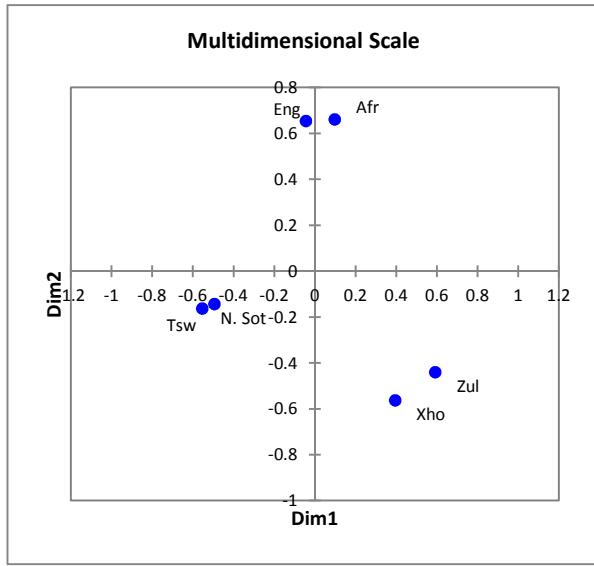

Figure 1. Multidimensional scale to represent dissimilarities between languages calculated from the dissimilarity matrix in Table 3.

In conjunction with multidimensional scaling, dendrograms also provide a visual representation of the pattern of similarities or dissimilarities among a set of objects. We again used the dissimilarity matrix in Table 3 with the statistical package XLSTAT.

Figure 2 illustrates the dendrogram derived from clustering the dissimilarities between the languages as depicted by the dissimilarity matrix in Table 3. The dendrogram shows three classes representing the previously defined language groupings, Nguni, Sotho and Germanic. This dendrogram closely relates to the language groupings described in (Heine & Nurse, 2000).

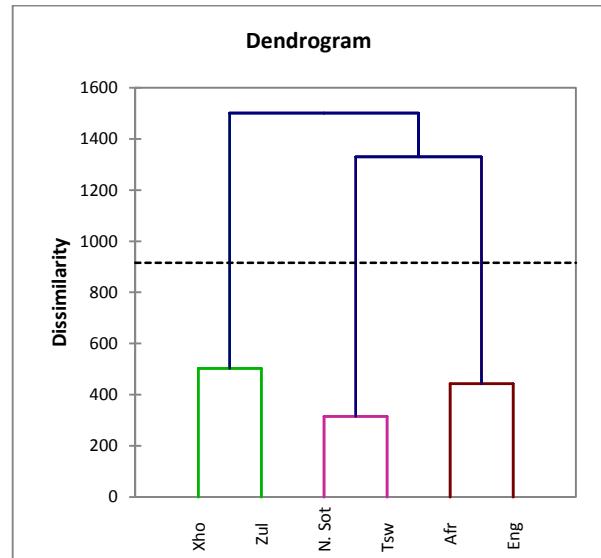

Figure 2. Dendrogram calculated from the dissimilarity matrix of Table 3.

3.2 Pitch Extraction and language grouping

The extraction of pitch contours was carried out with *Praat* (Boersma & Weenink, 2011), a free scientific software program for the analysis of speech and phonetics. The use of Praat is advantageous in that it is fairly easy to use, has high processing speed, is accurate and allows scripting, which is very useful in processing large numbers of files (in our case, speech recordings).

A Praat script was written specifying two main parameters; the expected minimum and maximum pitch values in Hertz, which were selected to be 75Hz and 600Hz respectively. The extraction of pitch contours is based on the detection of periodicities. The Praat command *To PointProcess (periodic, peaks)...* analyses the selected speech file and creates a sequence of points in time. The acoustic periodicity detection is performed on the basis of an accurate short-term analysis of the fundamental frequency and the harmonics-to-noise ratio working in the autocorrelation domain as described by Boersma (Boersma, 1993). This method was able to achieve more accurate and noise-resistant results when compared to combs or cepstrum based methods (Pokorny, 2011). The extracted acoustic periodicity contour is interpreted as being the frequency of an underlying sequence of glottal closures in vocal fold vibrations. For each speech file—for every voiced interval—a

number of points representing glottal pulses are found and their points in time are saved, forming the pitch contour for that particular speech file (Pokorny, 2011). Pitch contours were extracted from 5000 speech files per language for each of the six languages, with each language having approximately 200 different speakers (25 recordings per speaker) with a relatively equal distribution of males and females, all aged between 18 and 65 years.

The extracted pitch frequency points for all 5000 files were collected and placed in a single array for each language. Each array represents the pitch distribution for the specific language, and the mean frequency for each language was used to model the respective language. The dissimilarity matrix was then derived from the differences of these means for each pair of languages. Figure 3 illustrates the distribution of pitch frequencies for the selected languages. It clearly shows the relative pitch content variations of the different languages, which is key to determining the dissimilarity amongst the languages. Also of note in Figure 3 are the peak positions representing approximate positions of male and female fundamental frequencies—in the range of 85 to 180Hz for males and 165 to 255 Hz for females.

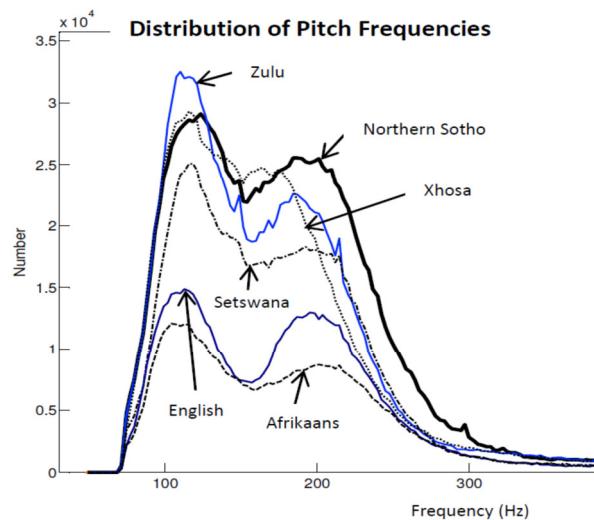

Figure 3. Distribution of pitch frequencies extracted from 6 South African languages.

Distance matrix

Table 4 represents the distance matrix—containing the distances taken pair-wise—between the differ-

ent languages as calculated from the mean pitch frequencies of the six languages. Again, higher numbers in the matrix reflect high dissimilarity between the selected pair of languages.

	Afr	Eng	Xho	Zul	N. Sot	Tsw

Tsw	12.61	7.51	3.48	4.5	2.95	0

Table 4. Distance matrix calculated from mean pitch frequencies of six South African languages.

Graphical representation

As with the Levenshtein Distance, the relationships between the languages are represented visually in Figures 4 and 5 using graphical techniques and multidimensional scaling. The language dissimilarities are mapped on to a 2-dimensional space shown in Figure 4. Here also, the languages from the same sub-families are grouped together. The relative closeness within the three sub-families is not as clearly indicated in Figure 4 as in Figure 1, but the distinction is clearly visible.

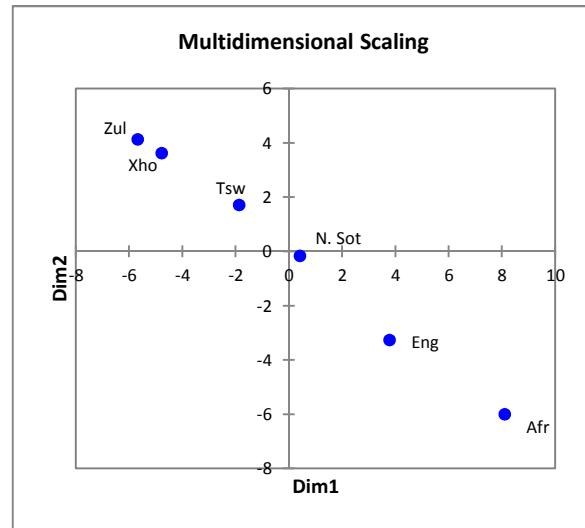

Figure 4. Multi-dimensional scale calculated from the pitch-based matrix of Table 4.

Figure 5 shows the dendrogram generated from the dissimilarity matrix of Table 4. As in Figure 2, the dendrogram shows three classes representing

the previously defined language sub-families. Figure 5 differs from Figure 2 in the branching of the three sub-families, where Figure 2 shows the Germanic languages branching from the same parent as the Sotho sub-family. Figure 5 offers a more accurate account by separating the Germanic subgroup from the Bantu languages. Thus, Figure 5 depicts a more refined grouping of the languages than Figure 2.

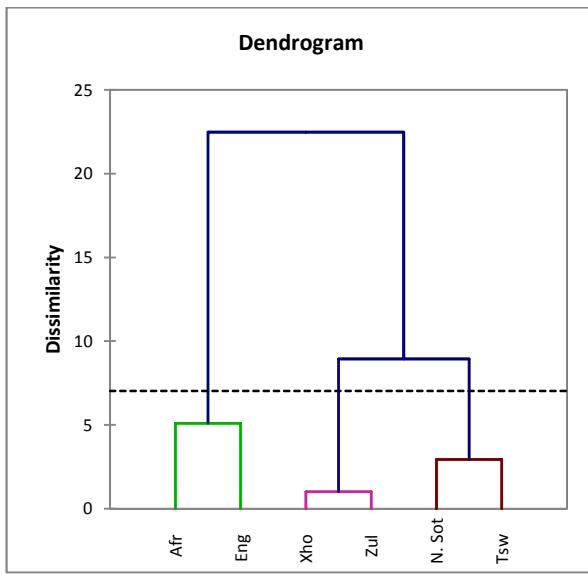

Figure 5. Dendrogram calculated from the pitch-based distance matrix of Table 4.

Conclusion

Both dissimilarity matrices resulting from the text-based Levenshtein Distance and the acoustic mean pitch frequency differences can effectively be combined with multidimensional scaling and dendograms to epitomize language relationships. Both methods reflect the known family relationships between the languages being studied. The main conclusion of this research is therefore that statistical methods, used with both text-based and acoustic-based methods and data, are able to provide useful objective measures of language similarities or dissimilarities. It is clear that these methods can be refined further using other inputs such as phonetic transcriptions or further acoustic measurements; such refinements are likely to be important when, for example, fine distinctions between dialects are required.

However, each approach has its advantages and disadvantages. Levenshtein Distance measures do not require much data to perform a reasonable classification of the data. With as few as 50 words per language, reasonable classification is possible. Also, the process of generating the distance matrix is not computationally taxing. However, this method is less discriminating in assessing languages with different writing styles, for example Chinese and English. Using pitch bares the advantage of using language data in its most natural form, but has its disadvantages in being computationally taxing when dealing with large amounts of data—which is generally required in order to produce good results.

It would be most interesting to see whether closer agreement between these methods can be achieved by measuring Levenshtein Distances between larger text collections—perhaps even parallel corpora rather than translations of word lists. Comparing these distance measures with measures derived from different acoustic parameters, or a combination of parameters, is another pressing concern. Finally, it would be valuable to compare various distance measures against other criteria for language similarity (e.g. historical separation or mutual intelligibility) in a rigorous fashion.

Improving Syntax-Augmented Machine Translation by Coarsening the Label Set

Greg Hanneman and Alon Lavie

Language Technologies Institute

Carnegie Mellon University

Pittsburgh, PA 15213 USA

{ghannema, alavie}@cs.cmu.edu

Abstract

We present a new variant of the Syntax-Augmented Machine Translation (SAMT) formalism with a category-coarsening algorithm originally developed for tree-to-tree grammars. We induce bilingual labels into the SAMT grammar, use them for category coarsening, then project back to monolingual labeling as in standard SAMT. The result is a “collapsed” grammar with the same expressive power and format as the original, but many fewer nonterminal labels. We show that the smaller label set provides improved translation scores by 1.14 BLEU on two Chinese–English test sets while reducing the occurrence of sparsity and ambiguity problems common to large label sets.

1 Introduction

The formulation of statistical machine translation in terms of synchronous parsing has become both theoretically and practically successful. In a parsing-based MT formalism, synchronous context-free grammar rules that match a source-language input can be hierarchically composed to produce a corresponding target-language output. SCFG translation grammars can be extracted automatically from data. While *formally* syntactic approaches with a single grammar nonterminal have often worked well (Chiang, 2007), the desire to exploit linguistic knowledge has motivated the use of translation grammars with richer, *linguistically* syntactic nonterminal inventories (Galley et al., 2004; Liu et al., 2006; Lavie et al., 2008; Liu et al., 2009).

Linguistically syntactic MT systems can derive their label sets, either monolingually or bilingually, from parallel corpora that have been annotated with source- and/or target-side parse trees provided by a statistical parser. The MT system may exactly adopt the parser’s label set or modify it in some way. Larger label sets are able to represent more precise, fine-grained categories. On the other hand, they also exacerbate a number of computational and modeling problems by increasing grammar size, derivational ambiguity, and data sparsity.

In this paper, we focus on the Syntax-Augmented MT formalism (Zollmann and Venugopal, 2006), a monolingually labeled version of Hiero that can create up to 4000 “extended” category labels based on pairs of parse nodes. We take a standard SAMT grammar with target-side labels and extend its labeling to a bilingual format (Zollmann, 2011). We then coarsen the bilingual labels following the “label collapsing” algorithm of Hanneman and Lavie (2011). This represents a novel extension of the tree-to-tree collapsing algorithm to the SAMT formalism. After removing the source-side labels, we obtain a new SAMT grammar with coarser target-side labels than the original.

Coarsened grammars provide improvement of up to 1.14 BLEU points over the baseline SAMT results on two Chinese–English test sets; they also outperform a Hiero baseline by up to 0.60 BLEU on one of the sets. Aside from improved translation quality, in analysis we find significant reductions in derivational ambiguity and rule sparsity, two problems that make large nonterminal sets difficult to work with.

Section 2 provides a survey of large syntax-based

MT label sets, their associated problems of derivational ambiguity and rule sparsity, and previous attempts at addressing those problems. The section also summarizes the tree-to-tree label collapsing algorithm and the process of SAMT rule extraction. We then describe our method of label collapsing in SAMT grammars in Section 3. Experimental results are presented in Section 4 and analyzed in Section 5. Finally, Section 6 offers some conclusions and avenues for future work.

2 Background

2.1 Working with Large Label Sets

Aside from the SAMT method of grammar extraction, which we treat more fully in Section 2.3, several other lines of work have explored increasing the nonterminal set for syntax-based MT. Huang and Knight (2006), for example, augmented the standard Penn Treebank labels for English by adding lexicalization to certain types of nodes. Chiang (2010) and Zollmann (2011) worked with a bilingual extension of SAMT that used its notion of “extended categories” on both the source and target sides. Taking standard monolingual SAMT as a baseline, Baker et al. (2012) developed a tagger to augment syntactic labels with some semantically derived information. Ambati et al. (2009) extracted tree-to-tree rules with similar extensions for sibling nodes, resulting again in a large number of labels.

Extended categories allow for the extraction of a larger number of rules, increasing coverage and translation performance over systems that are limited to exact constituent matches only. However, the gains in coverage come with a corresponding increase in computational and modeling complexity due to the larger label set involved.

Derivational ambiguity — the condition of having multiple derivations for the same output string — is a particular problem for parsing-based MT systems. The same phrase pair may be represented with a large number of different syntactic labels. Further, new hierarchical rules are created by abstracting smaller phrase pairs out of larger ones; each of these substitutions must also be marked by a label of some kind. Keeping variantly labeled copies of the same rules fragments probabilities during grammar scoring and creates redundant hypotheses in the

decoder at run time.

A complementary problem — when a desired rule application is impossible because its labels do not match — has been variously identified as “data sparsity,” the “matching constraint,” and “rule sparsity” in the grammar. It arises from the definition of SCFG rule application: in order to compose two rules, the left-hand-side label of the smaller rule must match a right-hand-side label in the larger rule it is being plugged in to. With large label sets, it becomes less likely that two arbitrarily chosen rules can compose, making the grammar less flexible for representing new sentences.

Previous research has attempted to address both of these problems in different ways. Preference grammars (Venugopal et al., 2009) are a technique for reducing derivational ambiguity by summing scores over labeled variants of the same derivation during decoding. Chiang (2010) addressed rule sparsity by introducing a soft matching constraint: the decoder may pay a learned label-pair-specific penalty for substituting a rule headed by one label into a substitution slot marked for another. Combining properties of both of the above methods, Huang et al. (2010) modeled monolingual labels as distributions over latent syntactic categories and calculated similarity scores between them for rule composition.

2.2 Label Collapsing in Tree-to-Tree Rules

Aiming to reduce both derivational ambiguity and rule sparsity, we previously presented a “label collapsing” algorithm for systems in which bilingual labels are used (Hanneman and Lavie, 2011). It coarsens the overall label set by clustering monolingual labels based on which labels they appear joined with in the other language.

The label collapsing algorithm takes as its input a set of SCFG rule instances extracted from a parallel corpus. Each time a tree-to-tree rule is extracted, its left-hand side is a label of the form $s::t$, where s is a label from the source-language category set S and t is a label from the target-language category set T . Operationally, the joint label means that a source-side subtree rooted at s was the translational equivalent of a target-side subtree rooted at t in a parallel sentence. Figure 1 shows several such subtrees, highlighted in grey and numbered. Joint left-hand-side labels for the collapsing algorithm,

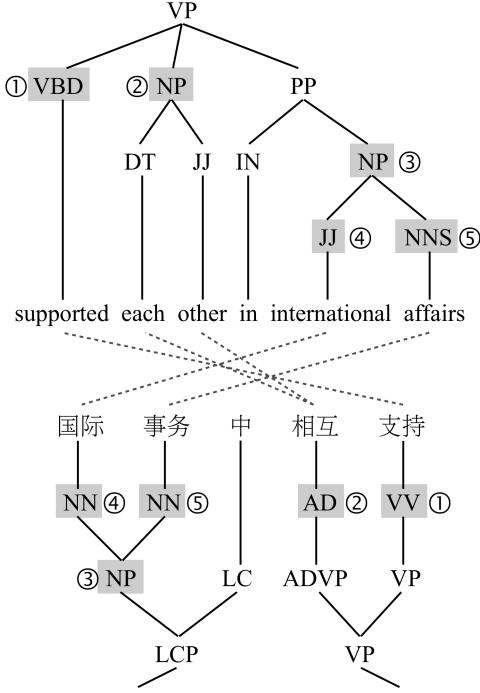

Figure 1: Sample extraction of bilingual nonterminals for label collapsing. Labels extracted from this tree pair include VBD::VV and NP::AD.

such as VBD::VV and NP::AD, can be assembled by matching co-numbered nodes.

From the counts of the extracted rules, it is thus straightforward to compute for all values of s and t the observed $P(s|t)$ and $P(t|s)$, the probability of one half of a joint nonterminal label appearing in the grammar given the other half. In the figure, for example, $P(JJ|NN) = 0.5$. The conditional probabilities accumulated over the whole grammar give rise to a simple L_1 distance metric over any pair of monolingual labels:

$$d(s_1, s_2) = \sum_{t \in T} |P(t|s_1) - P(t|s_2)| \quad (1)$$

$$d(t_1, t_2) = \sum_{s \in S} |P(s|t_1) - P(s|t_2)| \quad (2)$$

An agglomerative clustering algorithm then combines labels in a series of greedy iterations. At each step, the algorithm finds the pair of labels that is currently the closest together according to the distance metrics of Equations (1) and (2), combines those two labels into a new one, and updates the set of $P(s|t)$

and $P(t|s)$ values appropriately. The choice of label pair to collapse in each iteration can be expressed formally as

$$\arg \min_{(s_i, s_j) \in S^2, (t_k, t_\ell) \in T^2} \{d(s_i, s_j), d(t_k, t_\ell)\} \quad (3)$$

That is, either a source label pair or a target label pair may be chosen by the algorithm in each iteration.

2.3 SAMT Rule Extraction

SAMT grammars pose a challenge to the label collapsing algorithm described above because their label sets are usually monolingual. The classic SAMT formulation (Zollmann and Venugopal, 2006) produces a grammar labeled on the target side only. Nonterminal instances that exactly match a target-language syntactic constituent in a parallel sentence are given labels of the form t . Labels of the form $t_1 + t_2$ are assigned to nonterminals that span exactly two contiguous parse nodes. Categorial grammar labels such as t_1/t_2 and $t_1 \setminus t_2$ are given to nonterminals that span an incomplete t_1 constituent missing a t_2 node to its right or left, respectively. Any non-terminal that cannot be labeled by one of the above three schemes is assigned the default label X.

Figure 2(a) shows the extraction of a VP-level SAMT grammar rule from part of a parallel sentence. At the word level, the smaller English phrase *supported each other* (and its Chinese equivalent) is being abstracted as a nonterminal within the larger phrase *supported each other in international affairs*. The larger phrase corresponds to a parsed VP node on the target side; this will become the label of the extracted rule's left-hand side. Since the abstracted sub-phrase does not correspond to a single constituent, the SAMT labeling conventions assign it the label VBD+NP. We can thus write the extracted rule as:

$$\text{VP} \rightarrow [\text{国际 事务 中 VBD+NP}^1]:: \\ [\text{VBD+NP}^1 \text{ in international affairs}] \quad (4)$$

While the SAMT label formats can be trivially converted into joint labels $X::t$, $X::t_1+t_2$, $X::t_1/t_2$, $X::t_1 \setminus t_2$, and $X::X$, they cannot be usefully fed into the label collapsing algorithm because the necessary conditional label probabilities are meaningless. To acquire meaningful source-side labels, we turn to a

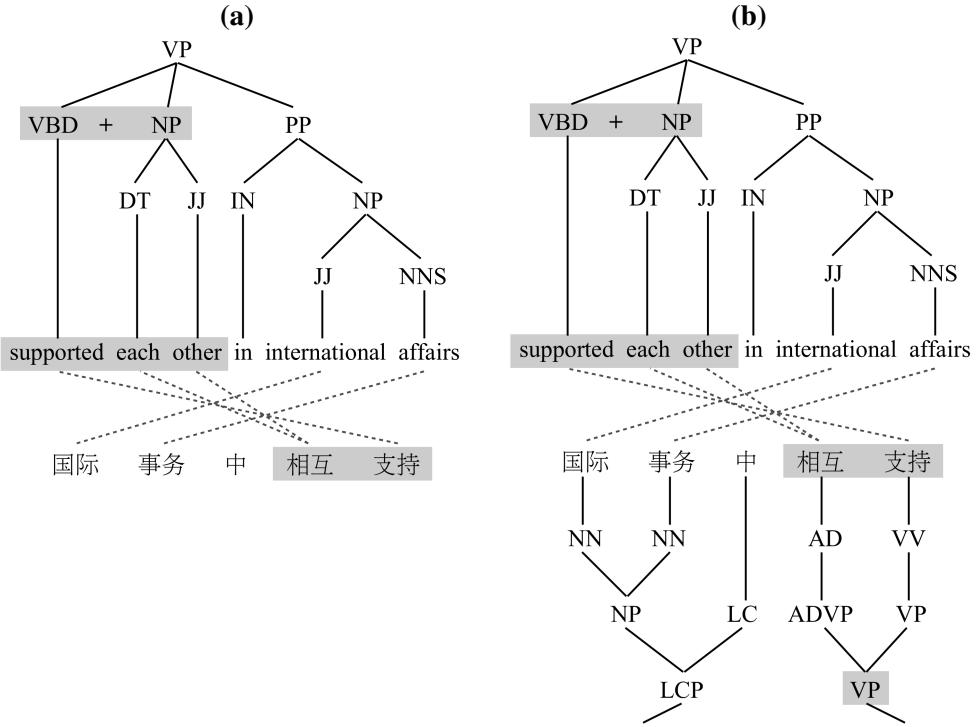

Figure 2: Sample extraction of an SAMT grammar rule: (a) with monolingual syntax and (b) with bilingual syntax.

bilingual SAMT extension used by Chiang (2010) and Zollmann (2011). Both a source- and a target-side parse tree are used to extract rules from a parallel sentence; two SAMT-style labels are worked out independently on each side for each nonterminal instance, then packed into a joint label. It is therefore possible for a nonterminal instance to be labeled $s::t$, $s_1 \setminus s_2 :: t$, $s_1 + s_2 :: t_1 / t_2$, or various other combinations depending on what parse nodes the nonterminal spans in each tree.

Such a bilingually labeled rule is extracted in Figure 2(b). The target-side labels from Figure 2(a) are now paired with source-side labels extracted from an added Chinese parse tree. In this case, the abstracted sub-phrase *supported each other* is given the joint label $VP::VBD+NP$, while the rule’s left-hand side becomes $LCP+VP::VP$.

We implement bilingual SAMT grammar extraction by modifying Thrax (Weese et al., 2011), an open-source, Hadoop-based framework for extracting standard SAMT grammars. By default, Thrax can produce grammars labeled either on the source or target side, but not both. It also outputs rules that are already scored according to a user-specified

set of translation model features, meaning that the raw rule counts needed to compute the label conditional probabilities $P(s|t)$ and $P(t|s)$ are not directly available. We implement a new subclass of grammar extractor with logic for independently labeling both sides of an SAMT rule in order to get the necessary bilingual labels; an adaptation to the existing Thrax “rarity” feature provides the rule counts.

3 Label Collapsing in SAMT Rules

Our method of producing label-collapsed SAMT grammars is shown graphically in Figure 3.

We first obtain an SAMT grammar with bilingual labels, together with the frequency count for each rule, using the modified version of Thrax described in Section 2.3. The rules can be grouped according to the target-side label of their left-hand sides (Figure 3(a)).

The rule counts are then used to compute labeling probabilities $P(s|t)$ and $P(t|s)$ over left-hand-side usages of each source label s and each target label t . These are simple maximum-likelihood estimates: if $\#(s_i, t_j)$ represents the combined frequency counts of all rules with $s_i :: t_j$ on the left-hand

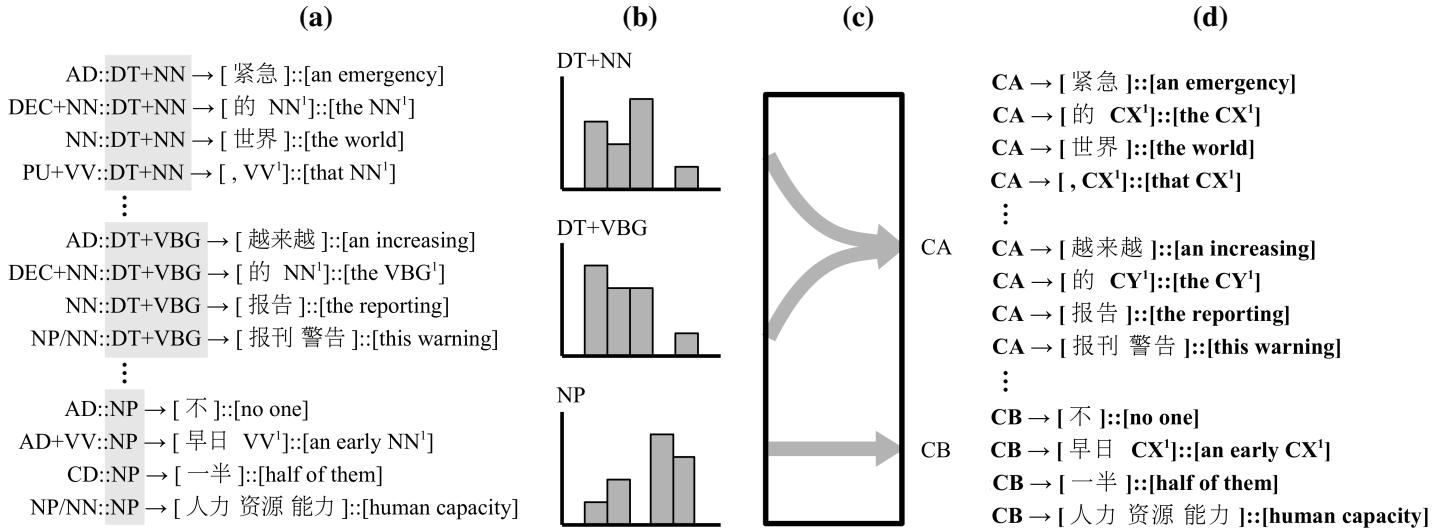

Figure 3: Stages of preparing label-collapsed rules for SAMT grammars. (a) SAMT rules with bilingual nonterminals are extracted and collected based on their target left-hand sides. (b) Probabilities $P(t|s)$ and $P(s|s)$ are computed. (c) Nonterminals are clustered according to the label collapsing algorithm. (d) Source sides of nonterminals are removed to create a standard SAMT grammar.

side, the source-given-target labeling probability is:

$$P(s_i | t_j) = \frac{\#(s_i :: t_j)}{\sum_{t \in T} \#(s_i :: t)} \quad (5)$$

The computation for target given source is analogous. Each monolingual label can thus be represented as a distribution over the labels it is aligned to in the opposite language (Figure 3(b)).

Such distributions over labels are the input to the label-collapsing algorithm, as described in Section 2.2. As shown in Figure 3(c), the algorithm results in the original target-side labels being combined into different groups, denoted in this case as new labels CA and CB. We run label collapsing for varying numbers of iterations to produce varying degrees of coarsened label sets.

Given a mapping from original target-side labels to collapsed groups, all nonterminals in the original SAMT grammar are overwritten accordingly. The source-side labels are dropped at this point: we use them only for the purpose of label collapsing, but not in assembling or scoring the final grammar. The resulting monolingual SAMT-style grammar with collapsed labels (Figure 3(d)) can now be scored and used for decoding in the usual way.

For constructing a baseline SAMT grammar without label collapsing, we merely extract a bilingual

grammar as in the first step of Figure 3, immediately remove the source-side labels from it, and proceed to grammar scoring.

All grammars are scored according to a set of eight features. For an SCFG rule with left-hand-side label t , source right-hand side f , and target right-hand side e , they are:

- Standard maximum-likelihood phrasal translation probabilities $P(f|e)$ and $P(e|f)$
- Maximum-likelihood labeling probability $P(t|f, e)$
- Lexical translation probabilities $P_{lex}(f|e)$ and $P_{lex}(e|f)$, as calculated by Thrax
- Rarity score $\frac{\exp(\frac{1}{c}) - 1}{\exp(1) - 1}$ for a rule with extracted count c
- Binary indicator features that mark phrase pair (as opposed to hierarchical) rules and glue rules

Scored grammars are filtered down to the sentence level, retaining only those rules whose source-side terminals match an individual tuning or testing sentence. In addition to losslessly filtering grammars in this way, we also carry out two types of lossy pruning in order to reduce overall grammar

System	Labels	Rules	Per Sent.
SAMT	4181	69,401,006	48,444
Collapse 1	913	64,596,618	35,004
Collapse 2	131	60,526,479	24,510
Collapse 3	72	58,483,310	20,445
Hiero	1	36,538,657	7,738

Table 1: Grammar statistics for different degrees of label collapsing: number of target-side labels, unique rules in the whole grammar, and average number of pruned rules after filtering to individual sentences.

size. One pruning pass keeps only the 80 most frequently observed target right-hand sides for each source right-hand side. A second pass globally removes hierarchical rules that were extracted fewer than six times in the training data.

4 Experiments

We conduct experiments on Chinese-to-English MT, using systems trained from the FBIS corpus of approximately 302,000 parallel sentence pairs. We parse both sides of the training data with the Berkeley parsers (Petrov and Klein, 2007) for Chinese and English. The English side is lowercased after parsing; the Chinese side is segmented beforehand. Unidirectional word alignments are obtained with GIZA++ (Och and Ney, 2003) and symmetrized, resulting in a parallel parsed corpus with Viterbi word alignments for each sentence pair. Our modified version of Thrax takes the parsed and aligned corpus as input and returns a list of rules, which can then be label-collapsed and scored as previously described.

In Thrax, we retain most of the default settings for Hiero- and SAMT-style grammars as specified in the extractor’s configuration file. Inheriting from Hiero, we require the right-hand side of all rules to contain at least one pair of aligned terminals, no more than two nonterminals, and no more than five terminals and nonterminal elements combined. Nonterminals are not allowed to be adjacent on the source side, and they may not contain unaligned boundary words. Rules themselves are not extracted from any span in the training data longer than 10 tokens.

Our initial bilingual SAMT grammar uses 2699 unique source-side labels and 4181 unique target-side labels, leading to the appearance of 29,088 joint

bilingual labels in the rule set. We provide the joint labels (along with their counts) to the label collapsing algorithm, while we strip out the source-side labels to create the baseline SAMT grammar with 4181 unique target-side labels. Table 1 summarizes how the number of target labels, unique extracted rules, and the average number of pruned rules available per sentence change as the initial grammar is label-collapsed to three progressively coarser degrees. Once the collapsing process has occurred exhaustively, the original SAMT grammar becomes a Hiero-format grammar with a single nonterminal.

Each of the five grammars in Table 1 is used to build an MT system. All systems are tuned and decoded with cdec (Dyer et al., 2010), an open-source decoder for SCFG-based MT with arbitrary rule formats and nonterminal labels. We tune the systems on the 1664-sentence NIST Open MT 2006 data set, optimizing towards the BLEU metric. Our test sets are the NIST 2003 data set of 919 sentences and the NIST 2008 data set of 1357 sentences. The tuning set and both test sets all have four English references.

We evaluate systems on BLEU (Papineni et al., 2002), METEOR (Denkowski and Lavie, 2011), and TER (Snover et al., 2006), as calculated in all three cases by MultEval version 0.5.0.¹ These scores for the MT ’03 test set are shown in Table 2, and those for the MT ’08 test set in Table 3, combined by MultEval over three optimization runs on the tuning set.

MultEval also implements statistical significance testing between systems based on multiple optimizer runs and approximate randomization. This process (Clark et al., 2011) randomly swaps outputs between systems and estimates the probability that the observed score difference arose by chance. We report these results in the tables as well for three MERT runs and a p -value of 0.05. Systems that were judged statistically different from the SAMT baseline have triangles in the appropriate “Sig. SAMT?” columns; systems judged different from the Hiero baseline have triangles under the “Sig. Hiero?” columns. An up-triangle (\blacktriangle) indicates that the system was better, while a down-triangle (\triangledown) means that the baseline was better.

5 Analysis

Tables 2 and 3 show that the coarsened grammars significantly improve translation performance over the SAMT baseline. This is especially true for the “Collapse 3” setting of 72 labels, which scores 1.14 BLEU higher on MT ’03 and 1.51 BLEU higher on MT ’08 than the uncollapsed system.

On the easier MT ’03 set, label-collapsed systems do not generally outperform Hiero, although Collapse 3 achieves a statistical tie according to BLEU (+0.02) and a statistical improvement over Hiero according to METEOR (+0.33). MT ’08 appears as a significantly harder test set: metric scores for all systems are drastically lower, and we find approximately 7% to 8% fewer phrase pair matches per sentence. In this case the label-collapsed systems perform better, with all three of them achieving statistical significance over Hiero in at least one metric and statistical ties in the other. The coarsened systems’ comparatively better performance on the harder test set suggests that the linguistic information encoded in multiple-nonterminal grammars helps the systems more accurately parse new types of input.

Table 1 already showed at a global scale the strong effect of label collapsing on reducing derivational ambiguity, as labeled variants of the same basic structural rule were progressively combined. Since category coarsening is purely a relabeling operation, any reordering pattern implemented in the original SAMT grammar still exists in the collapsed versions; therefore, any reduction in the size of the grammar is a reduction in variant labelings. Figure 4 shows this process in more detail for the baseline SAMT grammar and the three collapsed grammars. For each grammar, labels are arranged in decreasing order of extracted frequency, and the frequency count of each label is plotted. The long tail of rare categories in the SAMT grammar (1950 labels seen fewer than 100 times each) is combined into a progressively sharper distribution at each step. Not only are there fewer rare labels, but these hard-to-model categories consume a proportionally smaller fraction of the total label set: from 47% in the baseline grammar down to 26% in Collapse 3.

We find that label collapsing disproportionately affects frequently extracted and hierarchical rules over rarer rules and phrase pairs. The 15.7% re-

duction in total grammar size between the SAMT baseline and the Collapse 3 system affects 18.0% of the hierarchical rules, but only 1.6% of the phrase pairs. If rules are counted separately each time they match another source sentence, the average reduction in size of a sentence-filtered grammar is 57.8%.

Intuitively, hierarchical rules are more affected by label collapsing because phrase pairs do not have many variant left-hand-side labels to begin with, while the same hierarchical rule pattern may be instantiated in the grammar by a large number of variant labelings. We can see this situation in more detail by counting variants of a particular set of rules. Labeled forms of the Hiero-style rule

$$X \rightarrow [X^1 \text{ 的 } X^2] :: [\text{the } X^2 \text{ of } X^1] \quad (6)$$

are among the most frequently used rules in all five of our systems. The way they are treated by label collapsing thus has a strong impact on the results of runtime decoding.

In the SAMT baseline, Rule (6) appears in the grammar with 221 different labels in the X^1 nonterminal slot, 53 labels for the X^2 slot, and 90 choices of left-hand side — a total of 1330 different labelings all together. More than three-fourths of these variants were extracted three times or fewer from the training data; even if they can be used in a test sentence, statistical features for such low-count rules are poorly estimated. During label collapsing, the number of labeled variations of Rule (6) drops from 1330 to 325, to 96, and finally to 63 in the Collapse 3 grammar. There, the pattern is instantiated with 14 possible X^1 labels, five X^2 labels, and three different left-hand sides.

It is difficult to measure rule sparsity directly (i.e. to count the number of rules that are missing during decoding), but a *reduction* in rule sparsity between systems should be manifested as an increased number of hierarchical rule applications. Figure 5 shows the average number of hierarchical rules applied per sentence, distinguishing syntactic rules from glue rules, on both test sets. The collapsed grammars allow for approximately one additional syntactic rule application per sentence compared to the SAMT baseline, or three additional applications compared to Hiero. This shows an implicit reduction in missing syntactic rules in the collapsed grammars. In the

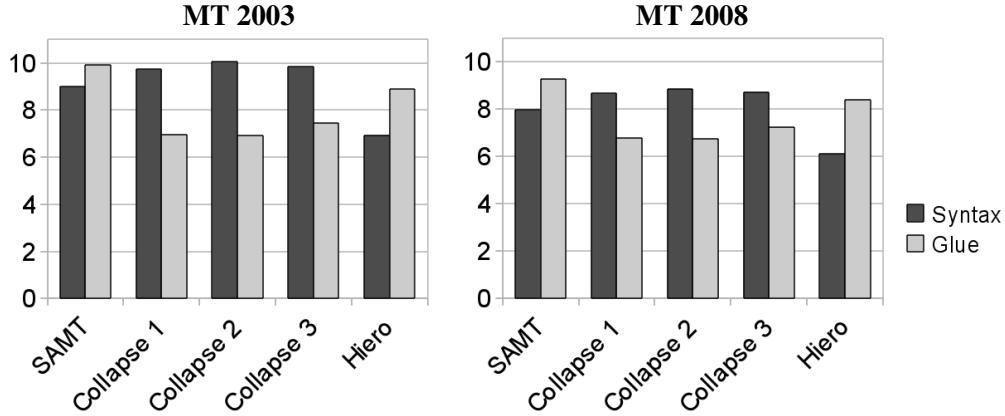

Figure 5: Average number of hierarchical rules (both syntactic and glue rules) applied per sentence on each test set.

glue rule columns, we note that label collapsing also promotes a shift away from generic glue rules, possibly via the creation of more permissive — but still meaningfully labeled — syntactic rules.

6 Conclusion

We demonstrated a viable technique for reducing the label set size in SAMT grammars by temporarily inducing bilingual syntax and using it in an existing tree-to-tree category coarsening algorithm. In collapsing SAMT category labels, we were able to significantly improve translation quality while using a grammar less than half the size of the original. We believe it is also more robust to test-set or domain variation than a single-nonterminal Hiero grammar. Collapsed grammars confer practical benefits during both model estimation and runtime decoding. We showed that, in particular, they suffer less from rule sparsity and derivational ambiguity problems that are common to larger label sets.

We can highlight two areas for potential improvements in future work. In our current implementation of label collapsing, we indiscriminately allow either source labels or target labels to be collapsed at each iteration of the algorithm (see Equation 3). This is an intuitively sensible setting when collapsing bilingual labels, but it is perhaps less obviously so for a monolingually labeled system such as SAMT. An alternative would be to collapse target-side labels only, leaving the source-side labels alone since they do not appear in the final grammar anyway. In this case, the target labels would be represented and clustered as

distributions over a static set of latent categories.

A larger area of future concern is the stopping point of the collapsing algorithm. In our previous work (Hanneman and Lavie, 2011), we manually identified iterations in our run of the algorithm where the L_1 distance between the most recently collapsed label pair was markedly lower than the L_1 difference of the pair in the previous iteration. Such an approach is more feasible in our previous runs of 120 iterations than in ours here of nearly 2100, where it is not likely that three manually chosen stopping points represent the optimal collapsing results. In future work, we plan to work towards the development of an automatic stopping criterion, a more principled test for whether each successive iteration of label collapsing provides some useful benefit to the underlying grammar.

Acknowledgments

This research work was supported in part by computing resources provided by the NSF-sponsored XSEDE program under grant TG-CCR110017. Thanks to Chris Dyer for providing the word-aligned and preprocessed corpus we used in our experiments. We also thank the anonymous reviewers for helpful comments and suggestions for analysis.

Keyphrase Extraction for N-best Reranking in Multi-Sentence Compression

Florian Boudin and Emmanuel Morin

LINA - UMR CNRS 6241, Université de Nantes, France

{florian.boudin, emmanuel.morin}@univ-nantes.fr

Abstract

Multi-Sentence Compression (MSC) is the task of generating a short single sentence summary from a cluster of related sentences. This paper presents an N-best reranking method based on keyphrase extraction. Compression candidates generated by a word graph-based MSC approach are reranked according to the number and relevance of keyphrases they contain. Both manual and automatic evaluations were performed using a dataset made of clusters of newswire sentences. Results show that the proposed method significantly improves the informativity of the generated compressions.

1 Introduction

Multi-Sentence Compression (MSC) can be broadly described as the task of generating a short single sentence summary from a cluster of related sentences. It has recently attracted much attention, mostly because of its relevance to single or multi-document extractive summarization. A standard way to generate summaries consists in ranking sentences by importance, cluster them by similarity and select a sentence from the top ranked clusters (Wang et al., 2008). One difficulty is then to generate concise, non-redundant summaries. Selected sentences almost always contain additional information specific to the documents from which they came, leading to readability issues in the summary.

Sentence Compression (SC), i.e. the task of summarizing a sentence while retaining most of the informational content and remaining grammatical (Jing, 2000), is a straightforward solution to this

problem. Another solution would be to create, for each cluster of related sentences, a concise and fluent fusion of information, reflecting facts common to all sentences. Originally defined as sentence fusion (Barzilay and McKeown, 2005), MSC is a text-to-text generation process in which a novel sentence is produced as a result of summarizing common information across a set of similar sentences.

Most of the previous MSC approaches rely on syntactic parsers for producing grammatical compressions, e.g. (Filippova and Strube, 2008; Elsner and Santhanam, 2011). Recently, (Filippova, 2010) proposed a word graph-based approach which only requires a Part-Of-Speech (POS) tagger and a list of stopwords. The key assumption behind her approach is that redundancy within the set of related sentences provides a reliable way of generating informative and grammatical sentences. Although this approach seemingly works well, 48% to 60% of the generated sentences are missing important information about the set of related sentences. In this study, we aim at producing more informative sentences by maximizing the range of topics they cover.

Keyphrases are words that capture the main topics of a document. Extracting keyphrases can benefit various Natural Language Processing tasks such as summarization, information retrieval and question-answering (Kim et al., 2010). In summarization, keyphrases provide semantic metadata that represent the content of a document. Sentences containing the most relevant keyphrases are used to generate the summary (D’Avanzo and Magnini, 2005). In the same way, we hypothesize that keyphrases can be used to better generate sentences that convey the gist

of the set of related sentences.

In this paper, we present a reranking method of N-best multi-sentence compressions based on keyphrase extraction and describe a series of experiments conducted on a manually constructed evaluation corpus. More precisely, the main contributions of our work are as follows:

- We extend Filippova (2010)’s word graph-based MSC approach to produce well-punctuated and more informative compressions.
- We investigate the use of automatic Machine Translation (MT) and summarization evaluation metrics to evaluate MSC performance.
- We introduce a French evaluation dataset made of 40 sets of related sentences along with reference compressions composed by humans.

The rest of this paper is organized as follows. We first briefly review the previous work, followed by a description of the method we propose. Next, we give the details of the evaluation dataset we have constructed and present our experiments and results. Lastly, we conclude with a discussion and directions for further work.

2 Related work

2.1 Multi-sentence compression

MSC have received much attention recently and many different approaches have been proposed. The pioneering work of (Barzilay and McKeown, 2005) introduced the framework used by many subsequent works: input sentences are represented by dependency trees, some words are aligned to merge the trees into a lattice, and the lattice is linearized using tree traversal to produce fusion sentences. (Filippova and Strube, 2008) cast MSC as an integer linear program, and show promising results for German. Later, (Elsner and Santhanam, 2011) proposed a supervised approach trained on examples of manually fused sentences.

Previously described approaches require the use of a syntactic parser to control the grammaticality of the output. As an alternative, several word graph-based approaches that only require a POS tagger were proposed. The key assumption is

that redundancy provides a reliable way of generating grammatical sentences. First, a directed word graph is constructed from the set of input sentences in which nodes represent unique words, defined as word and POS tuples, and edges express the original structure of sentences (i.e. word ordering). Sentence compressions are obtained by finding commonly used paths in the graph. Word graph-based MSC approaches were used in different tasks, such as guided microblog summarization (Sharifi et al., 2010), opinion summarization (Ganesan et al., 2010) and newswire summarization (Filippova, 2010).

2.2 Keyphrase extraction

Keyphrases are words that are representative of the main content of documents. Extracting keyphrases can benefit various Natural Language Processing tasks such as summarization, information retrieval and question-answering (Kim et al., 2010). Previous works fall into two categories: supervised and unsupervised methods. The idea behind supervised methods is to recast keyphrase extraction as a binary classification task. A model is trained using annotated data to determine whether a given phrase is a keyphrase or not (Frank et al., 1999; Turney, 2000).

Unsupervised approaches proposed so far have involved a number of techniques, including language modeling (Tomokiyo and Hurst, 2003), graph-based ranking (Mihalcea and Tarau, 2004; Wan and Xiao, 2008) and clustering (Liu et al., 2009). While supervised approaches have generally proven more successful, the need for training data and the bias towards the domain on which they are trained remain two critical issues.

3 Method

In this section, we first describe Filippova (2010)’s word graph-based MSC approach. Then, we present the keyphrase extraction approach we use and our method for reranking generated compressions.

3.1 Description of Filippova’s approach

Let $G = (V, E)$ be a directed graph with the set of vertices (nodes) V and a set of directed edges E , where E is a subset of $V \times V$. Given a set of related sentences $S = \{s_1, s_2, \dots, s_n\}$, a word graph is constructed by iteratively adding sentences to it.

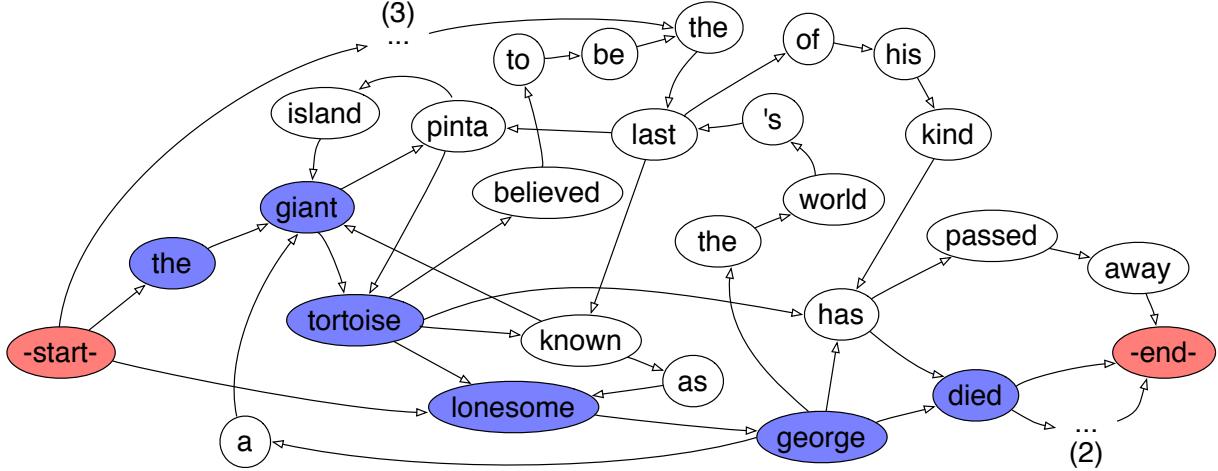

Figure 1: Word graph constructed from the set of related sentences, a possible compression path is also given.

Figure 1 is an illustration of the word graph constructed from the following sentences. For clarity, edge weights are omitted and italicized fragments from the sentences are replaced with dots.

1. Lonesome George, the world's last Pinta Island giant tortoise, has passed away.
2. The giant tortoise known as Lonesome George died *Sunday at the Galapagos National Park in Ecuador*.
3. *He was only about a hundred years old, but* the last known giant Pinta tortoise, Lonesome George, has passed away.
4. Lonesome George, a giant tortoise believed to be the last of his kind, has died.

At the first step, the graph simply represents one sentence plus the start and end symbols (`-start-` and `-end-` in Figure 1). A node is added to G for each word in the sentence, and words adjacent in the sentence are connected with directed edges. A word from the following sentences is mapped onto an existing node in the graph if they have the same lower-cased word form and POS and that no word from this sentence has already been mapped onto this node. A new node is created if there is no suitable candidate in the graph.

Words are added to the graph in the following order:

- i. non-stopwords for which no candidate exists in the graph or for which an unambiguous mapping is possible;
- ii. non-stopwords for which there are either several possible candidates in the graph or which occur more than once in the sentence;
- iii. stopwords.

For the last two groups of words where mapping is ambiguous (i.e. there are two or more nodes in the graph that refer to the same word/POS tuple), the immediate context (the preceding and following words in the sentence and the neighboring nodes in the graph) or the frequency (i.e. the node which has words mapped onto it) are used to select the candidate node. We use the stopword list included in nltk¹ extended with temporal nouns (e.g. monday, yesterday).

In Filippova's approach, punctuation marks are excluded. To generate well-punctuated compressions, we simply added a fourth step for adding punctuation marks in the graph. When mapping is ambiguous, we select the candidate which has the same immediate context.

Once the words from a sentence are added to the graph, words adjacent in the sentence are connected with directed edges. Edge weights are calculated using the weighting function defined in Equation 1.

¹<http://nltk.org/>

$$w(i, j) = \frac{\text{cohesion}(i, j)}{\text{freq}(i) \times \text{freq}(j)} \quad (1)$$

$$\text{cohesion}(i, j) = \frac{\text{freq}(i) + \text{freq}(j)}{\sum_{s \in S} d(s, i, j)^{-1}} \quad (2)$$

where $\text{freq}(i)$ is the number of words mapped to the node i . The function $d(s, i, j)$ refers to the distance between the offset positions of words i and j in sentence s .

The purpose of this function is two fold: i. to generate a grammatical compression, links between words which appear often in this order are favored (see Equation 2); ii. to generate an informative compression, the weight of edges connecting salient nodes is decreased.

A K-shortest paths algorithm is then used to find the 50 shortest paths from start to end nodes in the graph. Paths shorter than eight words or that do not contain a verb are filtered. The remaining paths are reranked by normalizing the total path weight over its length. The path which has the lightest average edge weight is then considered as the best compression.

3.2 Reranking paths using keyphrases

The main difficulty of MSC is to generate sentences that are both informative and grammatically correct. Here, redundancy within the set of input sentences is used to identify important words and salient links between words. Although this approach seemingly works well, important information is missing in 48% to 60% of the generated sentences (Filippova, 2010). One of the reasons for this is that node salience is estimated only with the frequency measure. To tackle this issue, we propose to rerank the N-best list of compressions using keyphrases extracted from the set of related sentences. Intuitively, an informative sentence should contain the most relevant keyphrases. We propose to rerank generated compressions according to the number and relevance of keyphrases they contain.

An unsupervised method based on (Wan and Xiao, 2008) is used to extract keyphrases from each set of related sentences. This method is based on the assumption that a word recommends other co-occurring words, and the strength of the recommen-

dation is recursively computed based on the importance of the words making the recommendation. Keyphrase extraction can be divided into two steps. First, a weighted graph is constructed from the set of related sentences, in which nodes represent words defined as word and POS tuples. Two nodes (words) are connected if their corresponding lexical units co-occur within a sentence. Edge weights are the number of times two words co-occur. TextRank (Mihalcea and Tarau, 2004), a graph-based ranking algorithm that takes into account edge weights, is applied for computing a salience score for each node. The score for node V_i is initialized with a default value and is computed in an iterative manner until convergence using this equation:

$$S(V_i) = (1 - d) + d \times \sum_{V_j \in \text{adj}(V_i)} \frac{w_{ji}}{\sum_{V_k \in \text{adj}(V_i)} w_{jk}} S(V_k)$$

where $\text{adj}(V_i)$ denotes the neighbors of V_i and d is the damping factor set to 0.85.

The second step consists in generating and scoring keyphrase candidates. Sequences of adjacent words satisfying a specific syntactic pattern are collapsed into multi-word phrases. We use $(\text{ADJ})^* (\text{NPP}|\text{NC}) + (\text{ADJ})^*$ for French, in which ADJ are adjectives, NPP are proper nouns and NC are common nouns.

The score of a candidate keyphrase k is computed by summing the salience scores of the words it contains normalized by its length + 1 to favor longer n-grams (see equation 3).

$$\text{score}(k) = \frac{\sum_{w \in k} \text{TextRank}(w)}{\text{length}(k) + 1} \quad (3)$$

The small vocabulary size as well as the high redundancy within the set of related sentences are two factors that make keyphrase extraction easier to achieve. On the other hand, a large number of the generated keyphrases are redundant. Some keyphrases may be contained within larger ones, e.g. *giant tortoise* and *Pinta Island giant tortoise*. To solve this problem, generated keyphrases are clustered using word overlap. For each cluster, we then select the keyphrase with the highest score. This filtering process enables the generation of a smaller subset of keyphrases while having a better coverage of the cluster content.

Reranking techniques can suffer from the limited scope of the N-best list, which may rule out many potentially good candidates. For this reason, we use a larger number of paths than the one in (Filippova, 2010). Accordingly, the K-shortest paths algorithm is used to find the 200 shortest paths. We rerank the paths by normalizing the total path weight over its length multiplied by the sum of keyphrase scores it contains. The score of a sentence compression c is given by:

$$\text{score}(c) = \frac{\sum_{i,j \in \text{path}(c)} w_{(i,j)}}{\text{length}(c) \times \sum_{k \in c} \text{score}(k)} \quad (4)$$

4 Experimental settings

4.1 Construction of the evaluation dataset

To our knowledge, there is no dataset available to evaluate MSC in an automatic way. The performance of the previously described approaches was assessed by human judges. In this work, we introduce a new evaluation dataset made of 40 sets of related sentences along with reference compressions composed by human assessors. The purpose of this dataset is to investigate the use of existing automatic evaluation metrics for the MSC task.

Similar to (Filippova, 2010), we collected news articles presented in clusters on the French edition of Google News² over a period of three months. Clusters composed of at least 20 news articles and containing one single prevailing event were manually selected. To obtain the sets of related sentences, we extracted the first sentences from each article in the cluster, removing duplicates. Leading sentences in news articles are known to provide a good summary of the article content and are used as a baseline in summarization (Dang, 2005).

The resulting dataset contains 618 sentences (33 tokens on average) spread over 40 clusters. The number of sentences within each cluster is on average 15, with a minimum of 7 and a maximum of 36. The word redundancy rate within the dataset, computed as the number of unique words over the number of words for each cluster, is 38.8%.

Three reference compressions were manually composed for each set of sentences. Human annotators, all native French speakers, were asked to

²<http://news.google.fr>

carefully read the set of sentences, extract the most salient facts and generate a sentence (compression) that summarize the set of sentences. Annotators were also told to introduce as little new vocabulary as possible in their compressions. The purpose of this guideline is to reduce the number of possible mismatches, as existing evaluation metrics are based on n-gram comparison. Reference compressions have a compression rate of 60%.

4.2 Automatic evaluation

The use of automatic methods for evaluating machine-generated text has gradually become the mainstream in Computational Linguistics. Well known examples are the ROUGE (Lin, 2004) and BLEU (Papineni et al., 2002) evaluation metrics used in the summarization and MT communities. These metrics assess the quality of a system output by computing its similarity to one or more human-generated references.

Prior work in sentence compression use the F1 measure over grammatical relations to evaluate candidate compressions (Riezler et al., 2003). It was shown to correlate significantly with human judgments (Clarke and Lapata, 2006) and behave similarly to BLEU (Unno et al., 2006). However, this metric is not entirely reliable as it depends on parser accuracy and the type of dependency relations used (Napoles et al., 2011). In this work, the following evaluation measures are considered relevant: BLEU³, ROUGE-1 (unigrams), ROUGE-2 (bigrams) and ROUGE-SU4 (bigrams with skip distance up to 4 words)⁴. ROUGE measures are computed using stopword removal and French stemming⁵.

4.3 Manual evaluation

The quality of the generated compressions was assessed in an experiment with human raters. Two aspects were considered: grammaticality and informativity. Following previous work (Barzilay and McKeown, 2005), we asked raters to assess grammaticality on a 3-points scale: *perfect* (2 pts), if the compression is a complete grammatical sentence; *almost*

³<ftp://jaguar.ncsl.nist.gov/mt/resources/mteval-v13a.pl>

⁴We use the version 1.5.5 of the ROUGE package available from <http://www.berouge.com>

⁵<http://snowball.tartarus.org/>

(1 pt), if it requires minor editing, e.g. one mistake in articles, agreement or punctuation; *ungrammatical* (0 pts), if it is none of the above. Raters were explicitly asked to ignore lack of capitalization while evaluating grammaticality.

Informativity is evaluated according to the 3-points scale defined in (Filippova, 2010): *perfect* (2 pts), if the compression conveys the gist of the main event and is more or less like the summary the person would produce himself; *related* (1 pt), if it is related to the the main theme but misses something important; *unrelated* (0 pts), if the compression is not related to the main theme.

Three raters, all native French speakers, were hired to assess the generated compressions.

5 Results

To evaluate the effectiveness of our method, we compare the compressions generated with Filippova’s approach (denoted as baseline) against the ones obtained by reranking paths using keyphrases (denoted as KeyRank). We evaluated the agreement between the three raters using Fleiss’s kappa (Artstein and Poesio, 2008). The κ value is 0.56 which denotes a moderate agreement.

Table 1 presents the average grammaticality and informativity scores. Results achieved by the baseline are consistent with the ones presented in (Filippova, 2010). We observe a significant improvement in informativity for KeyRank. Grammaticality scores are, however, slightly decreased. One reason for that is the reranking we added to the shortest path method that outputs longer compressions. The average length for our method is nevertheless drastically shorter than the average length of the input sentences (19 vs. 33 tokens). This corresponds to a compression rate (58%) that is close to the one observed on reference compressions (60%).

Table 2 shows the distributions over the three scores for both grammaticality and informativity. We observe that 97.5% of the compressions generated with KeyRank are related to the main theme of the cluster, and 62.5% convey the very gist of it without missing any important information. This represents an absolute increase of 19.2% over the baseline. Although our reranking method has lower grammaticality scores, 65% of the generated sen-

Method	Gram.	Info.	Length		CompR
			Avg.	Std.Dev.	
Baseline	1.63	1.33	16.3	4.8	50%
KeyRank	1.53	1.60 [†]	19	6.1	58%

Table 1: Average ratings over all clusters and raters along with average compression length (in tokens), standard deviation and corresponding compression rate ([†] indicates significance at the 0.01 level using Student’s t-test).

tences are perfectly grammatical.

Method	Gram.			Info.		
	0	1	2	0	1	2
Baseline	9.2%	18.3%	72.5%	10.0%	46.7%	43.3%
KeyRank	11.7%	23.3%	65.0%	2.5%	35.0%	62.5%

Table 2: Distribution over possible manual ratings for grammaticality and informativity. Ratings are expressed on a scale of 0 to 2.

Table 3 shows the performance of the baseline and our reranking method in terms of ROUGE and BLEU scores. KeyRank significantly outperforms the baseline according to the different ROUGE metrics. This indicates an improvement in informativity for the compressions generated using our method. We observe a large but not significant increase in BLEU scores. The slightly decreased grammaticality scores could be a reason for this. BLEU is essentially a precision metric, and it measures how well a compression candidate overlaps with multiple references. Longer n-grams used by BLEU⁶ tend to score for grammaticality rather than content.

Metric	Baseline	KeyRank
ROUGE-1	0.57441	0.65677 [‡]
ROUGE-2	0.39212	0.44140 [†]
ROUGE-SU4	0.37004	0.43443 [‡]
BLEU	0.61560	0.65770

Table 3: Automatic evaluation scores ([†] and [‡] indicate significance at the 0.01 and 0.001 levels respectively using Student’s t-test)

To assess the effectiveness of automatic evalua-

⁶BLEU measures are computed using 4-grams.

tion metrics, we compute the Pearson’s correlation coefficient between ROUGE and BLEU scores and averaged manual ratings. According to Table 4, results show medium to strong correlation between ROUGE scores and informativity ratings. On the other hand, BLEU scores better correlate with grammaticality ratings. Overall, automatic evaluation metrics are not highly correlated with manual ratings. One reason for that may be that the manual score assignments are arbitrary (i.e. 0, 1, 2), and that a score of one is in fact closer to two than to zero. Results suggest that automatic metrics do give an indication of the compression quality, but can not replace manual evaluation.

Metric	Gram.	Info.
ROUGE-1	0.402	0.591
ROUGE-2	0.432	0.494
ROUGE-SU4	0.386	0.542
BLEU	0.444	0.401

Table 4: Pearson correlation coefficients for automatic metrics vs. average human ratings.

6 Conclusion

This paper presented a multi-sentence compression approach that uses keyphrases to generate more informative compressions. We extended Filippova (2010)’s word graph-based MSC approach by adding a re-ranking step that favors compressions that contain the most relevant keyphrases of the input sentence set. An implementation of the proposed multi-sentence compression approach is available for download⁷. We constructed an evaluation dataset made of 40 sets of related sentences along with reference compressions composed by humans. This dataset is freely available for download⁸. We performed both manual and automatic evaluations and showed that our method significantly improves the informativity of the generated compressions. We also investigated the correlation between manual and automatic evaluation metrics and found that ROUGE and BLEU have a medium correlation with manual ratings.

⁷<https://github.com/boudinfl/takahe>

⁸<https://github.com/boudinfl/lina-msc>

In future work, we intend to examine how grammaticality of the generated compressions can be enhanced. Similar to the work of Hasan et al. (2006) in the Machine Translation field, we plan to experiment with high order POS language models reranking.

Abstract

This paper describes the annotation process and linguistic properties of the Persian syntactic dependency treebank. The treebank consists of approximately 30,000 sentences annotated with syntactic roles in addition to morpho-syntactic features. One of the unique features of this treebank is that there are almost 4800 distinct verb lemmas in its sentences making it a valuable resource for educational goals. The treebank is constructed with a bootstrapping approach by means of available tagging and parsing tools and manually correcting the annotations. The data is splitted into standard train, development and test set in the CoNLL dependency format and is freely available to researchers.

1 Introduction¹

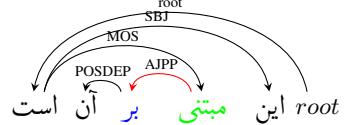

The process of manually annotating linguistic data from a huge amount of naturally occurring texts is a very expensive and time consuming task. Due to the recent success of machine learning methods and the rapid growth of available electronic texts, language processing tasks have been facilitated greatly. Considering the value of annotated data, a great deal of budget has been allotted to creating such data.

Among all linguistic datasets, treebanks play an important role in the natural language processing tasks especially in parsing because of its applica-

tions in tasks such as machine translation. Dependency treebanks are collections of sentences with their corresponding dependency trees. In the last decade, many dependency treebanks have been developed for a large number of languages. There are at least 29 languages for which at least one dependency treebank is available (Zeman et al., 2012). Dependency trees are much more similar to the human understanding of language and can easily represent the free word-order nature of syntactic roles in sentences (Kübler et al., 2009).

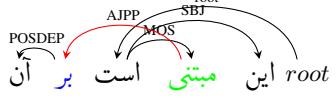

Persian is a language with about 110 million speakers all over the world (Windfuhr, 2009), yet in terms of the availability of teaching materials and annotated data for text processing, it is undoubtedly a low-resourced language. The need for more language teaching materials together with an ever-increasing need for Persian-language data processing has been the incentive for the inception of our project which has defined the development of the syntactic treebank of Persian as its ultimate aim. In this paper, we review the process of creating the Persian syntactic treebank based on dependency grammar. In this treebank, approximately 30,000 sentences from contemporary Persian-language texts are manually tokenized and annotated at morphological and syntactic levels. One valuable aspect of the treebank is its containment of near 5000 distinct verb lemmas in its sentences making it a good resource for educational goals. The dataset is developed after the creation of the syntactic valency lexicon of Persian verbs (Rasooli et al., 2011c). This treebank is developed with a bootstrapping approach by automatically building dependency trees based on the

(b) A simple non-projective dependency tree for a Persian sentence: “It is based on that”.

Figure 1: Examples of Persian sentences with the dependency-based syntactic trees. 1(a) and 1(b) are examples of a projective and a non-projective dependency tree, respectively. The first lines show the original words in Persian. The pronunciation and their meanings are shown in the second line and the third line respectively. In the fourth line, the part of speech (POS) tags of the words are presented. Note that the words are written from right to left (the direction of Perso-Arabic script). The dependency relations are described in Table 2. The relation is shown with an arc pointing from the head to the dependent.

previous annotated trees. In the next step, automatic annotation is corrected manually.

The remainder of this paper is as follows. In Section 2, we briefly review the challenges in Persian language processing. In Sections 3 and 4, the details about the annotation process, linguistic and statistical information about the data and the annotator agreement are reported. In Section 5, the conclusion and suggestions for future research are presented.

2 Persian Language Processing Challenges

Persian is an Indo-European language that is written in Arabic script. There are lots of problems in its orthography such as encoding problems, hidden diacritics and writing standards (Kashefi et al., 2010). A number of challenges such as the free or-

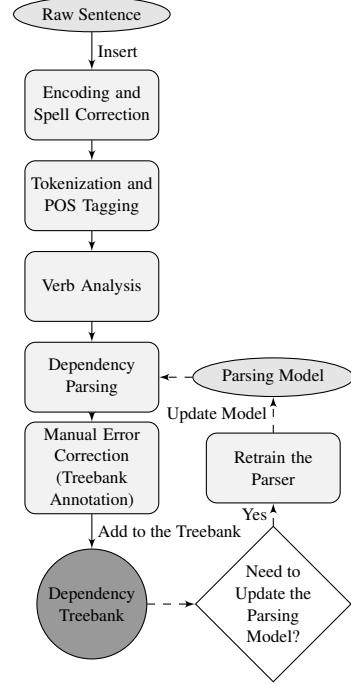

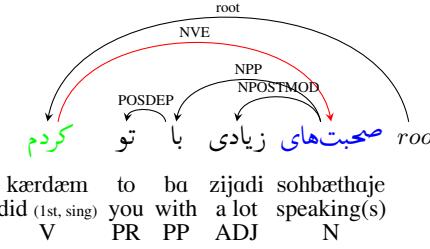

Figure 2: Diagram of bootstrapping approach in the development of the dependency treebank.

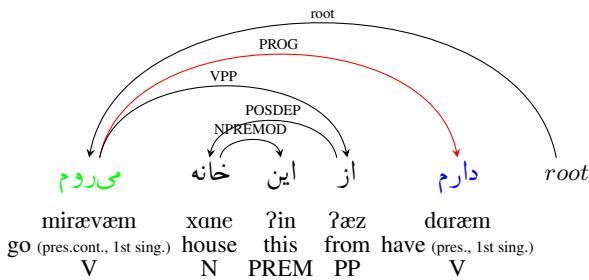

der of words, the existence of colloquial texts, the pro-drop nature of the Persian language and its complex inflections (Shamsfard, 2011) in addition to the lack of efficient annotated linguistic data have made the processing of Persian texts very difficult; e.g. there are more than 100 conjugates and 2800 declensions for some word forms in Persian (Rasooli et al., 2011b), some words in the Persian language do not have a clear word category (i.e. the lexical category “mismatch”) (Karimi-Doostan, 2011a) and many compound verbs (complex predicates) can be separable (i.e. the non-verbal element may be separated from the verbal element by one or more other words) (Karimi-Doostan, 2011b).

After the development of the Bijankhan corpus (Bijankhan, 2004) with the annotation of word categories, other kinds of datasets have been created to address the need for Persian language processing. Among them, a Persian parser based on link grammar (Dehdari and Lonsdale, 2008), a computational grammar based on GPSG (Bahrani et al., 2011), syntactic treebank based on HPSG (Ghayoomi, 2012) and Uppsala dependency treebank (Seraji et al., 2012) are the efforts to satisfy the need for

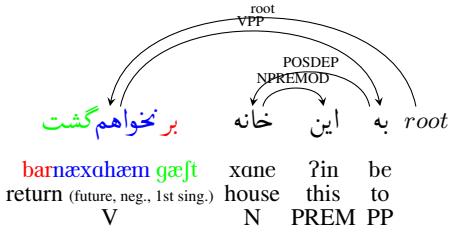

syntactic processing in the Persian language.

(a) A simple dependency tree with compound verb for a Persian sentence: "I spoke with you a lot". The *NVE* is a relation between a light verb and its nonverbal element. As shown in the tree, not only the nonverbal element is not near the light verb, but also it is inflected for plurality (i.e. speakings).

(b) A simple dependency tree for a Persian sentence with a progressive auxiliary: "I am going from this house". The *PROG* is a relation between a verb and its progressive auxiliary.

(c) A simple dependency tree for a Persian sentence with a an inflected form of a prefixed verb "I will not return to this house.". The word *بر* is the prefix, the word *نخواهم* is the auxiliary for the future and the word *گشت* is the main verb. Notice that the prefix is attached to the auxiliary without any space and the remaining part of the verb is separated by a space.

Figure 3: Examples of Persian sentences with the dependency-based syntactic trees. The format of the representation is the same as Figure 1.

3 Persian Dependency Treebank

3.1 Motivation

With the creation of the Virastyar spell checker software (Kashefi et al., 2010), many open-source libraries were released for Persian word processing such as POS tagging, encoding refinement, tokenization, etc. Regarding the need for syntactic analysis of Persian texts, we decided to prepare a valuable linguistic data infrastructure for Persian syntax. In the first step, there was a need for choosing from the existing theories of grammar that best suits Persian. Among grammatical theories, we decided to choose the dependency grammar. In dependency grammar, syntactic relations are shown with dependencies between the words. In computational dependency grammar, each word has one head and the head of the sentence is the dependent of an artificial root word (Kübler et al., 2009). A sample dependency tree is shown in Figure 1(a) for a Persian sentence. Note that Persian sentences are written from right to left.

There are several reasons for the preference of dependency grammar to grammars such as phrase-based structure grammars. Although in both of the representations, one can show the syntactic analysis of a sentence, dependency representation has the power to account for the free word order of many languages such as Turkish (Oflazer et al., 2003) and Czech (Hajic, 1998) and also Persian. As an example, a sample non-projective dependency tree for the Persian language is shown in Figure 1(b). The recent advances in very fast dependency parsing models (e.g. (Nivre, 2009; Bohnet and Nivre, 2012)), has made the syntactic processing task very popular in the recent decade.

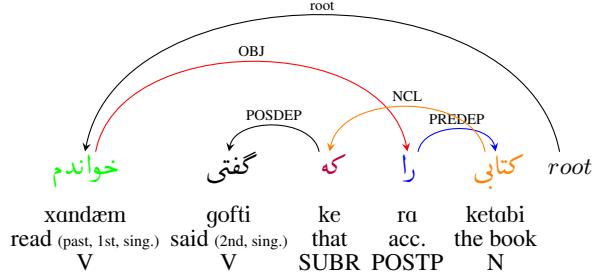

In the Persian language, in addition to the abundance of crossings of the arcs, another problem occurs with compound verbs and verbs in the progressive aspect: compound and progressive verbs are multi-word expressions that may be separated depending on the context. Persian compound verbs consist of a light verb and a non-verbal element and the non-verbal element can be a noun, an adjective (in rare cases) or a sequence of a preposition and a noun (Dabir-Moghaddam, 1997). In addition, the nonverbal elements can also be inflected. The distance between the nonverbal element and the light

verb on the one hand and the possibility of the non-verbal element being inflected on the other hand have made the task of compound verb identification very difficult. For example, in Bijankhan (Peykare) corpus (Bijankhan et al., 2011), approximately 9% of nonverbal elements of compound verbs are placed away from the light verb for the compound verbs with the light verb کردن /kærdaen/ (to do) (Rasooli et al., 2011a). A group of Persian progressive verbs are composed of two words, the first being the simple past or the simple present form derived from the infinitive داشتن /daftæn/ (to have) and the second being the past continuous or the present continuous form of the main verb. The first verb (an auxiliary) agrees with the second in number and person. The problem is that the progressive auxiliary can be away from the main verb. The sample trees with compound verbs and progressive auxiliary verbs are shown in Figures 3(a) and 3(b) respectively.

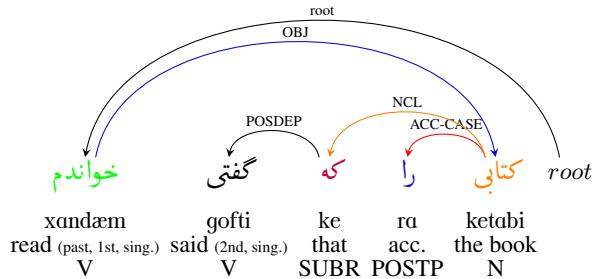

3.2 Representation and Dependency Relation

In this treebank, we followed the format of the CoNLL tab-separated format for dependency parsing (Buchholz and Marsi, 2006). In addition to the lemma, we annotated part of speech tags (both coarse and fine grained) and person, number and tense-mood-aspect (only for verbs) of words in sentences. The details of the part of speech tags and other morphosyntactic features and dependency relations are shown in Tables 1 and 2, respectively. The part of speech tag set in this treebank is not the same as that of Bijankhan (Peykare) corpus (Bijankhan et al., 2011) and it is essential to convert the tagset in Peykare corpus to the tagset in this treebank, in order to use both datasets². We also tried to use the writing standard of the Academy of Persian Language and Literature except for the cases where for a word there were several standards all of which were used in Persian written texts (e.g. آنچه /?antse/ and آنچه /?antse/ (whatever)).

We also prepared two representations for objects accompanied by the accusative case marker. In the first representation (done manually), we assume the accusative case marker را /ra/ as the head of the two-

(a) “I read the book that you mentioned.”

(b) “I read the book that you mentioned.”

Figure 4: A sample sentence with two kinds of representations of object-verb relation. The first one is done manually and the second automatically by converting the dependencies in the first representation.

word sequence object plus ra. The second representation, that is the automatic conversion of the first, is the reverse order of the first one in which the accusative case marker is the dependent of the direct object and the direct object is considered as the head of the aforementioned sequence. In the first representation, objects are much easier to find by the parser (because of the uniqueness of the accusative case marker in Persian and less distance of it from the verb as its head) but it may increase the number of non-projective arcs to the syntactic tree. We prepared both of the representations in two separate data packs. A sample comparison between the two structures is shown in Figure 4.

In the treebank, all words are single word forms (without spaces). There is only one exception for simple verb inflections where even multi-word tokens of simple verbs are shown as only one unit. The reason is that for many cases such as the case of inflections for prefixed verbs it is more straightforward to analyze the whole part instead of analyzing each

²It is important to note that the conversion between the coarse-grained POS tags is straightforward and does not need any special effort.

Morphosyntactic features in the Persian dependency treebank				
CPOS	FPOS	Person	Number	TMA
ADJ (adjective)	AJP (positive) AJCM (comparative) AJSUP (superlative)			
ADR (address term)	PRADR (pre-noun) POSADR (post-noun)			
ADV (adverb)	SADV (genuine)			
CONJ (coordinating conjunction)	CONJ (conjunction)			
IDEN (title)	IDEN (title)			
N (noun)	ANM (animate) IANM (inanimate)		SING (singular) PLUR (plural)	
PART (particle)	PART (particle)			
POSDNUM (post-noun modifier)	POSDNUM (post-noun modifier)			
POSTP (postposition)	POSTP (postposition)			
PR (pronoun)	SEPER (separate personal) JOPER (enclitic personal) DEMON (demonstrative) INTG (interrogative) CREFX (common reflexive) UCREFX (noncommon reflexive) RECPR (reciprocal)	1 2 3	SING (singular) PLUR (plural)	
PREM (pre-modifier)	EXAJ (exclamatory) QUAJ (interrogative) DEMAJ (demonstrative) AMBAJ (ambiguous)			
PRENUM (pre-noun numeral)	PRENUM (pre-noun numeral)			
PREP (preposition)	PREP (preposition)			
PSUS (pseudo-sentence)	PSUS (pseudo-sentence)			
PUNC (punctuation)	PUNC (punctuation)			
V (verb)	ACT (active) PAS (passive) MOD (modal)	1 2 3	SING (singular) PLUR (plural)	See Table 3
SUBR (subordinating clause)	SUBR (subordinating clause)			

Table 1: Morphosyntactic features in the Persian dependency treebank. Empty cells indicate that the mentioned feature is not present for the POS. *TMA* stands for *Tense/Mood/Aspect*, *CPOS* for *Coarse grained POS* and *FPOS* for *Fine grained POS*. There is also another feature for representing the typographical connectedness of words that are separated into two or more tokens with the values ISO (isolated word), NXT (attached to the next token) and PRV (attached to the previous token).

part separately³. In Table 3, possible types of the Persian verb inflections are shown. As seen in Table 3, 6 forms of 14 inflection types of Persian verbs are multi-word tokens and for passive verbs they may be composed of more words than their active counterparts (since for passive verbs an auxiliary form derived from the infinitive شدن /ʃdæn/ is used). In Figure 3(c), a sample tree with a multi-token pre-

fixed verb is shown. As shown in the case of colored tokens, it seems more beneficial to put all morphemes of the word together before parsing. Furthermore, with the available Persian verb analyzer it is very easy to first preprocess the verbs⁴.

³In (Seraji et al., 2012), multi-token verbs are considered as separate words.

⁴If it is needed to respect the exact format of CoNLL, spaces between the verb tokens should be replaced by a character such as underscore. Regarding the special fine-grained morphological tags for the verb such as tense-mood-aspect, it is also straightforward to separate all of the multi-word verbs and add new dependency relations between their words.

Abbreviation	Description	Abbreviation	Description
ACL	Complement Clause of Adjective	ADV	Adverb
ADVC	Adverbial Complement of Verb	AJCONJ	Conjunction of Adjective
AJPP	Prepositional Complement of Adjective	AJUCL	Adjunct Clause

3.3 Annotation Process

The annotation process consists of several consecutive steps. In Figure 2, a summary of the bootstrapping approach in the annotation process is shown. At first, a collection of independent sentences have

been collected randomly from the web. For the first 5000 sentences, we crawled Persian news texts and randomly sampled the sentences. For the remaining sentences, we first listed the absent verb lemmas in the 5000 sentences based on the verb list ex-

tracted from the valency lexicon of Persian verbs (Rasooli et al., 2011c) and collected random sentences that included the absent verb lemmas in their words. We listed all possible inflections and per each verb lemma, sampled at most 8 sentences from the web. These sentences had to contain at least one present tense, one past tense, one passive voice and one future tense inflection unless we could not find them and were obliged to reduce the number. The sentences were not shortened and were kept with their original length and words. Finally, we manually removed sentences containing colloquial words. However, we did not remove loan words or cases of code-switching between latin-script words and Persian words in the sentences. The raw sentences were fed to the encoding and spell checking module. After spell correction, all sentences were tokenized and tagged with part of speech tags. All of the word processing steps were done using Virastyr library (Kashefi et al., 2010). After tokenization and POS tagging, the tokenized sentences were fed to the Persian verb analyzing tool (Rasooli et al., 2011a). In the next step, the preprocessed sentences were given to the dependency parser. We used MST parser (McDonald et al., 2005) for parsing the sentences.

In the final step, annotators corrected the errors of tokenization, POS tagging and parsing. In about every one to two weeks, the parser model was updated by training on the new version of the treebank. This process lasted 9 months and the number of annotators increased by time to speed up the process. In the first 6 months, we used 8 annotators and for the next 5 months, we hired 6 more annotators to speed up the process. The annotators and linguistic experts consisted of 1 PhD graduate (linguistics), 4 PhD candidates (linguistics), and 9 MA graduates or graduate students (7 linguistics, 1 Persian language and literature and 1 computational linguistics). All of the annotators were native Persian speakers.

After finalizing the annotation of all raw sentences, we applied a rule-based potential error finder to find the potentially erroneous sentences. The rules were gradually collected in the process of the annotation by the annotators. All the potentially erroneous sentences were given to the annotators to be checked for potential errors. In Section 4.1, the statistics about the changes after the correction is reported. One of the main reasons for the double

checking phase in the process is that based on our manual investigations of the annotations, we found some inevitable mistakes by annotators that could be solved by manual rules. Mistakes such as scrolling the drop-down list unintentionally and changing the part of speech tag or dependency relation and mistakes caused by tiredness and lack of concentration in addition to some of the changes of the linguistic conventions in the annotation. Since all cases of dependency relations in this treebank may be usually either a left-branching relation or a right-branching one and most of the relations are restricted to certain types of parts of speech, it is easy to capture the potential errors in the annotations based on the rules mentioned and to keep track of the changes in the linguistic conventions by searching the cues for those conventions (most of the changed conventions were made to very rare relations in the syntactic structure).

In (Dligach and Palmer, 2011), it is concluded that although doubly annotated corpora are more reliable, annotating more sentences only once is more beneficial; i.e. annotating each sentence only once is less time-consuming and more cost-effective. We annotated all the sentences only once (with an additional checking phase) except for the 5% of the sentences in order to estimate the quality of our linguistic conventions and agreement among the annotators. The statistics about the annotators agreement is reported in Section 4.1.

4 Statistics of the Treebank

Finally, 29,982 sentences were manually annotated. The details about the statistics is shown in Table 4. It is worth mentioning that 39.24% of the words in the treebank are tagged as noun, 12.62% as verb, 11.64% as preposition and 7.39% as adjective. The most frequent dependency relations are post-dependent (15.08%) and Ezafeh construction (10.17%). As shown in Table 5, the number of non-projective arcs in the second representation is a little bit less than the first. As mentioned earlier, the main reason is the dependencies between the direct object and words after the accusative case marker such as the example in Figure 4. The change percentage after the correction of the potential errors is shown in Table 6. It seems that the rules for finding the poten-

Number of Sentences	29,982

tial errors were useful for correcting the errors.

4.1 Annotators Agreement

The statistics about the agreement among the annotators is shown in Table 7. We can also use the Kappa (Cohen, 1960) to measure the quality of the annotation based on the agreement among the annotators ($pr(a)$ in Eq. 1) and the expected agreement or probability of chance ($pr(e)$ in Eq. 1). If we consider the accuracy of the parser on the raw text without gold POS tags (approximately 75% labeled and 80% unlabeled accuracy based on our experience during the bootstrapping) and the POS tagger that we used during the annotation process (approximately 94%) as the probability of chance, we see that for all of the tasks in Table 7, the quality of the annotation is more than 0.81 and is considered as almost perfect according to (Landis and Koch, 1977).

$$k = \frac{pr(a) - pr(e)}{1 - pr(e)} \quad (1)$$

5 Conclusion

As mentioned earlier, Persian is a language with its own challenges. We tried to overcome some of those challenges by preparing valuable linguistic

datasets⁵. In addition to the preparation of the treebank, we prepared some useful desktop and web-based tools for searching in the dataset, obtaining statistics and viewing syntactic structures graphically. We hope to report more details about the linguistic aspects and the findings of the project in addition to our detailed experiments on the parsing task in future publications. We believe that this treebank is just the very first step to satisfy the need for Persian language processing. Our future aim is to add a semantic level to the annotation.

Acknowledgments

The project is funded by Iran Supreme Council of Information and Communication Technology (SCICT). We really appreciate the linguists who helped us in annotating: Farzaneh Bakhtiary, Parinaz Dadras, Maryam Faal-Hamedanchi, Saeedeh Ghadrdoost-Nakhchi, Mostafa Mahdavi, Azadeh Mirzaei, Sahar Oulapoor, Neda Poormorteza-Khameneh, Morteza Rezaei-Sharifabadi, Sude Resalatpoo, Akram Shafie, and Salimeh Zamani; and the programmers who helped us in the process of the development of the treebank: Seyed Mahdi Hoseini, Alireza Noorian, Yasser Souris, and Mohsen Hosseini-Alizadeh; and also our colleagues who helped us find linguistic sources from the web: Azadeh Abbasi Abyaneh, Shima Zamanpoor, Narmin Ghaderi, Houra Nouri and Seyedeh Maneli Hashemian; and other colleagues especially Mahdi Behniafar. We thank Nizar Habash for his support of this paper and Weiwei Guo and three anonymous reviewers for their useful comments on the paper.

⁵A comprehensive description of the syntactic relations and morphosyntactic features is reported in the treebank official report (Dadegan Research Group, 2012) in the treebank package both in Persian and English.

Abstract

Recent work has shown that word aligned data can be used to learn a model for reordering source sentences to match the target order. This model learns the cost of putting a word immediately before another word and finds the best reordering by solving an instance of the Traveling Salesman Problem (TSP). However, for efficiently solving the TSP, the model is restricted to pairwise features which examine only a pair of words and their neighborhood. In this work, we go beyond these pairwise features and learn a model to rerank the n -best reorderings produced by the TSP model using higher order and structural features which help in capturing longer range dependencies. In addition to using a more informative set of source side features, we also capture target side features indirectly by using the translation score assigned to a reordering. Our experiments, involving Urdu-English, show that the proposed approach outperforms a state-of-the-art PBSMT system which uses the TSP model for reordering by 1.3 BLEU points, and a publicly available state-of-the-art MT system, Hiero, by 3 BLEU points.

1 Introduction

Handling the differences in word orders between pairs of languages is crucial in producing good machine translation. This is especially true for language pairs such as Urdu-English which have significantly different sentence structures. For example, the typical word order in Urdu is Subject Object Verb whereas the typical word order in English is Subject Verb Object. Phrase based systems (Koehn et al., 2003) rely on a lexicalized distortion model

(Al-Onaizan and Papineni, 2006; Tillman, 2004) and the target language model to produce output words in the correct order. This is known to be inadequate when the languages are very different in terms of word order (refer to Table 3 in Section 3).

Pre-ordering source sentences while training and testing has become a popular approach in overcoming the word ordering challenge. Most techniques for pre-ordering (Collins et al., 2005; Wang et al., 2007; Ramanathan et al., 2009) depend on a high quality source language parser, which means these methods work only if the source language has a parser (this rules out many languages). Recent work (Visweswarah et al., 2011) has shown that it is possible to learn a reordering model from a relatively small number of hand aligned sentences. This eliminates the need of a source or target parser.

In this work, we build upon the work of Visweswarah et al. (2011) which solves the reordering problem by treating it as an instance of the Traveling Salesman Problem (TSP). They learn a model which assigns costs to all pairs of words in a sentence, where the cost represents the penalty of putting a word immediately preceding another word. The best permutation is found via the chained Lin-Kernighan heuristic for solving a TSP. Since this model relies on solving a TSP efficiently, it cannot capture features other than pairwise features that examine the words and neighborhood for each pair of words in the source sentence. In the remainder of this paper we refer to this model as the TSP model.

Our aim is to go beyond this limitation of the TSP model and use a richer set of features instead of using pairwise features only. In particular, we are interested in features that allow us to examine triples of words/POS tags in the candidate reordering per-

mation (this is akin to going from bigram to trigram language models), and also structural features that allow us to examine the properties of the segmentation induced by the candidate permutation. To go beyond the set of features incorporated by the TSP model, we do not solve the search problem which would be NP-hard. Instead, we restrict ourselves to an n -best list produced by the base TSP model and then search in that list. Using a richer set of features, we learn a model to rerank these n -best reorderings. The parameters of the model are learned using the averaged perceptron algorithm. In addition to using a richer set of source side features we also indirectly capture target side features by interpolating the score assigned by our model with the score assigned by the decoder of a MT system.

To justify the use of these informative features, we point to the example in Table 1. Here, the head (*driver*) of the underlined English Noun Phrase (*The driver of the car*) appears to the left of the Noun Phrase whereas the head (*chaalak {driver}*) of the corresponding Urdu Noun Phrase (*gaadi {car} ka {of} chaalak {driver}*) appears to the right of the Noun Phrase. To produce the correct reordering of the source Urdu sentence the model has to make an unusual choice of putting *gaadi {car}* before *bola {said}*. We say this is an unusual choice because the model examines only pairwise features and it is unlikely that it would have seen sentences having the bigram “*car said*”. If the exact segmentation of the source sentence was known, then the model could have used the information that the word *gaadi {car}* appears in a segment whose head is the noun *chaalak {driver}* and hence its not unusual to put *gaadi {car}* before *bola {said}* (because the construct “*NP said*” is not unusual). However, since the segmentation of the source sentence is not known in advance, we use a heuristic (explained later) to find the segmentation induced by a reordering. We then extract features (such as *first_word_current_segment*, *end_word_current_segment*) to approximate these long range dependencies.

Using this richer set of features with Urdu-English as the source language pair, our approach outperforms the following state of the art systems: (i) a PBSMT system which uses TSP model for reordering (by 1.3 BLEU points), (ii) a hierarchical PBSMT system (by 3 BLEU points). The overall

<i>Input Urdu:</i>	fir <u>gaadi</u> ka <u>chaalak</u> kuch bola
<i>Gloss:</i>	then <u>car</u> of <u>driver</u> said something
<i>English:</i>	Then <u>the driver of the car</u> said something.
<i>Ref. reordering:</i>	fir <u>chaalak</u> <u>ka gaadi</u> bola kuch

Table 1: Example motivating the use of structural features

gain is 6.3 BLEU points when compared to a standard PBSMT system which uses a lexicalized distortion model (Al-Onaizan and Papineni, 2006).

The rest of this paper is organized as follows. In Section 2 we discuss our approach of re-ranking the n -best reorderings produced by the TSP model. This includes a discussion of the model used, the features used and the algorithm used for learning the parameters of the model. It also includes a discussion on the modification to the Chained Lin-Kernighan heuristic to produce n -best reorderings. Next, in Section 3 we describe our experimental setup and report the results of our experiments. In Section 4 we present some discussions based on our study. In section 5 we briefly describe some prior related work. Finally, in Section 6, we present some concluding remarks and highlight possible directions for future work.

2 Re-ranking using higher order and structural features

As mentioned earlier, the TSP model (Visweswarah et al., 2011) looks only at local features for a word pair (w_i, w_j). We believe that for better reordering it is essential to look at higher order and structural features (*i.e.*, features which look at the overall structure of a sentence). The primary reason why Visweswarah et al. (2011) consider only pairwise bigram features is that with higher order features the reordering problem can no longer be cast as a TSP and hence cannot be solved using existing efficient heuristic solvers. However, we do not have to deal with an NP-Hard search problem because instead of considering all possible reorderings we restrict our search space to only the n -best reorderings produced by the base TSP model. Formally, given a set of reorderings, $\Pi = [\pi_1, \pi_2, \pi_3, \dots, \pi_n]$, for a source sentence s , we are interesting in assigning a score, $score(\pi)$, to each of these reorderings and pick the reordering which has the highest score. In this paper, we parametrize this score as:

$$score(\pi) = \theta^T \phi(\pi) \quad (1)$$

where, θ is the weight vector and $\phi(\pi)$ is a vector of features extracted from the reordering π . The aim then is to find,

$$\pi^* = \arg \max_{\pi \in \Pi} score(\pi) \quad (2)$$

In the following sub-sections, we first briefly describe our overall approach towards finding π^* . Next, we describe our modification to the Lin-Kernighan heuristic for producing n -best outputs for TSP instead of the 1-best output used by (Visweswarah et al., 2011). We then discuss the features used for re-ranking these n -best outputs, followed by a discussion on the learning algorithm used for estimating the parameters of the model. Finally, we describe how we interpolate the score assigned by our model with the score assigned by the decoder of a SMT engine to indirectly capture target side features.

2.1 Overall approach

The training stage of our approach involves two phases : (i) Training a TSP model which will be used to generate n -best reorderings and (ii) Training a re-ranking model using these n -best reorderings. For training both the models we need a collection of sentences where the desired reordering $\pi^*(x)$ for each input sentence x is known. These reference orderings are derived from word aligned source-target sentence pairs (see first 4 rows of Figure 1). We first divide this word aligned data into N parts and use A^{-i} to denote the alignments leaving out the i -th part. We then train a TSP model M^{-i} using reference reorderings derived from A^{-i} as described in (Visweswarah et al., 2011). Next, we produce n -best reorderings for the source sentences using the algorithm $getNBestReorderings(sentence)$ described later. Dividing the data into N parts is necessary to ensure that the re-ranking model is trained using a realistic n -best list rather than a very optimistic n -best list (which would be the case if part i is reordered using a model which has already seen part i during training).

Each of the n -best reorderings is then represented as a feature vector comprising of higher order and structural features. The weights of these features are then estimated using the averaged perceptron method. At test time,

$getNBestReorderings(sentence)$ is used to generate the n -best reorderings for the test sentence using the trained TSP model. These reorderings are then represented using higher order and structural features and re-ranked using the weights learned earlier. We now describe the different stages of our algorithm.

2.2 Generating n-best reorderings for the TSP model

The first stage of our approach is to train a TSP model and generate n -best reorderings using it. The decoder used by Visweswarah et al. (2011) relies on the Chained Lin-Kernighan heuristic (Lin and Kernighan, 1973) to produce the 1-best permutation for the TSP problem. Since our algorithm aims at re-ranking an n -best list of permutations (reorderings), we made a modification to the Chained Lin-Kernighan heuristic to produce this n -best list as shown in Algorithm 1 .

Algorithm 1 $getNBestReorderings(sentence)$

```

 $NbestSet = \phi$ 
 $\pi^* = \text{Identity permutation}$ 
 $\pi^* = linkernighan(\pi^*)$ 
 $insert(NbestSet, \pi^*)$ 
for  $i = 1 \rightarrow nIter$  do
     $\pi' = perturb(\pi^*)$ 
     $\pi' = linkernighan(\pi')$ 
    if  $C(\pi') < max_{\pi \in NbestSet} C(\pi)$  then
         $InsertOrReplace(NbestSet, \pi')$ 
    end if
    if  $C(\pi') < C(\pi^*)$  then
         $\pi^* = \pi'$ 
    end if
end for

```

In Algorithm 1 $perturb()$ is a four-edge perturbation described in (Applegate et al., 2003), and $linkernighan()$ is the Lin-Kernighan heuristic that applies a sequence of flips that potentially returns a lower cost permutation as described in (Lin and Kernighan, 1973). The cost $C(\pi)$ is calculated using a trained TSP model.

2.3 Features

We represent each of the n -best reorderings obtained above as a vector of features which can be divided into two sets : (i) higher order features and (ii) struc-

Segmentation Based Features (extracted for every segment in the induced segmentation)	Features fired for the segment [mere(PRP) ghar(NN)] in Figure1
<i>end_lex.current_segment</i>	<i>ghar</i>
<i>end_lex.prev_segment</i>	<i>Shyam</i>
<i>end_pos.current_segment</i>	<i>NN</i>
<i>end_pos.prev_segment</i>	<i>NN</i>
<i>length_of.current_segment</i>	2
<i>first_lex.current_segment</i>	<i>mere</i>
<i>first_lex.next_segment</i>	<i>aaye</i>
<i>first_pos.current_segment</i>	<i>PRP</i>
<i>first_pos.next_segment</i>	<i>VRB</i>
Higher order features	Features fired for the triplet Shyam(NN) the(Vaux) aaye(VRB) in Figure1
<i>lex.triplet.jumps</i>	<i>lex.triplet</i> = “Shyam the aaye” && <i>jumps</i> = [4, -1]
<i>pos.triplet.jumps</i>	<i>pos.triplet</i> = “NN Vaux VRB” && <i>jumps</i> = [4, -1]

Table 2: Features used in our model.

tural features. The higher order features are essentially trigram lexical and pos features whereas the structural features are derived from the sentence structure induced by a reordering (explained later).

2.3.1 Higher Order Features

Since deriving a good reordering would essentially require analyzing the syntactic structure of the source sentence, the tasks of reordering and parsing are often considered to be related. The main motivation for using higher order features thus comes from a related work on parsing (Koo and Collins, 2010) where the performance of a state of the art parser was improved by considering higher order dependencies. In our model we use trigram features (see Table 2) of the following form:

$\phi(ru_i, ru_{i+1}, ru_{i+2}, J(ru_i, ru_{i+1}), J(ru_{i+1}, ru_{i+2}))$
where ru_i = word at position i in the reordered source sentence and $J(x, y)$ = difference between the positions of x and y in the original source sentence.

Figure 1 shows an example of jumps between different word pairs in an Urdu sentence. Since such higher order features will typically be sparse, we also use some back-off features. For example, instead of using the absolute values of jumps we divide the jumps into 3 buckets, viz., high, low and medium and use these buckets in conjunction with the triplets as back-off features.

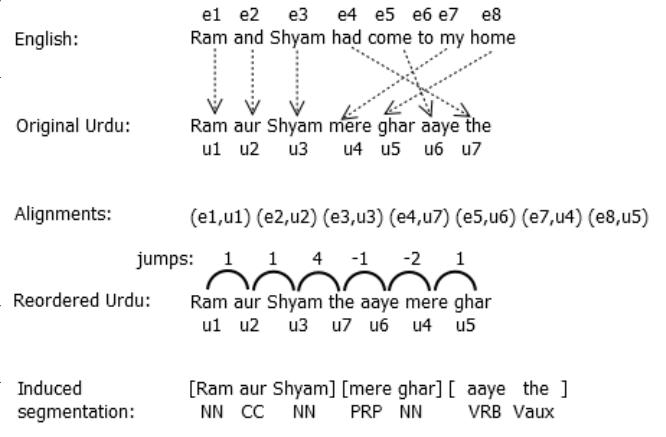

Figure 1: Segmentation induced on the Urdu sentence when it is reordered according to its English translation. Note that the words *Shyam* and *mere* are adjacent to each other in the original Urdu sentence but not in the reordered Urdu sentence. Hence, the word *mere* marks the beginning of a new segment.

2.3.2 Structural Features

The second set of features is based on the hypothesis that any reordering of the source sentence induces a segmentation on the sentence. This segmentation is based on the following heuristic: if w_i and w_{i+1} appear next to each other in the original sentence but do not appear next to each other in the reordered sentence then w_i marks the end of a segment and w_{i+1} marks the beginning of the next segment. To understand this better please refer to Figure 1 which shows the correct reordering of an Urdu sentence based on its English translation and the corresponding segmentation induced on the Urdu sentence. If the correct segmentation of a sentence is known in advance then one could use a hierarchical model where the goal would be to reorder segments instead of reordering words individually (basically, instead of words, treat segments as units of reordering. In principle, this is similar to what is done by parser based reordering methods). Since the TSP model does not explicitly use segmentation based features it often produces wrong reorderings (refer to the motivating example in Section 1).

Reordering such sentences correctly requires some knowledge about the hierarchical structure of the sentence. To capture such hierarchical information, we use features which look at the elements

(words, pos tags) of a segment and its neighboring segments. These features along with examples are listed in Table 2. These features should help us in selecting a reordering which induces a segmentation which is closest to the correct segmentation induced by the reference reordering. Note that every feature listed in Table 2 is a binary feature which takes on the value 1 if it fires for the given reordering and value 0 if it does not fire for the given reordering. In addition to the features listed in Table 2 we also use the score assigned by the TSP model as a feature.

2.4 Estimating model parameters

We use perceptron as the learning algorithm for estimating the parameters of our model described in Equation 1. To begin with, all parameters are initialized to 0 and the learning algorithm is run for N iterations. During each iteration the parameters are updated after every training instance is seen. For example, during the i -th iteration, after seeing the j -th training sentence, we update the k -th parameter θ_k using the following update rule:

$$\theta_k^{(i,j)} = \theta_k^{(i,j-1)} + \phi_k(\pi_j^{gold}) - \phi_k(\pi_j^*) \quad (3)$$

where, $\theta_k^{(i,j)}$ = value of the k -th parameter after seeing sentence j in iteration i

ϕ_k = k -th feature

π_j^{gold} = gold reordering for the j -th sentence

$$\pi_j^* = \arg \max_{\pi \in \Pi_j} \theta^{(i,j-1)^T} \phi(\pi)$$

where Π_j is the set of n -best reorderings for the j -th sentence. π_j^* is thus the highest-scoring reordering for the j -th sentence under the current parameter vector. Since the averaged perceptron method is known to perform better than the perceptron method, we used the averaged values of the parameters at the end of N iterations, calculated as:

$$\theta_k^{avg} = \frac{1}{N \cdot t} \sum_{i=1}^N \sum_{j=1}^t \theta_k^{(i,j)} \quad (4)$$

where, N = Number of iterations

t = Number of training instances

We observed that in most cases the reference reordering is not a part of the n -best list produced by the TSP model. In such cases instead of using

$\phi_k(\pi_j^{gold})$ for updating the weights in Equation 3 we use $\phi_k(\pi_j^{closest_to_gold})$ as this is known to be a better strategy for learning a re-ranking model (Arun and Koehn, 2007). $\pi_j^{closest_to_gold}$ is given by:

$$\arg \max_{\pi_j^i \in \Pi_j} \frac{\# \text{ of common bigram pairs in } \pi_j^i \text{ and } \pi_j^{gold}}{\text{len}(\pi_j^{gold})}$$

where, Π_j = set of n -best reorderings for j^{th} sentence

$\pi_j^{closest_to_gold}$ is thus the reordering which has the maximum overlap with π_j^{gold} in terms of the number of word pairs (w_m, w_n) where w_n is put next to w_m .

2.5 Interpolating with MT score

The approach described above aims at producing a better reordering by extracting richer features from the source sentence. Since the final aim is to improve the performance of an MT system, it would potentially be beneficial to interpolate the scores assigned by Equation 1 to a given reordering with the score assigned by the decoder of an MT system to the translation of the source sentence under this reordering. Intuitively, the MT score would allow us to capture features from the target sentence which are obviously not available to our model. With this motivation, we use the following interpolated score ($score_I$) to select the best translation.

$$score_I(t_i) = \lambda \cdot score_\theta(\pi_i) + (1 - \lambda) \cdot score_{MT}(t_i)$$

where, t_i = translation produced under the i -th

reordering of the source sentence

$score_\theta(\pi_i)$ = score assigned by our model to the i -th reordering

$score_{MT}(t_i)$ = score assigned by the MT system to t_i

The weight λ is used to ensure that $score_\theta(\pi_i)$ and $score_{MT}(\pi_i)$ are in the same range (it just serves as a normalization constant). We acknowledge that the above process is expensive because it requires the MT system to decode n reorderings for every source sentence. However, the aim of this work is to show that interpolating with the MT score which implicitly captures features from the target sentence helps in improving the performance. Ideally, this interpolation should (and can) be done at decode time without having to decode n reorderings for every source

sentence (for example by expressing the n reorderings as a lattice), but, we leave this as future work.

3 Empirical evaluation

We evaluated our reordering approach on Urdu-English. We use two types of evaluation, one intrinsic and one extrinsic. For intrinsic evaluation, we compare the reordered source sentence in Urdu with a reference reordering obtained from the hand alignments using BLEU (referred to as monolingual BLEU or mBLEU by (Viswesvariah et al., 2011)). Additionally, we evaluate the effect of reordering on MT performance using BLEU (extrinsic evaluation).

As mentioned earlier, our training process involves two phases : (i) Generating n-best reorderings for the training data and (ii) using these n-best reorderings to train a perceptron model. We use the same data for training the reordering model as well as our perceptron model. This data contains 180K words of manual alignments (part of the NIST MT-08 training data) and 3.9M words of automatically generated machine alignments (1.7M words from the NIST MT-08 training data¹ and 2.2M words extracted from sources on the web²). The machine alignments were generated using a supervised maximum entropy model (Ittycheriah and Roukos, 2005) and then corrected using an improved correction model (McCarley et al., 2011). We first divide the training data into 10 folds. The n -best reorderings for each fold are then generated using a model trained on the remaining 9 folds. This division into 10 folds is done for reasons explained earlier in Section 2.1. These n -best reorderings are then used to train the perceptron model as described in Section 2.4. Note that Viswesvariah et al. (2011) used only manually aligned data for training the TSP model. However, we use machine aligned data in addition to manually aligned data for training the TSP model as it leads to better performance. We used this improvised TSP model as the state of the art baseline (rows 2 and 3 in Tables 3 and 4 respectively) for comparing with our approach.

We observed that the perceptron algorithm converges after 5 iterations beyond which there is very little (<1%) improvement in the bigram precision on

the training data itself (bigram precision is the fraction of word pairs which are correctly put next to each other). Hence, for all the numbers reported in this paper, we used 5 iterations of perceptron training. Similarly, while generating the n -best reorderings, we experimented with following values of n : 10, 25, 50, 100 and 200. We observed that, by restricting the search space to the top-50 reorderings we get the best reordering performance (mBLEU) on a development set. Hence, we used $n=50$ for our MT experiments.

For intrinsic evaluation we use a development set of 8017 Urdu tokens reordered manually. Table 3 compares the performance of the top-1 reordering output by our algorithm with the top-1 reordering generated by the improved TSP model in terms of mBLEU. We see a gain of 1.8 mBLEU points with our approach.

Next, we see the impact of the better reorderings produced by our system on the performance of a state-of-the-art MT system. For this, we used a standard phrase based system (Al-Onaizan and Papineni, 2006) with a lexicalized distortion model with a window size of +/-4 words (Tillmann and Ney, 2003). As mentioned earlier, our training data consisted of 3.9M words including the NIST MT-08 training data. We use HMM alignments along with higher quality alignments from a supervised aligner (McCarley et al., 2011). The Gigaword English corpus was used for building the English language model. We report results on the NIST MT-08 evaluation set, averaging BLEU scores from the News and Web conditions to provide a single BLEU score. Table 4 compares the MT performance obtained by reordering the training and test data using the following approaches:

- 1. No pre-ordering:** A baseline system which does not use any source side reordering as a pre-processing step
- 2. HERO :** A state of the art hierarchical phrase based translation system (Chiang, 2007)
- 3. TSP:** A system which uses the 1-best reordering produced by the TSP model
- 4. Higher order & structural features:** A system

Approach	mBLEU
Unordered	31.2
TSP	56.6
Higher order & structural features	58.4

Table 3: mBLEU scores for Urdu to English reordering using different models.

Approach	BLEU
No pre-ordering	21.9
HIERO	25.2
TSP	26.9
Higher order & structural features	27.5
Interpolating with MT score	28.2

Table 4: MT performance for Urdu to English without reordering and with reordering using different approaches.

which reranks n -best reorderings produced by TSP using higher order and structural features

5. Interpolating with MT score : A system which interpolates the score assigned to a reordering by our model with the score assigned by a MT system

We used Joshua 4.0 (Ganitkevitch et al., 2012) which provides an open source implementation of HIERO. For training, tuning and testing HIERO we used the same experimental setup as described above. As seen in Table 4, we get an overall gain of 6.2 BLEU points with our approach as compared to a baseline system which does not use any reordering. More importantly, we outperform (i) a PBSMT system which uses the TSP model by 1.3 BLEU points and (ii) a state of the art hierarchical phrase based translation system by 3 points.

4 Discussions

We now discuss some error corrections and ablation tests.

4.1 Example of error correction

We first give an example where the proposed approach performed better than the TSP model. In the example below, I = input sentence, E = gold English translation, T = incorrect reordering produced by TSP and O = correct reordering produced by our approach. Note that the words *roman catholic aur protestant* in the input sentence get translated as

Sentence length	mBLEU		
	Unordered	TSP	Our approach
1-14 words (small)	29.7	58.7	57.8
15-22 words (med.)	28.2	56.8	59.2
23+ words (long)	33.4	55.8	58.2
All	31.2	56.6	58.4

Table 5: mBLEU improvements on sentences of different lengths

a continuous phrase in English (*Roman Catholic and Protestant*) and hence should be treated as a single unit by the reordering model. The TSP model fails to keep this segment intact whereas our model (which uses segmentation based features) does so and matches the reference reordering.

I : ab roman catholic aur protestant ke darmiyaan ikhtilafat khatam ho chuke hai

E : The differences between Roman Catholics and Protestants have now ended

T : ab roman ikhtilafat ke darmiyaan catholic aur protestant hai khatam ho chuke

O : ab ikhtilafat ke darmiyaan roman catholic aur protestant hai khatam ho chuke

4.2 Performance based on sentence length

We split the test data into roughly three equal parts based on length, and calculated the mBLEU improvements on each of these parts as reported in Table 5. These results show that the model works much better for medium-to-long sentences. In fact, we see a drop in performance for small sentences. A possible reason for this could be that the structural features that we use are derived through a heuristic that is error-prone, and in shorter sentences, where there would be fewer reordering problems, these errors hurt more than they help. While this needs to be analyzed further, we could meanwhile combine the two models fruitfully by using the base TSP model for small sentences and the new model for longer sentences.

Disabled feature	mBLEU
<i>end_lex_current_segment</i>	57.6
<i>end_lex_prev_segment</i>	57.6
<i>end_pos_current_segment</i>	57.8
<i>end_pos_prev_segment</i>	57.4
<i>length</i>	57.6
<i>lex_triplet_jumps</i>	58.0
<i>pos_triplet_jumps</i>	56.1
<i>first_lex_current_segment</i>	58.2
<i>first_lex_next_segment</i>	58.2
<i>first_pos_current_segment</i>	57.6
<i>first_pos_next_segment</i>	57.6
<i>NONE</i>	58.4

Table 6: Ablation test indicating the contribution of each feature to the reordering performance.

4.3 Ablation test

To study the contribution of each feature to the reordering performance, we did an ablation test wherein we disabled one feature at a time and measured the change in the mBLEU scores. Table 6 summarizes the results of our ablation test. The maximum drop in performance is obtained when the *pos_triplet_jumps* feature is disabled. This observation supports our claim that higher order features (more than bigrams) are essential for better reordering. The *lex_triplet_jumps* feature has the least impact on the performance mainly because it is a lexicalized feature and hence very sparse. Also note that there is a high correlation between the performances obtained by dropping one feature from each of the following pairs :

- i) *first_lex_current_segment, first_lex_next_segment*
- ii) *first_pos_current_segment, first_pos_next_segment*
- iii) *end_lex_current_segment, end_lex_next_segment*.

This is because these pairs of features are highly dependent features. Note that similar to the *pos_triplet_jumps* feature we also tried a *pos_quadruplet_jumps* feature but it did not help (mainly due to overfitting and sparsity).

5 Related Work

There are several studies which have shown that reordering the source side sentence to match the target side order leads to improvements in Machine Translation. These approaches can be broadly classified into three types. First, approaches which reorder source sentences by applying rules to the source side

parse; the rules are either hand-written (Collins et al., 2005; Wang et al., 2007; Ramanathan et al., 2009) or learned from data (Xia and McCord, 2004; Genzel, 2010; Viswesvariah et al., 2010). These approaches require a source side parser which is not available for many languages. The second type of approaches treat machine translation decoding as a parsing problem by using source and/or target side syntax in a Context Free Grammar framework. These include Hierarchical models (Chiang, 2007) and syntax based models (Yamada and Knight, 2002; Galley et al., 2006; Liu et al., 2006; Zollmann and Venugopal, 2006). The third type of approaches, avoid the use of a parser (as required by syntax based models) and instead train a reordering model using reference reorderings derived from aligned data. These approaches (Tromble and Eisner, 2009; Viswesvariah et al., 2011; DeNero and Uszkoreit, 2011; Neubig et al., 2012) have a low decode time complexity as reordering is done as a pre-processing step and not integrated with the decoder.

Our work falls under the third category, as it improves upon the work of (Viswesvariah et al., 2011) which is closely related to the work of (Tromble and Eisner, 2009) but performs better. The focus of our work is to use higher order and structural features (based on segmentation of the source sentence) which are not captured by their model. Some other works have used collocation based segmentation (Henríquez Q. et al., 2010) and Multiword Expressions as segments (Bouamor et al., 2012) to improve the performance of SMT but without much success. The idea of improving performance by re-ranking a n -best list of outputs has been used recently for the related task of parsing (Katz-Brown et al., 2011) using targeted self-training for improving the performance of reordering. However, in contrast, in our work we directly aim at improving the performance of a reordering model.

6 Conclusion

In this work, we proposed a model for re-ranking the n -best reorderings produced by a state of the art reordering model (TSP model) which is limited to pair wise features. Our model uses a more informative set of features consisting of higher order features, structural features and target side features

(captured indirectly using translation scores). The problem of intractability is solved by restricting the search space to the n -best reorderings produced by the TSP model. A detailed ablation test shows that of all the features used, the pos triplet features are most informative for reordering. A gain of 1.3 and 3 BLEU points over a state of the art phrase based and hierarchical machine translation system respectively provides good extrinsic validation of our claim that such long range features are useful.

As future work, we would like to evaluate our algorithm on other language pairs. We also plan to integrate the score assigned by our model into the decoder to avoid having to do n decodings for every source sentence. Also, it would be interesting to model the segmentation explicitly, where the aim would be to first segment the sentence and then use a two level hierarchical reordering model which first reorders these segments and then reorders the words within the segment.

Abstract

Translation models in statistical machine translation can be scaled to large corpora and arbitrarily-long phrases by looking up translations of source phrases “on the fly” in an indexed parallel corpus using suffix arrays. However, this can be slow because on-demand extraction of phrase tables is computationally expensive. We address this problem by developing novel algorithms for general purpose graphics processing units (GPUs), which enable suffix array queries for phrase lookup and phrase extraction to be massively parallelized. Compared to a highly-optimized, state-of-the-art serial CPU-based implementation, our techniques achieve at least an order of magnitude improvement in terms of throughput. This work demonstrates the promise of massively parallel architectures and the potential of GPUs for tackling computationally-demanding problems in statistical machine translation and language processing.

1 Introduction

Efficiently handling large translation models is a perennial problem in statistical machine translation. One particularly promising solution (§2) is to use the parallel text itself as an *implicit* representation of the translation model and extract translation units “on the fly” when they are needed to decode new input (Brown, 2004). This idea has been applied to phrase-based (Callison-Burch et al., 2005; Zhang and Vogel, 2005), hierarchical (Lopez, 2007; Lopez, 2008b; Lopez, 2008a), and syntax-based (Cromieres

and Kurohashi, 2011) models. A benefit of this technique is that it scales to arbitrarily large models with very little pre-processing. For instance, Lopez (2008b) showed that a translation model trained on a large corpus with sparse word alignments and loose extraction heuristics substantially improved Chinese-English translation. An explicit representation of the model would have required nearly a terabyte of memory, but its implicit representation using the parallel text required only a few gigabytes.

Unfortunately, there is substantial computational cost in searching a parallel corpus for source phrases, extracting their translations, and scoring them on the fly. Since the number of possible translation units may be quite large (for example, all substrings of a source sentence) and their translations are numerous, both phrase lookup and extraction are performance bottlenecks. Despite considerable research and the use of efficient indexes like suffix arrays (Manber and Myers, 1990), this problem remains not fully solved.

We show how to exploit the massive parallelism offered by modern general purpose graphics processing units (GPUs) to eliminate the computational bottlenecks associated with “on the fly” phrase extraction. GPUs have previously been applied to DNA sequence matching using suffix trees (Schatz et al., 2007) and suffix arrays (Gharaibeh and Ripeanu, 2010). Building on this work, we present two novel contributions: First, we describe improved GPU algorithms for suffix array queries that achieve greater parallelism (§3). Second, we propose novel data structures and algorithms for phrase extraction (§4) and scoring (§5) that are amenable to GPU par-

allelization. The resulting implementation achieves at least an order of magnitude higher throughput than a state-of-the-art single-threaded CPU implementation (§6). Since our experiments verify that the GPU implementation produces *exactly* the same results as a CPU reference implementation on a full extraction, we can simply replace that component and reap significant performance advantages with no impact on translation quality. To the best of our knowledge, this is the first reported application of GPU acceleration techniques for statistical machine translation. We believe these results reveal a promising yet unexplored future direction in exploiting parallelism to tackle perennial performance bottlenecks in state-of-the-art translation models.

2 Phrase Extraction On Demand

Lopez (2008b) provides the following recipe for “translation by pattern matching”, which we use as a guide for the remainder of this paper:

Algorithm 1 Translation by pattern matching

```

1: for each input sentence do
2:   for each possible phrase in the sentence do
3:     Find its occurrences in the source text
4:     for each occurrence do
5:       Extract its aligned target phrase (if any)
6:     for each extracted phrase pair do
7:       Compute feature values
8:   Decode as usual using the scored rules

```

The computational bottleneck occurs in lines 2–7: there are vast numbers of query phrases, matching occurrences, and extracted phrase pairs to process in the loops. In the next three sections, we attack each problem in turn.

3 Finding Every Phrase

First, we must find all occurrences of each source phrase in the input (line 3, Algorithm 1). This is a classic application of string pattern matching: given a short query pattern, the task is to find all occurrences in a much larger text. Solving the problem efficiently is crucial: for an input sentence F of length $|F|$, each of its $O(|F|^2)$ substrings is a potential query pattern.

3.1 Pattern Matching with Suffix Arrays

Although there are many algorithms for pattern matching, all of the examples that we are aware of for machine translation rely on *suffix arrays*. We briefly review the classic algorithms of Manber and Myers (1990) here since they form the basis of our techniques and analysis, but readers who are familiar with them can safely skip ahead to additional optimizations (§3.2).

A suffix array represents all suffixes of a corpus in lexicographical order. Formally, for a text T , the i th suffix of T is the substring of the text beginning at position i and continuing to the end of T . Each suffix can therefore be uniquely identified by the index i of its first word. A suffix array $S(T)$ of T is a permutation of these suffix identifiers $[1, |T|]$ arranged by the lexicographical order of the corresponding suffixes—in other words, the suffix array represents a sorted list of all suffixes in T . With both T and $S(T)$ in memory, we can find any query pattern Q in $O(|Q| \log |T|)$ time by comparing pattern Q against the first $|Q|$ characters of up to $\log |T|$ different suffixes using binary search.

An inefficiency in this solution is that each comparison in the binary search algorithm requires comparing all $|Q|$ characters of the query pattern against some suffix of text T . We can improve on this using an observation about the *longest common prefix* (LCP) of the query pattern and the suffix against which it is compared. Suppose we search for a query pattern Q in the span of the suffix array beginning at suffix L and ending at suffix R . For any suffix M which falls lexicographically between those at L and R , the LCP of Q and M will be at least as long as the LCP of Q and L or Q and R . Hence if we know the quantity $h = \text{MIN}(\text{LCP}(Q, L), \text{LCP}(Q, R))$ we can skip comparisons of the first h symbols between Q and the suffix M , since they must be the same.

The solution of Manber and Myers (1990) exploits this fact along with the observation that each comparison in binary search is carried out according to a fixed recursion scheme: a query is only ever compared against a specific suffix M for a single range of suffixes bounded by some fixed L and R . Hence if we know the longest common prefix between M and each of its corresponding L and R according to the fixed recursions in the

algorithm, we can maintain a bound on h and reduce the aggregate number of symbol comparisons to $O(|Q| + \log |T|)$. To accomplish this, in addition to the suffix array, we pre-compute two other arrays of size $|T|$ for both left and right recursions (called the LCP arrays).

Memory use is an important consideration, since GPUs have less memory than CPUs. For the algorithms described here, we require four arrays: the original text T , the suffix array $S(T)$, and the two LCP arrays. We use a representation of T in which each word has been converted to a unique integer identifier; with 32-bit integers the total number of bytes is $16|T|$. As we will show, this turns out to be quite modest, even for large parallel corpora (§6).

3.2 Suffix Array Efficiency Tricks

Previous work on translation by pattern matching using suffix arrays on serial architectures has produced a number of efficiency optimizations:

1. Binary search bounds for longer substrings are initialized to the bounds of their longest prefix. Substrings are queried only if their longest prefix string was matched in the text.
2. In addition to conditioning on the longest prefix, Zhang and Vogel (2005) and Lopez (2007) condition on a successful query for the longest proper suffix.
3. Lopez (2007) queries each unique substring of a sentence exactly once, regardless of how many times it appears in an input sentence.
4. Lopez (2007) directly indexes one-word substrings with a small auxiliary array, so that their positions in the suffix array can be found in constant time. For longer substrings, this optimization reduces the $\log |T|$ term of query complexity to $\log(\text{count}(a))$, where a is the first word of the query string.

Although these efficiency tricks are important in the serial algorithms that serve as our baseline, not all of them are applicable to parallel architectures. In particular, optimizations (1), (2), and (3) introduce order dependencies between queries; they are disregarded in our GPU implementation so that we can fully exploit parallelization opportunities. We have not yet fully implemented (4), which is orthogonal to parallelization: this is left for future work.

3.3 Finding Every Phrase on a GPU

Recent work in computational biology has shown that suffix arrays are particularly amenable to GPU acceleration: the suffix-array-based DNA sequence matching system MummurGPU++ (Ghraibeh and Ripeanu, 2010) has been reported to outperform the already fast MummurGPU 2 (Trapnell and Schatz, 2009), based on suffix trees (an alternative indexing structure). Here, we apply the same ideas to machine translation, introducing some novel improvements to their algorithms in the process.

A natural approach to parallelism is to perform all substring queries in parallel (Ghraibeh and Ripeanu, 2010). There are no dependencies between iterations of the loop beginning on line 2 of Algorithm 1, so for input sentence F , we can parallelize by searching for all $O(|F|^2)$ substrings concurrently. We adopt this approach here.

However, naïve application of query-level parallelism leads to a large number of wasted threads, since most long substrings of an input sentence will not be found in the text. Therefore, we employ a novel two-pass strategy: in the first pass, we simply compute, for each position i in the input sentence, the length j of the longest substring in F that appears in T . These computations are carried out concurrently for every position i . During this pass, we also compute the suffix array bounds of the one-word substring $F[i]$, to be used as input to the second pass—a variant of optimizations (1) and (4) discussed in §3.2. On the second pass, we search for all substrings $F[i, k]$ for all $k \in [i+1, i+j]$. These computations are carried out concurrently for all substrings longer than one word.

Even more parallelization is possible. As we saw in §3.1, each query in a suffix array actually requires two binary searches: one each for the first and last match in $S(T)$. The abundance of inexpensive threads on a GPU permits us to perform both queries concurrently on separate threads. By doing this in both passes we utilize more of the GPU’s processing power and obtain further speedups.

As a simple example, consider an input sentence “The government puts more tax on its citizens”, and suppose that substrings “The government”, “government puts”, and “puts more tax” are found in the training text, while none of the words in “on

Initial Word	Longest Match	Substrings	Threads	
			1st pass	2nd pass
The	2	The, The government	2	2
government	2	government, government puts	2	2
puts	3	puts, puts more, puts more tax	2	4
more	2	more, more tax	2	2
tax	1	tax	2	0
on	0	–	2	0
its	0	–	2	0
citizens	0	–	2	0
Total Threads:			16	10

Table 1: Example of how large numbers of suffix array queries can be factored across two highly parallel passes on a GPU with a total of 26 threads to perform all queries for this sample input sentence.

its citizens” are found. The number of threads spawned is shown in Table 1: all threads during a pass execute in parallel, and each thread performs a binary search which takes no more than $O(|Q| + \log |T|)$ time. While spawning so many threads may seem wasteful, this degree of parallelization still under-utilizes the GPU; the hardware we use (§6) can manage up to 21,504 concurrent threads in its resident occupancy. To fully take advantage of the processing power, we process multiple input sentences in parallel. Compared with previous algorithms, our two-pass approach and our strategy of thread assignment to increase the amount of parallelism represent novel contributions.

4 Extracting Aligned Target Phrases

The problem at line 5 of Algorithm 1 is to extract the target phrase aligned to each matching source phrase instance. Efficiency is crucial since some source phrases occur hundreds of thousands of times.

Phrase extraction from word alignments typically uses the consistency check of Och et al. (1999). A *consistent* phrase is one for which no words inside the phrase pair are aligned to words outside the phrase pair. Usually, consistent pairs are computed offline via dynamic programming over the alignment grid, from which we extract all consistent phrase pairs up to a heuristic bound on phrase length.

The online extraction algorithm of Lopez (2008a) checks for consistent phrases in a different manner. Rather than finding all consistent phrase pairs in a sentence, the algorithm asks: given a specific source phrase, is there a consistent phrase pair

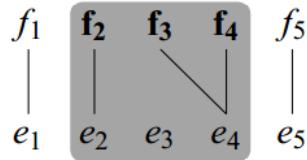

Figure 1: Source phrase $f_2f_3f_4$ and target phrase $e_2e_3e_4$ are extracted as a consistent pair, since the back-projection is contained within the original source span.

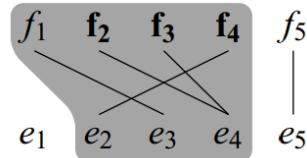

Figure 2: Source phrase $f_2f_3f_4$ and target phrase $e_2e_3e_4$ should not be extracted, since the back-projection is *not* contained within the original source span.

of which it is one side? To answer this, it first computes the projection of the source phrase in the target sentence: the minimum span containing all words that are aligned to any word of the source span. It then computes the projection of the target span back into the source; if this back-projection is contained within the original source span, the phrase pair is consistent, and the target span is extracted as the translation of the source. Figure 1 shows a “good” pair for source phrase $f_2f_3f_4$, since the back-projection is contained within the original source span, whereas Figure 2 shows a “bad” pair for source phrase $f_2f_3f_4$ since the back-projection is *not* contained within the original source span.

4.1 Sampling Consistent Phrases

Regardless of how efficient the extraction of a single target phrase is made, the fact remains that there are many phrases to extract. For example, in our Chinese Xinhua dataset (see §6), from 8,000 input query sentences, about 20 million source substrings can be extracted. The standard solution to this problem is to sample a set of occurrences of each source phrase, and only extract translations for those occurrences (Callison-Burch et al., 2005; Zhang and Vogel, 2005). As a practical matter, this can be done by sampling at uniform intervals from the matching span of a suffix array. Lopez (2008a) reports a sample size of 300; for phrases occurring fewer than 300 times, all translations are extracted.

4.2 GPU Implementation

We present novel data structures and an algorithm for efficient phrase extraction, which together are amenable to massive parallelization on GPUs. The basic insight is to pre-compute data structures for the source-to-target alignment projection and back-projection procedure described by Lopez (2008a) for checking consistent alignments.

Let us consider a single matching substring (from the output of the suffix array queries), span $[i, j]$ in the source text T . For each k , we need to know the leftmost and rightmost positions that it aligns to in the target T' . For this purpose we can define the target span $[i', j']$, along with leftmost and rightmost arrays L and R as follows:

$$\begin{aligned} i' &:= \min_{k \in [i, j]} L(k) \\ j' &:= \max_{k \in [i, j]} R(k) \end{aligned}$$

The arrays L and R are each of length $|T|$, indexed by absolute corpus position. Each array element contains the leftmost and rightmost extents of the source-to-target alignments (in the target), respectively. Note that in order to save space, the values stored in the arrays are sentence-relative positions (e.g., token count from the beginning of each sentence), so that we only need one byte per array entry. Thus, i' and j' are sentence-relative positions (in the target).

Similarly, for the back-projection, we use two arrays L' and R' on the target side (length $|T'|$) to

keep track of the leftmost and rightmost positions that k' in the target training text align to, as below:

$$\begin{aligned} i'' &:= \min_{k' \in [s'+i', s'+j']} L'(k') \\ j'' &:= \max_{k' \in [s'+i', s'+j']} R'(k') \end{aligned}$$

The arrays L' and R' are indexed by absolute corpus positions, but their contents are sentence relative positions (on the source side). To index the arrays L' and R' , we also need to obtain the corresponding target sentence start position s' . Note that the back-projected span $[i'', j'']$ may or may not be the same as the original span $[i, j]$. In fact, this is exactly what we must check for to ensure a consistent alignment.

The suffix array gives us i , which is an absolute corpus position, but we need to know the sentence-relative position, since the spans computed by R, L, R', L' are all sentence relative. To solve this, we introduce an array P (length $|T|$) that gives the relative sentence position of each source word.

We then pack the three source side arrays (R, L , and P) into a single RLP array of 32-bit integers (note that we are actually wasting one byte per array element). Finally, since the end-of-sentence special token is not used in any of R, L , or P , its position in RLP can be used to store an index to the start of the corresponding target sentence in the target array T' . Now, given a source phrase spanning $[i, j]$ (recall, these are absolute corpus positions), our phrase extraction algorithm is as follows:

Algorithm 2 Efficient Phrase Extraction Algorithm

```

1: for each source span  $[i, j]$  do
2:   Compute  $[i', j']$ 
3:    $s := i - P[i] - 1$ 
4:    $s' := RLP[s]$ 
5:    $i'' := \min_{k' \in [s'+i', s'+j']} L'(k')$ 
6:    $j'' := \max_{k' \in [s'+i', s'+j']} R'(k')$ 
7:   If  $i - s = i''$  and  $j - s = j''$  then
8:     Extract  $T[i, j]$  with  $T'[s' + i', s' + j']$ 
```

where s is the source sentence start position of a given source phrase and s' is the target sentence start position. If the back-projected spans match the original spans, the phrase pair $T[i, j]$ and $T'[s' + i', s' + j']$ is extracted.

In total, the data structures RLP , R' , and L' require $4|T| + 2|T'|$ bytes. Not only is this phrase

extraction algorithm fast—requiring only a few indirect array references—the space requirements for the auxiliary data structures are quite modest.

Given sufficient resources, we would ideally parallelize the phrase table creation process for each occurrence of the matched source substring. However, the typical number of source substring matches for an input sentence is even larger than the number of threads available on GPUs, so this strategy does not make sense due to context switching overhead. Instead, GPU thread blocks (groups of 512 threads) are used to process each source substring. This means that for substrings with large numbers of matches, one thread in the GPU block would process multiple occurrences. This strategy is widely used, and according to GPU programming best practices from NVIDIA, allocating more work to a single thread maintains high GPU utilization and reduces the cost of context switches.

5 Computing Every Feature

Finally, we arrive at line 7 in Algorithm 3, where we must compute feature values for each extracted phrase pair. Following the implementation of grammar extraction used in cdec (Lopez, 2008a), we compute several widely-used features:

1. Pair count feature, $c(e, f)$.
2. The joint probability of all target-to-source phrase translation probabilities, $p(e|f) = c(e, f)/c(f)$, where e is target phrase, f is the source phrase.
3. The logarithm of the target-to-source lexical weighting feature.
4. The logarithm of the source-to-target lexical weighting feature.
5. The coherence probability, defined as the ratio between the number of successful extractions of a source phrase to the total count of the source phrase in the suffix array.

The output of our phrase extraction is a large collection of phrase pairs. To extract the above features, aggregate statistics need to be computed over phrase pairs. To make the solution both compact and efficient, we first sort the unordered collection of phrases from the GPU into an array, then the aggregate statistics can be obtained in a single pass

over the array, since identical phrase pairs are now grouped together.

6 Experimental Setup

We tested our GPU-based grammar extraction implementation under the conditions in which it would be used for a Chinese-to-English machine translation task, in particular, replicating the data conditions of Lopez (2008b). Experiments were performed on two data sets. First, we used the source (Chinese) side of news articles collected from the Xinhua Agency, with around 27 million words of Chinese in around one million sentences (totaling 137 MB). Second, we added source-side parallel text from the United Nations, with around 81 million words of Chinese in around four million sentences (totaling 561 MB). In a pre-processing phase, we mapped every word to a unique integer, with two special integers representing end-of-sentence and end-of-corpus, respectively.

Input query data consisted of all sentences from the NIST 2002–2006 translation campaigns, tokenized and integerized identically to the training data. On average, sentences contained around 29 words. In order to fully stress our GPU algorithms, we ran tests on batches of 2,000, 4,000, 6,000, 8,000, and 16,000 sentences. Since there are only around 8,000 test sentences in the NIST data, we simply duplicated the test data as necessary.

Our experiments used NVIDIA’s Tesla C2050 GPU (Fermi Generation), which has 448 CUDA cores with a peak memory bandwidth 144 GB/s. Note that the GPU was released in early 2010 and represents previous generation technology. NVIDIA’s current GPUs (Kepler) boasts raw processing power in the 1.3 TFlops (double precision) range, which is approximately three times the GPU we used. Our CPU is a 3.33 GHz Intel Xeon X5260 processor, which has two cores.

As a baseline, we compared against the publicly available implementation of the CPU-based algorithms described by Lopez (2008a) found in the pycdec (Chahuneau et al., 2012) extension of the cdec machine translation system (Dyer et al., 2010). Note that we only tested grammar extraction for continuous pairs of phrases, and we did not test the slower and more complex queries for hierarchical

Input Sentences		2,000	4,000	6,000	8,000	16,000

Table 2: Comparing the GPU and CPU implementations for phrase extraction on two different corpora. Throughput is measured in words per second under different test set sizes; the 95% confidence intervals across five trials are given in parentheses, along with relative speedups comparing the two implementations.

(gappy) patterns described by Lopez (2007). Both our implementation and the baseline are written primarily in C/C++.¹

Our source corpora and test data are the same as that presented in Lopez (2008b), and using the CPU implementation as a reference enabled us to confirm that our extracted grammars and features are identical (modulo sampling). We timed our GPU implementation as follows: from the loading of query sentences, extractions of substrings and grammar rules, until all grammars for all sentences are generated in memory. Timing does not include offline preparations such as the construction of the suffix array on source texts and the I/O costs for writing the per-sentence grammar files to disk. This timing procedure is exactly the same for the CPU

baseline. We are confident that our results represent a fair comparison between the GPU and CPU, and are not attributed to misconfigurations or other flaws in experimental procedures. Note that the CPU implementation runs in a single thread, on the same machine that hosts the GPU (described above).

7 Results

Table 2 shows performance results comparing our GPU implementation against the reference CPU implementation for phrase extraction. In one experimental condition, the sampling parameter for frequently-matching phrases is set to 300, per Lopez (2008a), denoted s_{300} . The experimental condition without sampling is denoted s_{∞} . Following standard settings, the maximum length of the source phrase is set to 5 and the maximum length of the target phrase is set to 15 (same for both GPU and CPU implementations). The table is divided into two sections: the top shows results on the Xinhua data, and the bottom on Xinhua + UN data. Columns report results for different numbers

¹The Chahuneau et al. (2012) implementation is in Cython, a language for building Python applications with performance-critical components in C. In particular, all of the suffix array code that we instrumented for these experiments are compiled to C/C++. The implementation is a port of the original code written by Lopez (2008a) in Pyrex, a precursor to Cython. Much of the code is unchanged from the original version.

# Sent.	2000	4000	6000	8000	16000
Speedup	9.6×	14.3×	17.5×	20.9×	40.9×
Phrases	2.1×	1.8×	1.7×	1.6×	1.6×

Table 3: Comparing no sampling on the GPU with sampling on the CPU in terms of performance improvements (GPU over CPU) and increases in the number of phrase pairs extracted (GPU over CPU).

of input sentences. Performance is reported in terms of throughput: the number of processed words per second on average (i.e., total time divided by the batch size in words). The results are averaged over five trials, with 95% confidence intervals shown in parentheses. Note that as the batch size increases, we achieve higher throughput on the GPU since we are better saturating its full processing power. In contrast, performance is constant on the CPU regardless of the number of sentences processed.

The CPU throughput on the Xinhua data is 1.13 words per second without sampling and 200 words per second with sampling. On 16,000 test sentences, we have mostly saturated the GPU’s processing power, and observe a 7217× speedup over the CPU implementation without sampling and 62× speedup with sampling. On the larger (Xinhua + UN) corpus, we observe 43× and 10836× speedup with sampling and no sampling, respectively.

Interestingly, a run without sampling on the GPU is still substantially faster than a run with sampling on the CPU. On the Xinhua corpus, we observe speedups ranging from nine times to forty times, as shown in Table 3. Without sampling, we are able to extract up to twice as many phrases.

In previous CPU implementations of on-the-fly phrase extraction, restrictions were placed on the maximum length of the source and target phrases due to computational constraints (in addition to sampling). Given the massive parallelism afforded by the GPU, might we be able to lift these restrictions and construct the complete phrase table? To answer this question, we performed an experiment without sampling and without any restrictions on the length of the extracted phrases. The complete phrase table contained about 0.5% more distinct pairs, with negligible impact on performance.

When considering these results, an astute reader might note that we are comparing performance

of a single-threaded implementation with a fully-saturated GPU. To address this concern, we conducted an experiment using a multi-threaded version of the CPU reference implementation to take full advantage of multiple cores on the CPU (by specifying the `-j` option in `cdec`); we experimented with up to four threads to fully saturate the dual-core CPU. In terms of throughput, the CPU implementation scales linearly, i.e., running on four threads achieves roughly 4× throughput. Note that the CPU and GPU implementations take advantage of parallelism in completely different ways: `cdec` can be characterized as embarrassingly parallel, with different threads processing each complete sentence in isolation, whereas our GPU implementation achieves intra-sentential parallelism by exploiting many threads to concurrently process each sentence. In terms of absolute performance figures, even with the 4× throughput improvement from fully saturating the CPU, our GPU implementation remains faster by a wide margin. Note that neither our GPU nor CPU represents state-of-the-art hardware, and we would expect the performance advantage of GPUs to be even greater with latest generation hardware, since the number of available threads on a GPU is increasing faster than the number of threads available on a CPU.

Since phrase extraction is only one part of an end-to-end machine translation system, it makes sense to examine the overall performance of the entire translation pipeline. For this experiment, we used our GPU implementation for phrase extraction, serialized the grammar files to disk, and used `cdec` for decoding (on the CPU). The comparison condition used `cdec` for all three stages. We used standard phrase length constraints (5 on source side, 15 on target side) with sampling of frequent phrases. Finally, we replicated the data conditions in Lopez (2008a), where our source corpora was the Xinhua data set and our development/test sets were the NIST03/NIST05 data; the NIST05 test set contains 1,082 sentences.

Performance results for end-to-end translation are shown in Table 4, broken down in terms of total amount of time for each of the processing stages for the entire test set under different conditions. In the decoding stage, we varied the number of CPU threads (note here we do not observe linear

Phrase Extraction	I/O	Decoding	
GPU: 11.0	3.7	1 thread	55.7
		2 threads	35.3
CPU: 166.5		3 threads	31.5
		4 threads	26.2

Table 4: End-to-end machine translation performance: time to process the NIST05 test set in seconds, broken down in terms of the three processing stages.

speedup). In terms of end-to-end results, complete translation of the test set takes 41 seconds with the GPU for phrase extraction and CPU for decoding, compared to 196 seconds using the CPU for both (with four decoding threads in both cases). This represents a speedup of $4.8\times$, which suggests that even selective optimizations of individual components in the MT pipeline using GPUs can make a substantial difference in overall performance.

8 Future Work

There are a number of directions that we have identified for future work. For computational efficiency reasons, previous implementations of the “translation by pattern matching” approach have had to introduce approximations, e.g., sampling and constraints on phrase lengths. Our results show that the massive amounts of parallelism available in the GPU make these approximations unnecessary, but it is unclear to what extent they impact translation quality. For example, Table 3 shows that we extract up to twice as many phrase pairs without sampling, but do these pairs actually matter? We have begun to examine the impact of various settings on translation quality and have observed small improvements in some cases (which, note, come for “free”), but so far the results have not been conclusive.

The experiments in this paper focus primarily on throughput, but for large classes of applications latency is also important. One current limitation of our work is that large batch sizes are necessary to fully utilize the available processing power of the GPU. This and other properties of the GPU, such as the high latency involved in transferring data from main memory to GPU memory, make low-latency processing a challenge, which we hope to address.

Another broad future direction is to “GPU-ify” other machine translation models and other com-

ponents in the machine translation pipeline. An obvious next step is to extend our work to the hierarchical phrase-based translation model (Chiang, 2007), which would involve extracting “gappy” phrases. Lopez (2008a) has tackled this problem on the CPU, but it is unclear to what extent the same types of algorithms he proposed can execute efficiently in the GPU environment. Beyond phrase extraction, it might be possible to perform decoding itself in the GPU—not only will this exploit massive amounts of parallelism, but also reduce costs in moving data to and from the GPU memory.

9 Conclusion

GPU parallelism offers many promises for practical and efficient implementations of language processing systems. This promise has been demonstrated for speech recognition (Chong et al., 2008; Chong et al., 2009) and parsing (Yi et al., 2011), and we have demonstrated here that it extends to machine translation as well. We believe that explorations of modern parallel hardware architectures is a fertile area of research: the field has only begun to examine the possibilities and there remain many more interesting questions to tackle. Parallelism is critical not only from the perspective of building real-world applications, but for overcoming fundamental computational bottlenecks associated with models that researchers are developing today.

Abstract

Until recently, the application of discriminative training to log linear-based statistical machine translation has been limited to tuning the weights of a limited number of features or training features with a limited number of parameters. In this paper, we propose to scale up discriminative training of (He and Deng, 2012) to train features with 150 million parameters, which is one order of magnitude higher than previously published effort, and to apply discriminative training to redistribute probability mass that is lost due to model pruning. The experimental results confirm the effectiveness of our proposals on NIST MT06 set over a strong baseline.

1 Introduction

State-of-the-art statistical machine translation systems based on a log-linear framework are parameterized by $\{\lambda, \Phi\}$, where the feature weights λ are discriminatively trained (Och and Ney, 2002; Chiang et al., 2008b; Simianer et al., 2012) by directly optimizing them against a translation-oriented metric such as BLEU. The feature parameters Φ can be roughly divided into two categories: dense feature that measures the plausibility of each translation rule from a particular aspect, e.g., the rule translation probabilities $p(f|e)$ and $p(e|f)$; and sparse feature that fires when certain phenomena is observed, e.g., when a frequent word pair co-occurred in a rule. In contrast to λ , feature parameters in Φ are usually modeled by generative models for dense features, or by indicator functions for sparse ones. It is therefore desirable to train the dense features for each rule in a discriminative fashion to maximize some translation criterion. The maximum expected BLEU training of (He and Deng, 2012) is a recent effort towards this

direction, and in this paper, we extend their work to a scaled-up task of discriminative training of the features of a strong hierarchical phrase-based model and confirm its effectiveness empirically.

In this work, we further consider the application of discriminative training to pruned model. Various pruning techniques (Johnson et al., 2007; Zens et al., 2012; Eck et al., 2007; Lee et al., 2012; Tomeh et al., 2011) have been proposed recently to filter translation rules. One common consequence of pruning is that the probability distribution of many surviving rules become deficient, i.e. $\sum_f p(f|e) < 1$. In practice, others have chosen either to leave the pruned rules as it-is, or simply to re-normalize the probability mass by distributing the pruned mass to surviving rules proportionally. We argue that both approaches are suboptimal, and propose a more principled method to re-distribute the probability mass, i.e. using discriminative training with some translation criterion. Our experimental results demonstrate that at various pruning levels, our approach improves performance consistently. Particularly at the level of 50% of rules being pruned, the discriminatively trained models performs better than the unpruned baseline grammar. This shows that discriminative training makes it possible to achieve smaller models that perform comparably or even better than the baseline model.

Our contributions in this paper are two-folded: First of all, we scale up the maximum expected BLEU training proposed in (He and Deng, 2012) in a number of ways including using 1) a hierarchical phrase-based model, 2) a richer feature set, and 3) a larger training set with a much larger parameter set, resulting in more than 150 million parameters in the model being updated, which is one order magnitude higher than the phrase-based model reported in (He and Deng, 2012). We are able to show a reasonable

improvement over this strong baseline. Secondly, we combine discriminative training with pruning techniques to reestimate parameters of pruned grammar. Our approach is shown to alleviate the loss due to pruning, and sometimes can even outperform the baseline unpruned grammar.

2 Discriminative Training of Φ

Given the entire training data $\{F_n, E_n\}_{n=1}^N$, and current parameterization $\{\lambda, \Phi\}$, we decode the source side of training data F_n to produce hypothesis $\{\hat{E}_n\}_{n=1}^N$. Our goal is to update Φ towards Φ' that maximizes the expected BLEU scores of the entire training data given the current λ :

$$U(\Phi) = \sum_{\forall \hat{E}_1 \dots \hat{E}_N} \tilde{P}_\Phi(\hat{E}_1 \dots \hat{E}_N | F_1 \dots F_N) B(\hat{E}_1 \dots \hat{E}_N) \quad (1)$$

where $B(\hat{E}_1 \dots \hat{E}_N)$ is the BLEU score of the concatenated hypothesis of the entire training data, following (He and Deng, 2012).

Eq. 1 summarizes over all possible combinations of $\hat{E}_1 \dots \hat{E}_N$, which is intractable. Hence we make two simplifying approximations as follows. First, let the k -best hypotheses of the n -th sentence, $\hat{E}_n = \{\hat{E}_n^1, \dots, \hat{E}_n^K\}$, approximate all its possible translation. In other words, we assume that $\sum_{k=1}^K \tilde{P}(\hat{E}_n^k | F_n) = 1, \forall n$. Second, let the sum of sentence-level BLEU approximate the corpus BLEU. We note that corpus BLEU is not strictly decomposable (Chiang et al., 2008a), however, as the training data's size N gets big as in our case, we expect them to become more positively correlated.

Under these assumptions and the fact that each sentence is decoded independently, Eq. 1 can be algebraically simplified into:

$$U(\Phi) = \sum_{n=1}^N \sum_{k=1}^K P_\Phi(\hat{E}_n^k | F_n) B(\hat{E}_n^k) \quad (2)$$

where $P_\Phi(\hat{E}_n^k | F_n) = \tilde{P}_\Phi(\hat{E}_n^k | F_n) / \sum_{\forall k} \tilde{P}_\Phi(\hat{E}_n^k | F_n)$. We detail the process in the Appendix.

To further simplify the problem and relate it with model pruning, we consider to update a subset of $\theta \subset \Phi$ while keeping other parameterization of Φ unchanged, where $\theta = \{\theta_{ij} = p(e_j | f_i)\}$ denotes our parameter set that satisfies $\sum_j \theta_{ij} = 1$ and $\theta_{ij} \geq 0$. In experiments, we also consider $\{\theta_{ji} = p(f_i | e_j)\}$.

To alleviate overfitting, we introduce KL-distance based regularization as in (He and Deng, 2012). We thus arrive at the following objective function:

$$O(\theta) = \log(U(\theta)) - \tau \cdot KL(\theta || \theta^0) / N \quad (3)$$

where τ controls the regularization term's contribution, and θ^0 represents a prior parameter set, e.g., from the conventional maximum likelihood training.

The optimization algorithm is based on the Extended Baum Welch (EBW) (Gopalakrishnan et al., 1991) as derived by (He and Deng, 2012). The final update rule is as follow:

$$\theta'_{ij} = \frac{\sum_n \sum_k \gamma(n, k, i, j) + U(\theta) \tau \theta_{ij}^0 / \lambda + D_i \theta_{ij}}{\sum_n \sum_k \sum_j \gamma(n, k, i, j) + U(\theta) \tau / \lambda + D_i} \quad (4)$$

where θ'_{ij} is the updated parameter, $\gamma(n, k, i, j) = P_\theta(\hat{E}_n^k | F_n) \{B(\hat{E}_n^k) - U_n(\theta)\} \sum_l 1(f_{n,k,l} = f_i, e_{n,k,l} = e_j); U_n(\theta) = \sum_{k=1}^K P_\theta(\hat{E}_n^k | F_n) B(\hat{E}_n^k); D_i = \sum_{n,k,j} \max(0, -\gamma(n, k, i, j))$ and λ is the current feature's weight.

3 DT is Beneficial for Pruning

Pruning is often a key part in deploying large-scale SMT systems for many reasons, such as for reducing runtime memory footprint and for efficiency. Many pruning techniques have been proposed to assess translation rules and filter rules out if they are less plausible than others. While different pruning techniques may use different criterion, they all assume that pruning does not affect the feature function values of the surviving rules. This assumption may be suboptimal for some feature functions that have probabilistic sense since pruning will remove a portion of the probability mass that is previously assigned to the pruned rules. To be concrete, for the rule translation probabilities θ_{ij} under consideration, the constraint $\sum_j \theta_{ij} = 1$ will not hold for all source rules i after pruning. Previous works typically left the probability mass as it-is, or simply renormalize the pruned mass, i.e. $\bar{\theta}_{ij} = \theta_{ij} / \sum_j \theta_{ij}$.

We argue that applying the DT techniques to a pruned grammar, as described in Sec. 2, provides a more principled method to redistribute the mass, i.e. by quantizing how each rule contributes to the expected BLEU score in comparison to other competing rules. To empirically verify this, we consider

the significance test based pruning (Johnson et al., 2007), though our general idea can be applied to any pruning techniques. For our experiments, we use the significance pruning tool that is available as part of Moses decoder package (Koehn et al., 2007).

4 Experiments

Our experiments are designed to serve two goals: 1) to show the performance of discriminative training of feature parameters θ in a large-scale task; and 2) to show the effectiveness of DT when applied to pruned grammar. Our baseline system is a state-of-the-art hierarchical phrase-based system as described in (Zhou et al., 2008), trained on six million parallel sentences corpora that are available to the DARPA BOLT Chinese-English task. The training corpora includes a mixed genre of news wire, broadcast news, web-blog and comes from various sources such as LDC, HK Hansard and UN data.

In total, there are 50 dense features in our translation system. In addition to the standard features which include the rule translation probabilities, we incorporate features that are found useful for developing a state-of-the-art baseline, e.g. provenance-based lexical features (Chiang et al., 2011). We use a large 6-gram language model, which we train on a 10 billion words monolingual corpus, including the English side of our parallel corpora plus other corpora such as Gigaword (LDC2011T07) and Google News. To prevent possible over-fitting, we only kept the rules that have at most three terminal words (plus up to two nonterminals) on the source side, resulting in a grammar with 167 million rules.

Our discriminative training procedure includes updating both λ and θ , and we follow (He and Deng, 2012) to optimize them in an alternate manner. That is, when we optimize θ via EBW, we keep λ fixed and when we optimize λ , we keep λ fixed. We use PRO (Hopkins and May, 2011) to tune λ .

For discriminative training of θ , we use a subset of 550 thousands of parallel sentences selected from the entire training data, mainly to allow for faster experimental cycle; they mainly come from news and web-blog domains. For each sentence of this subset, we generate 500-best of unique hypotheses using the baseline model. The 1-best and the oracle BLEU scores for this subset are 40.19 and 47.06 respec-

tively. Following (He and Deng, 2012), we focus on discriminative training of $p(f|e)$ and $p(e|f)$, which in practice affects around 150 million of parameters; hence the title.

For the tuning and development sets, we set aside 1275 and 1239 sentences respectively from LDC2010E30 corpus. The tune set is used by PRO for tuning λ while the dev set is used to decide the best DT model. As for the blind test set, we report the performance on the NIST MT06 evaluation set, which consists of 1644 sentences from news and web-blog domains. Our baseline system’s performance on MT06 is 39.91 which is among the best number ever published so far in the community.

Table 1 compares the key components of our baseline system with that of (He and Deng, 2012). As shown, we are working with a stronger system than (He and Deng, 2012), especially in terms of the number of parameters under consideration $|\theta|$.

	He&Deng(2012)	This paper
Model	phrase-based	hierarchical
n -gram lm	3-gram	6-gram
# features	10	50
Max terminal	4	3
$ \theta $	9.2 M	150M
# training data	750K	6M
N for DT	750K	550K
max K -best	100	500

Table 1: Our system compares to He&Deng’s (2012).

4.1 DT of 150 Million Parameters

To ensure the correctness of our implementation, we show in Fig 2, the first five EBW updates with $\tau = 0.10$. As shown, the utility function $\log(U(\theta))$ increases monotonically but is countered by the KL term, resulting in a smaller but consistent increase of the objective function $O(\theta)$. This monotonically-increasing trend of the objective function confirms the correctness of our implementation since EBW algorithm is a bound-based technique that ensures growth transformations between updates.

We then explore the optimal setting for τ which controls the contribution of the regularization term. Specifically, we perform grid search, exploring values of τ from 0.1 to 0.75. For each τ , we run several iterations of discriminative training where each iteration involves one simultaneous update of $p(f|e)$

and $p(e|f)$ according to Eq. 4, followed by one update of λ via PRO (as in (He and Deng, 2012)). In total, we run 10 such iterations for each τ .

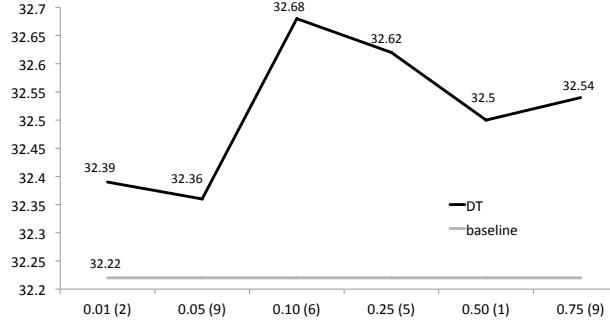

Figure 1: The dev set’s BLEU score (y-axis) on different setting of τ (x-axis). The grey line indicates the baseline performance on dev set. The number in bracket on the x-axis indicates the iteration at which the score is obtained.

Across different τ , we find that the first iteration provides most of the gain while the subsequent iterations provide additional, smaller gain with occasional performance degradation; thus the translation performance is not always monotonically increasing over iteration. We report the best score of each τ in Fig. 1 and at which iteration that score is produced. As shown in Fig. 1, all settings of τ improve over the baseline and $\tau = 0.10$ gives the highest gain of 0.45 BLEU score. This improvement is in the same ballpark as in (He and Deng, 2012) though on a scaled-up task. We next decode the MT06 using the best model (i.e. $\tau = 0.10$ at 6-th iteration) observed on the dev set, and obtained 40.33 BLEU with an improvement of around 0.4 BLEU point. We see this result as confirming the effectiveness of discriminative training but on a larger-scale task, adding to what was reported by (He and Deng, 2012).

4.2 DT for Significance Pruning

Next, we show the contribution of discriminative training for model pruning. To do so, we prune the translation grammar so that its size becomes 50%, 25%, 10% of the original grammar. Respectively, we delete rules whose significance value below 15, 50 and 500. Table 2 compares the statistics of the pruned grammars and the unpruned one. In particular, columns 4 and 5 show the total averaged probability mass of the remaining rules. This statistics provides some indication of how deficient the fea-

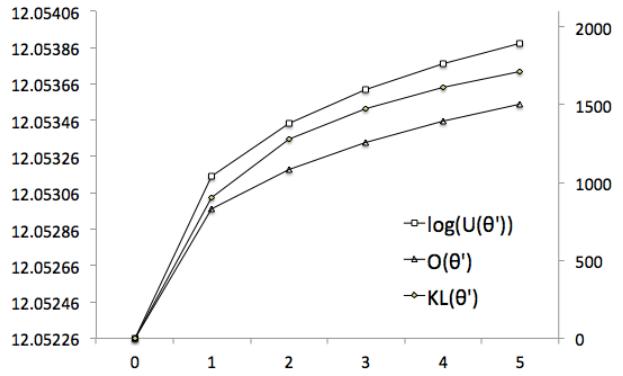

Figure 2: Objective function ($O(\theta')$), the regularization term ($KL(\theta')$) and the unregularized objective function ($\log(U(\theta'))$) for five EBW updates of updating $p(e_j|f_i)$

tures are after pruning. As shown, the total averaged probability mass after pruning is below 100% and even lower for the more aggressive pruning.

To show that the deficiency is suboptimal, we consider two baseline systems: models with/without mass renormalization. We tune a new λ for each model and use the new λ to decode the dev and test sets. The results are shown in columns 6 and 9 of Table 2 where we show the results for the unnormalized model in the brackets following the results for the re-normalized model. The results show that pruning degrades the performances and that naively re-normalizing the model provides no significant changes in performance. Subsequently, we will focus on the normalized models as the baseline as they represents the starting points of our EBW iteration.

Next, we run discriminative training that would reassign the probability mass to the surviving rules. First, we normalize $p(f|e)$ and $p(e|f)$, so that they satisfy the sum to one constraint required by the algorithm. Then, we run discriminative training on these pruned grammars using $\tau = 0.10$ (i.e. the setting that gives the best performance for the unpruned grammar as discussed in Section 4.1). We report the results in columns 7 and 9 for the dev and test sets respectively, as well as the gain over the baseline system in columns 8 and 10.

As shown in Table 2, DT provides a nice improvement over the baseline model of no mass reassignment. For all pruning levels, DT can compensate the loss associated with pruning. In particular, at 50% level of pruning, there is a loss about 0.4

size (%)	$ f $ (M)	$ e $ (M)	$p(*) e)$	$p(*) f)$	dev-set			test-set (MT06)		
					baseline (un)	DT (iter)	gain	baseline (un)	DT	gain
100	59	50	1.00	1.00	32.22(32.08)	32.68 (6)	+0.44	39.91 (39.71)	40.33	+0.42
50	38	35	0.92	0.94	31.84 (32.02)	32.31 (6)	+0.57	39.61(39.72)	40.08	+0.47
25	14	14	0.87	0.91	31.39 (31.43)	31.68 (2)	+0.29	39.23 (39.17)	39.43	+0.20
10	4	3	0.77	0.84	27.27 (27.10)	27.82 (2)	+0.55	36.01 (36.04)	36.43	+0.42

Table 2: The statistics of grammars pruned at various level (column 1), including the number of unique source and target phrases (columns 2 & 3), total probability mass of the remaining rules for $p(f|e)$ and $p(e|f)$ (columns 4 & 5), the performance of the pruned model before and after discriminative training as well as the gain on the dev and the test sets (columns 6 to 11). The iteration at which DT gives the best dev set is indicated by the number enclosed by bracket in column 7. The baseline performance is in *italics*, followed by a number in the bracket which refers to the performance of using unnormalized model. The above-the-baseline performances are in **bold**.

BLEU point after pruning. With the DT on pruned model, all pruning losses are reclaimed and the new pruned model is even better than the unpruned original model. This empirical result shows that leaving probability mass unassigned after pruning is sub-optimal and that discriminative training provides a principled way to redistribute the mass.

5 Conclusion

In this paper, we first extend the maximum expected BLEU training of (He and Deng, 2012) to train two features of a state-of-the-art hierarchical phrase-based system, namely: $p(f|e)$ and $p(e|f)$. Compared to (He and Deng, 2012), we apply the algorithm to a strong baseline that is trained on a bigger parallel corpora and comes with a richer feature set. The number of parameters under consideration amounts to 150 million. Our experiments show that discriminative training these two features (out of 50) gives around 0.40 BLEU point improvement, which is consistent with the conclusion of (He and Deng, 2012) but in a much larger-scale system.

Furthermore, we apply the algorithm to redistribute the probability mass of $p(f|e)$ and $p(e|f)$ that is commonly lost due to conventional model pruning. Previous techniques either leave the probability mass as it is or distribute it proportionally among the surviving rules. We show that our proposal of using discriminative training to redistribute the mass empirically performs better, demonstrating the effectiveness of our proposal.

Appendix

We describe the process to simplify Eq. 1 to Eq. 2, which is omitted in (He and Deng, 2012). For conciseness, we drop the conditions and write $P(\hat{E}_i|F_i)$ as $P(\hat{E}_i)$. We write Eq. 1 again below as Eq. 5 .

$$\sum_{\forall \hat{E}_1 \dots \hat{E}_N} \prod_{i=1}^N P(\hat{E}_i|F_i) \cdot \sum_{i=1}^N B(\hat{E}_i) \quad (5)$$

We first focus on the first sentence E_1/F_1 and expand the related terms from the equation as follow:

$$\sum_{\forall \hat{E}_1} \sum_{\forall \hat{E}_2 \dots \hat{E}_N} P(\hat{E}_1) \prod_{i=2}^N P(\hat{E}_i) \cdot \left[B(\hat{E}_1) + \sum_{i=2}^N B(\hat{E}_i) \right]$$

Expanding the inner summation, we arrive at:

$$\begin{aligned} & \sum_{\forall \hat{E}_1} P(\hat{E}_1) B(\hat{E}_1) \sum_{\forall \hat{E}_2 \dots \hat{E}_N} \prod_{i=2}^N P(\hat{E}_i) + \\ & \sum_{\forall \hat{E}_1} P(\hat{E}_1) \sum_{\forall \hat{E}_2 \dots \hat{E}_N} \prod_{i=2}^N P(\hat{E}_i) \sum_{i=2}^N B(\hat{E}_i) \end{aligned}$$

Due to the that $\sum_{k=1}^K \tilde{P}(\hat{E}_n^K|F_n) = 1$, we can equate $\sum_{\forall \hat{E}_2 \dots \hat{E}_N} \prod_{i=2}^N P(\hat{E}_i)$ and $\sum_{\forall \hat{E}_1} P(\hat{E}_1)$ to 1. Thus, we arrive at:

$$\sum_{\forall \hat{E}_1} P(\hat{E}_1) B(\hat{E}_1) + \sum_{\forall \hat{E}_2 \dots \hat{E}_N} \prod_{i=2}^N P(\hat{E}_i) \sum_{i=2}^N B(\hat{E}_i)$$

Notice that the second term has the same form as Eq. 5 except that the starting index starts from the second sentence. The same process can be performed and at the end, thus we can arrive at Eq. 2.

Applying Pairwise Ranked Optimisation to Improve the Interpolation of Translation Models

Barry Haddow

University of Edinburgh

Scotland

bhaddow@inf.ed.ac.uk

Abstract

In Statistical Machine Translation we often have to combine different sources of parallel training data to build a good system. One way of doing this is to build separate translation models from each data set and linearly interpolate them, and to date the main method for optimising the interpolation weights is to minimise the model perplexity on a heldout set. In this work, rather than optimising for this indirect measure, we directly optimise for BLEU on the tuning set and show improvements in average performance over two data sets and 8 language pairs.

1 Introduction

Statistical Machine Translation (SMT) requires large quantities of parallel training data in order to produce high quality translation systems. This training data, however, is often scarce and must be drawn from whatever sources are available. If these data sources differ systematically from each other, and/or from the test data, then the problem of combining these disparate data sets to create the best possible translation system is known as *domain adaptation*.

One approach to domain adaptation is to build separate models for each training domain, then weight them to create a system tuned to the test domain. In SMT, a successful approach to building domain specific language models is to build one from each corpus, then linearly interpolate them, choosing weights that minimise the perplexity on a suitable heldout set of in-domain data. This method has been applied by many authors (e.g. (Koehn and

Schroeder, 2007)), and is implemented in popular language modelling tools like IRSTLM (Federico et al., 2008) and SRILM (Stolcke, 2002).

Similar interpolation techniques have been developed for translation model interpolation (Foster et al., 2010; Sennrich, 2012) for phrase-based systems but have not been as widely adopted, perhaps because the efficacy of the methods is not as clear-cut. In this previous work, the authors used standard phrase extraction heuristics to extract phrases from a heldout set of parallel sentences, then tuned the translation model (i.e. the phrase table) interpolation weights to minimise the perplexity of the interpolated model on this set of extracted phrases.

In this paper, we try to improve on this perplexity optimisation of phrase table interpolation weights by addressing two of its shortcomings. The first problem is that the perplexity is not well defined because of the differing coverage of the phrase tables, and their partial coverage of the phrases extracted from the heldout set. Secondly, perplexity may not correlate with the performance of the final SMT system.

So, instead of optimising the interpolation weights for the indirect goal of translation model perplexity, we optimise them directly for translation performance. We do this by incorporating these weights into SMT tuning using a modified version of Pairwise Ranked Optimisation (PRO) (Hopkins and May, 2011).

In experiments on two different domain adaptation problems and 8 language pairs, we show that our method achieves comparable or improved performance, when compared to the perplexity minimisation method. This is an encouraging result as it

shows that PRO can be adapted to optimise translation parameters other than those in the standard linear model.

2 Optimising Phrase Table Interpolation Weights

2.1 Previous Approaches

In the work of Foster and Kuhn (2007), linear interpolation weights were derived from different measures of distance between the training corpora, but this was not found to be successful. Optimising the weights to minimise perplexity, as described in the introduction, was found by later authors to be more useful (Foster et al., 2010; Sennrich, 2012), generally showing small improvements over the default approach of concatenating all training data.

An alternative approach is to use log-linear interpolation, so that the interpolation weights can be easily optimised in tuning (Koehn and Schroeder, 2007; Bertoldi and Federico, 2009; Banerjee et al., 2011). However, this effectively multiplies the probabilities across phrase tables, which does not seem appropriate, especially for phrases absent from 1 table.

2.2 Tuning SMT Systems

The standard SMT model scores translation hypotheses as a linear combination of features. The model score of a hypothesis e is then defined to be $\mathbf{w} \cdot \mathbf{h}(e, f, a)$ where \mathbf{w} is a weight vector, and $\mathbf{h}(e, f, a)$ a vector of feature functions defined over source sentences (f), hypotheses, and their alignments (a). The weights are normally optimised (*tuned*) to maximise BLEU on a heldout set (the *tuning* set).

The most popular algorithm for this weight optimisation is the line-search based MERT (Och, 2003), but recently other algorithms that support more features, such as PRO (Hopkins and May, 2011) or MIRA-based algorithms (Watanabe et al., 2007; Chiang et al., 2008; Cherry and Foster, 2012), have been introduced. All these algorithms assume that the model score is a linear function of the parameters \mathbf{w} . However since the phrase table probabilities enter the score function in log form, if these probabilities are a linear interpolation, then the model score is not a linear function of the interpolation weights. We will show that PRO can be used

to simultaneously optimise such non-linear parameters.

2.3 Pairwise Ranked Optimisation

PRO is a *batch* tuning algorithm in the sense that there is an outer loop which repeatedly decodes a small (1000-2000 sentence) tuning set and passes the n -best lists from this tuning set to the core algorithm (also known as the *inner loop*). The core algorithm samples pairs of hypotheses from the n -best lists (according to a specific procedure), and uses these samples to optimise the weight vector \mathbf{w} .

The core algorithm in PRO will now be explained in more detail. Suppose that the N sampled hypothesis pairs (x_i^α, x_i^β) are indexed by i and have corresponding feature vectors pairs $(\mathbf{h}_i^\alpha, \mathbf{h}_i^\beta)$. If the gain of a given hypothesis (we use smoothed sentence BLEU) is given by the function $g(x)$, then we define y_i by

$$y_i \equiv \text{sgn}(g(x_i^\alpha) - g(x_i^\beta)) \quad (1)$$

For weights \mathbf{w} , and hypothesis pair (x_i^α, x_i^β) , the (model) score difference $\Delta s_i^\mathbf{w}$ is given by:

$$\Delta s_i^\mathbf{w} \equiv s^\mathbf{w}(x_i^\alpha) - s^\mathbf{w}(x_i^\beta) \equiv \mathbf{w} \cdot (\mathbf{h}_i^\alpha - \mathbf{h}_i^\beta) \quad (2)$$

Then the core PRO algorithm updates the weight vector to \mathbf{w}^* by solving the following optimisation problem:

$$\mathbf{w}^* = \arg \max_{\mathbf{w}} \sum_{i=1}^N \log(\sigma(y_i \Delta s_i^\mathbf{w})) \quad (3)$$

where $\sigma(x)$ is the standard sigmoid function. The derivative of the function can be computed easily, and the optimisation problem can be solved with standard numerical optimisation algorithms such as L-BFGS (Byrd et al., 1995). PRO is normally implemented by converting each sample to a training example for a 2 class maximum entropy classifier, with the feature values set to $\Delta \mathbf{h}_i$ and the responses set to the y_i , whereupon the log-likelihood is the objective given in Equation (3). As in maximum entropy modeling, it is usual to add a Gaussian prior to the objective (3) in PRO training.

2.4 Extending PRO for Mixture Models

We now show how to apply the PRO tuning algorithm of the previous subsection to simultaneously

optimise the weights of the translation system, and the interpolation weights.

In the standard phrase-based model, some of the features are derived from logs of phrase translation probabilities. If the phrase table is actually a linear interpolation of two (or more) phrase tables, then we can consider these features as also being functions of the interpolation weights. The interpolation weights then enter the score differences $\{\Delta s_i^w\}$ via the phrase features, and we can jointly optimise the objective in Equation (3) for translation model weights and interpolation weights.

To make this more concrete, suppose that the feature vector consists of m phrase table features and $n - m$ other features¹

$$\mathbf{h} \equiv (\log(p^1), \dots, \log(p^m), h^{m+1}, \dots, h^n) \quad (4)$$

where each p^j is an interpolation of two probability distributions p_A^j and p_B^j . So, $p^j \equiv \lambda^j p_A^j + (1 - \lambda^j) p_B^j$ with $0 \leq \lambda^j \leq 1$. Defining $\boldsymbol{\lambda} \equiv (\lambda^1 \dots \lambda^m)$, the optimisation problem is then:

$$(\mathbf{w}^*, \boldsymbol{\lambda}^*) = \arg \max_{(\mathbf{w}, \boldsymbol{\lambda})} \sum_{i=1}^N \log \left(\sigma \left(y_i \Delta s_i^{(\mathbf{w}, \boldsymbol{\lambda})} \right) \right) \quad (5)$$

where the sum is over the sampled hypothesis pairs and the Δ indicates the difference between the model scores of the two hypotheses in the pair, as before. The model score $s_i^{(\mathbf{w}, \boldsymbol{\lambda})}$ is given by

$$\begin{aligned} & \sum_{j=1}^m \left(w^j \cdot \log \left(\lambda^j p_{Ai}^j + (1 - \lambda^j) p_{Bi}^j \right) \right) \\ & + \sum_{j=m+1}^n w^j h_i^j \end{aligned} \quad (6)$$

where $\mathbf{w} \equiv (w^1 \dots w^n)$. A Gaussian regularisation term is added to the objective, as it was for PRO. By replacing the core algorithm of PRO with the optimisation above, the interpolation weights can be trained simultaneously with the other model weights.

Actually, the above explanation contains a simplification, in that it shows the phrase features interpolated at sentence level. In reality the phrase features

¹Since the phrase penalty feature is a constant across phrase pairs it is not interpolated, and so is classed with the “other” features. The lexical scores, although not actually probabilities, are interpolated.

are interpolated at the phrase level, then combined to give the sentence level feature value. This makes the definition of the objective more complex than that shown above, but still optimisable using bounded L-BFGS.

3 Experiments

3.1 Corpus and Baselines

We ran experiments with data from the WMT shared tasks (Callison-Burch et al., 2007; Callison-Burch et al., 2012), as well as OpenSubtitles data² released by the OPUS project (Tiedemann, 2009).

The experiments targeted both the news-commentary (nc) and OpenSubtitles (st) domains, with nc-devtest2007 and nc-test2007 for tuning and testing in the nc domain, respectively, and corresponding 2000 sentence tuning and test sets selected from the st data. The news-commentary v7 corpus and a 200k sentence corpus selected from the remaining st data were used as in-domain training data for the respective domains, with europarl v7 (ep) used as out-of-domain training data in both cases. The language pairs we tested were the WMT language pairs for nc (English (en) to and from Spanish (es), German (de), French (fr) and Czech (cs)), with Dutch (nl) substituted for de in the st experiments.

To build phrase-based translation systems, we used the standard Moses (Koehn et al., 2007) training pipeline, in particular employing the usual 5 phrase features – forward and backward phrase probabilities, forward and backward lexical scores and a phrase penalty. The 5-gram Kneser-Ney smoothed language models were trained by SRILM (Stolcke, 2002), with KenLM (Heafield, 2011) used at runtime. The language model is always a linear interpolation of models estimated on the in- and out-of-domain corpora, with weights tuned by SRILM’s perplexity minimisation³. All experiments were run three times with BLEU scores averaged, as recommended by Clark et al. (2011). Performance was evaluated using case-insensitive BLEU (Papineni et al., 2002), as implemented in Moses.

The baseline systems were tuned using the Moses version of PRO, a reimplementation of the original

²www.opensubtitles.org

³Our method could also be applied to language model interpolation but we chose to focus on phrase tables in this paper.

algorithm using the sampling scheme recommended by Hopkins and May. We ran 15 iterations of PRO, choosing the weights that maximised BLEU on the tuning set. For the PRO training of the interpolated models, we used the same sampling scheme, with optimisation of the model weights and interpolation weights implemented in Python using `scipy`⁴. The implementation is available in Moses, in the `contrib/promix` directory.

The phrase table interpolation and perplexity-based minimisation of interpolation weights used the code accompanying Sennrich (2012), also available in Moses.

3.2 Results

For each of the two test sets (`nc` and `st`), we compare four different translation systems (three baseline systems, and our new interpolation method):

in Phrase and reordering tables were built from just the in-domain data.

joint Phrase and reordering tables were built from the in- and out-of-domain data, concatenated.

perp Separate phrase tables built on in- and out-of-domain data, interpolated using perplexity minimisation. The reordering table is as for **joint**.

pro-mix As **perp**, but interpolation weights optimised using our modified PRO algorithm.

So the two interpolated models (**perp** and **pro-mix**) are the same as **joint** except that their 4 non-constant phrase features are interpolated across the two separate phrase tables. Note that the language models are the same across all four systems.

The results of this comparison over the 8 language pairs are shown in Figure 1, and summarised in Table 1, which shows the mean BLEU change relative to the **in** system. It can be seen that the **pro-mix** method presented here is out-performing the perplexity optimisation on the `nc` data set, and performing similarly on the `st` data set.

	joint	perp	pro-mix
<code>nc</code>	+0.18	+0.44	+0.91
<code>st</code>	-0.04	+0.55	+0.48

Table 1: Mean BLEU relative to **in** system for each data set. System names as in Figure 1

⁴www.scipy.org

4 Discussion and Conclusions

The results show that the **pro-mix** method is a viable way of tuning systems built with interpolated phrase tables, and performs better than the current perplexity minimisation method on one of two data sets used in experiments. On the other data set (`st`), the out-of-domain data makes much less difference to the system performance in general, most probably because the difference between the in and out-of-domain data sets is much larger (Haddow and Koehn, 2012). Whilst the differences between **pro-mix** and perplexity minimisation are not large on the `nc` test set (about +0.5 BLEU) the results have been demonstrated to apply across many language pairs.

The advantage of the **pro-mix** method over other approaches is that it directly optimises the measure that we are interested in, rather than optimising an intermediate measure and hoping that translation performance improves. In this work we optimise for BLEU, but the same method could easily be used to optimise for any sentence-level translation metric.

Dialectal Arabic to English Machine Translation: Pivoting through Modern Standard Arabic

Wael Salloum and Nizar Habash

Center for Computational Learning Systems

Columbia University

{wael, habash}@ccls.columbia.edu

Abstract

Modern Standard Arabic (MSA) has a wealth of natural language processing (NLP) tools and resources. In comparison, resources for dialectal Arabic (DA), the unstandardized spoken varieties of Arabic, are still lacking. We present ELISSA, a machine translation (MT) system for DA to MSA. ELISSA employs a rule-based approach that relies on morphological analysis, transfer rules and dictionaries in addition to language models to produce MSA paraphrases of DA sentences. ELISSA can be employed as a general preprocessor for DA when using MSA NLP tools. A manual error analysis of ELISSA’s output shows that it produces correct MSA translations over 93% of the time. Using ELISSA to produce MSA versions of DA sentences as part of an MSA-pivoting DA-to-English MT solution, improves BLEU scores on multiple blind test sets between 0.6% and 1.4%.

1 Introduction

Much work has been done on Modern Standard Arabic (MSA) natural language processing (NLP) and machine translation (MT), especially Statistical MT (SMT). MSA has a wealth of resources in terms of morphological analyzers, disambiguation systems, and parallel corpora. In comparison, research on dialectal Arabic (DA), the unstandardized spoken varieties of Arabic, is still lacking in NLP in general and MT in particular. In this paper we present ELISSA, our DA-to-MSA MT system, and show how it can help improve the translation of highly dialectal Arabic text into English by pivoting on MSA.

The ELISSA approach can be summarized as follows. First, ELISSA uses different techniques to identify dialectal words and multi-word constructions (phrases) in a source sentence. Then, ELISSA produces MSA paraphrases for the selected words

and phrase using a rule-based component that depends on the existence of a dialectal morphological analyzer, a list of morphosyntactic transfer rules, and DA-MSA dictionaries. The resulting MSA is in a lattice form that we pass to a language model for n-best decoding. The output of ELISSA, whether a top-1 choice sentence or n-best sentences, is passed to an MSA-English SMT system to produce the English translation sentence. ELISSA-based MSA-pivoting for DA-to-English SMT improves BLEU scores (Papineni et al., 2002) on three blind test sets between 0.6% and 1.4%. A manual error analysis of translated words shows that ELISSA produces correct MSA translations over 93% of the time.

The rest of this paper is structured as follows: Section 2 motivates the use of ELISSA to improve DA-English SMT with an example. Section 3 discusses some of the challenges associated with processing Arabic and its dialects. Section 4 presents related work. Section 5 details ELISSA and its approach and Section 6 presents results evaluating ELISSA under a variety of conditions.

2 Motivating Example

Table 1 shows a motivating example of how pivoting on MSA can dramatically improve the translation quality of a statistical MT system that is trained on mostly MSA-to-English parallel corpora. In this example, we use Google Translate’s online Arabic-English SMT system.¹ The table is divided into two parts. The top part shows a dialectal (Levantine) sentence, its reference translation to English, and its Google Translate translation. The Google Translate translation clearly struggles with most of the DA words, which were probably unseen in the training data (i.e., out-of-vocabulary – OOV) and were con-

¹The system was used on February 21, 2013.

Table 1: A motivating example for DA-to-English MT by pivoting (bridging) on MSA. The top half of the table displays a DA sentence, its human reference translation and the output of Google Translate. The bottom half of the table shows the result of human translation into MSA of the DA sentence before sending it to Google Translate.

sidered proper nouns (transliterated and capitalized). The lack of DA-English parallel corpora suggests pivoting on MSA can improve the translation quality. In the bottom part of the table, we show a human MSA translation of the DA sentence above and its Google translation. We see that the results are quite promising. The goal of ELISSA is to model this DA-MSA translation automatically. In Section 5.4, we revisit this example to discuss ELISSA’s performance on it. We show its output and its corresponding Google translation in Table 3.

3 Challenges for Processing Arabic and its Dialects

Contemporary Arabic is in fact a collection of varieties: MSA, the official language of the Arab World, which has a standard orthography and is used in formal settings; and DAs, the commonly used informal native varieties, which have no standard orthographies but have an increasing presence on the web. Arabic, in general, is a morphologically complex language which has rich inflectional morphology, expressed both templatically and affixationally, and several classes of attachable clitics. For example, the Arabic word *وسيكتبونها* $w+s+y-ktb-wn+hA^2$ ‘and they will write it’ has two proclitics (+ و $w+$ ‘and’ and + $s+$ ‘will’), one prefix -*y-* ‘3rd

person', one suffix -ون *-wn* 'masculine plural' and one pronominal enclitic ها+ *+hA* 'it/her'. DAs differ from MSA phonologically, morphologically and to a lesser degree syntactically. The morphological differences are most noticeably expressed in the use of clitics and affixes that do not exist in MSA. For instance, the Levantine Arabic equivalent of the MSA example above is **وحيكتبوها** *w+H+y-ktb-w+hA* 'and they will write it'. The optionality of vocalic diacritics helps hide some of the differences resulting from vowel changes; compare the diacritized forms: Levantine *wHayikitbuwhA* and MSA *wasayaktubuwnahA*.

All of the NLP challenges of MSA (e.g., optional diacritics and spelling inconsistency) are shared by DA. However, the lack of standard orthographies for the dialects and their numerous varieties pose new challenges. Additionally, DAs are rather impoverished in terms of available tools and resources compared to MSA, e.g., there is very little parallel DA-English corpora and almost no MSA-DA parallel corpora. The number and sophistication of morphological analysis and disambiguation tools in DA is very limited in comparison to MSA (Duh and Kirchhoff, 2005; Habash and Rambow, 2006; Abo Bakr et al., 2008; Habash, 2010; Salloum and Habash, 2011; Habash et al., 2012; Habash et al., 2013). MSA tools cannot be effectively used to handle DA, e.g., Habash and Rambow (2006) report that over one-third of Levantine verbs cannot be analyzed using an MSA morphological analyzer.

4 Related Work

Dialectal Arabic NLP. Several researchers have explored the idea of exploiting existing MSA rich resources to build tools for DA NLP (Chiang et al., 2006). Such approaches typically expect the presence of tools/resources to relate DA words to their MSA variants or translations. Given that DA and MSA do not have much in terms of parallel corpora, rule-based methods to translate DA-to-MSA or other methods to collect word-pair lists have been explored. For example, Abo Bakr et al. (2008) introduced a hybrid approach to transfer a sentence from Egyptian Arabic into MSA. This hybrid system consisted of a statistical system for tokenizing and tagging, and a rule-based system for constructing dialectized MSA sentences. Moreover, Al-Sabbagh and Girju (2010) described an approach of mining the web to build a DA-to-MSA lexicon. In the context of DA-to-English SMT, Riesa and Yarowsky (2006) presented a supervised algorithm for online morpheme segmentation on DA that cut the OOV words by half.

Machine Translation for Closely Related Languages. Using closely related languages has been shown to improve MT quality when resources are limited. Hajič et al. (2000) argued that for very close languages, e.g., Czech and Slovak, it is possible to obtain a better translation quality by using simple methods such as morphological disambiguation, transfer-based MT and word-for-word MT. Zhang (1998) introduced a Cantonese-Mandarin MT that uses transformational grammar rules. In the context of Arabic dialect translation, Sawaf (2010) built a hybrid MT system that uses both statistical and rule-based approaches for DA-to-English MT. In his approach, DA is normalized into MSA using a dialectal morphological analyzer. In previous work, we presented a rule-based DA-MSA system to improve DA-to-English MT (Salloum and Habash, 2011; Salloum and Habash, 2012). Our approach used a DA morphological analyzer (ADAM) and a list of hand-written morphosyntactic transfer rules. This use of “resource-rich” related languages is a specific variant of the more general approach of using pivot/bridge languages (Utiyama and Isahara, 2007; Kumar et al., 2007). In the case of MSA and DA variants, it is plausible to consider the MSA variants of a DA phrase as monolingual

paraphrases (Callison-Burch et al., 2006; Du et al., 2010). Also related is the work by Nakov and Ng (2011), who use morphological knowledge to generate paraphrases for a morphologically rich language, Malay, to extend the phrase table in a Malay-to-English SMT system.

Pivoting on MSA or acquiring more DA-English data? Zbib et al. (2012) demonstrated an approach to cheaply obtaining DA-English data. They used Amazon’s Mechanical Turk (MTurk) to create a DA-English parallel corpus of 1.5M words and added it to a 150M MSA-English parallel corpus to create the training corpus of their SMT system. They also used MTurk to translate their dialectal test set to MSA in order to compare the MSA-pivoting approach to the direct translation from DA to English approach. They showed that even though pivoting on MSA (produced by Human translators in an oracle experiment) can reduce OOV rate to 0.98% from 2.27% for direct translation (without pivoting), it improves by 4.91% BLEU while direct translation improves by 6.81% BLEU over their 12.29% BLEU baseline (direct translation using the 150M MSA system). They concluded that simple vocabulary coverage is not sufficient and the domain mismatch is a more important problem. The approach we take in this paper is orthogonal to such efforts to build parallel data. We plan to study interactions between the two types of solutions in the future.

Our work is most similar to Sawaf (2010)’s MSA-pivoting approach. In his approach, DA is normalized into MSA using character-based DA normalization rules, a DA morphological analyzer, a DA normalization decoder that relies on language models, and a lexicon. Similarly, we use some character normalization rules, a DA morphological analyzer, and DA-MSA dictionaries. In contrast, we use hand-written morphosyntactic transfer rules that focus on translating DA morphemes and lemmas to their MSA equivalents.

In our previous work (Salloum and Habash, 2011; Salloum and Habash, 2012), we applied our approach to tokenized Arabic and our DA-MSA transfer component used feature transfer rules only. We did not use a language model to pick the best path; instead we kept the ambiguity in the lattice and passed it to our SMT system. In contrast, in this paper, we run ELISSA on untokenized Arabic, we use

feature, lemma, and surface form transfer rules, and we pick the best path of the generated MSA lattice through a language model.

Certain aspects of our approach are similar to Riesa and Yarowsky (2006)’s, in that we use morphological analysis for DA to help DA-English MT; but unlike them, we use a rule-based approach to model DA morphology.

5 ELISSA

ELISSA is a DA-to-MSA MT System. ELISSA uses a rule-based approach (with some statistical components) that relies on the existence of a DA morphological analyzer, a list of hand-written transfer rules, and DA-MSA dictionaries to create a mapping of DA to MSA words and construct a lattice of possible sentences. ELISSA uses a language model to rank and select the generated sentences.

ELISSA supports untokenized (raw) input only. ELISSA supports three types of output: top-1 choice, an n-best list or a map file that maps source words/phrases to target phrases. The top-1 and n-best lists are determined using an untokenized MSA language model to rank the paths in the MSA translation output lattice. This variety of output types makes it easy to plug ELISSA with other systems and to use it as a DA preprocessing tool for other MSA systems, e.g., MADA (Habash and Rambow, 2005) or AMIRA (Diab et al., 2007).

ELISSA’s approach consists of three major steps preceded by a *preprocessing and normalization* step, that prepares the input text to be handled (e.g., UTF-8 cleaning, Alif/Ya normalization, word-lengthening normalization), and followed by a *post-processing* step, that produces the output in the desired form (e.g., encoding choice). The three major steps are **Selection**, **Translation**, and **Language Modeling**.

5.1 Selection

In the first step, ELISSA identifies which words or phrases to paraphrase and which words or phrases to leave as is. ELISSA provides different methods (techniques) for selection, and can be configured to use different subsets of them. In Section 6 we use the term “selection mode” to denote a subset of selection methods. Selection methods are classified into *Word-based selection* and *Phrase-based selection*.

Word-based selection. Methods of this type fall in the following categories:

- a. User token-based selection: The user can mark specific words for selection using the tag ‘/DIA’ (stands for ‘dialect’) after each word to select.
- b. User type-based selection: The user can specify a list of words to select from, e.g., OOVs. Also the user can provide a list of words and their frequencies and specify a cut-off threshold to prevent selecting a frequent word.
- c. Morphology-based word selection: ELISSA uses ADAM (Salloum and Habash, 2011) to select words that have DA analyses only (DIAONLY) or DA/MSA analyses (DIAMSA).
- d. Dictionary-based selection: ELISSA selects words based on their existence in the DA side of our DA-MSA dictionaries.
- e. All: ELISSA selects every word in an input sentence.

Phrase-based selection. This selection type uses hand-written rules to identify dialectal multi-word constructions that are mappable to single or multi-word MSA constructions. The current count of these rules is 25. Table 2 presents some rule categories and related examples.

In the current version of ELISSA, words can be selected using either the phrase-based selection method or a word-based selection method, but not both. Phrase-based selection has precedence. We evaluate different settings for selection step in Section 6.

5.2 Translation

In this step, ELISSA translates the selected words and phrases to their MSA equivalent paraphrases. The specific type of selection determines the type of the translation, e.g., phrase-based selected words are translated using phrase-based translation rules. The MSA paraphrases are then used to form an MSA lattice.

Word-based translation. This category has two types of translation techniques: *surface translation* that uses DA-to-MSA surface-to-surface (S2S) transfer rules (TRs) and *deep (morphological) translation* that uses the classic rule-based machine translation flow: analysis, transfer and generation. The

Rule Category	Selection Examples	Translation Examples
Dialectal Idafa	الجيش الوطني بتاعنا Aljyš AlwTny btAṣnA 'the-army the-national ours'	جيشنا الوطني jyšnA AlwTny 'our-army the-national'
Verb + flipped direct and indirect objects	حضر لها ياهن HDrlhA yAhn 'he-prepared-for-her them'	حضرهم لها HDrhm lhA 'he-prepared-them for-her'
Special dialectal expressions	بدو ايها bdw AyAhA 'his-desire her'	يريدها yrydhA 'he-desires-her'
Negation + verb	وما حيكتبوا لو wmA Hyktbwlw 'and-not they-will-write-to-him'	ولن يكتبوا له wln yktbwA lh 'and-will-not they-write to-him'
Negation + agent noun	فمش لاقية fmš lAqyħ 'so-not finding'	فلا تجد flA tjd 'so-not she-finds'
Negation + closed-class words	ما عدكم mA ṣdkm 'not with-you'	ليس لديكم lys ldikm 'not with-you'

Table 2: Examples of some types of phrase-based selection and translation rules.

DA Phrase	و ما راحولا <i>wmA rAHwlA</i> ‘And they did not go to her’				
Analysis	Word 1		Word 2		
	Proclitics	[Lemma & Features]	[Lemma & Features]	[Lemma & Features]	Enclitic
Transfer	w+	mA	rAHw	+l	+A
	conj+	[neg]	[rAH PV subj:3MP]	+prep	+pron _{3FS}
Generation	and+	not	they go	+to	+her
	conj+	[lam]	[ðahab IV subj:3MP]	[Āly]	+pron _{3FS}
MSA Phrase	and+	did not	they go	to	+her
	w+	lm	yðhbwA	Āly	+hA
MSA Phrase	ولم يذهبوا إليها <i>wlm yðhbwA ĀlyhA</i> ‘And they did not go to her’				

Figure 1: An example illustrating the analysis-transfer-generation steps to translate a dialectal multi-word expression into its MSA equivalent phrase.

dialectal morphological analysis step uses ADAM (Salloum and Habash, 2011) to get a list of dialectal analyses. The morphosyntactic transfer step uses lemma-to-lemma (L2L) and features-to-features (F2F) transfer rules to change lemmas, clitics or features, and even split up the dialectal word into multiple MSA word analyses (such as splitting negation words and indirect objects). The MSA morphological generation step uses the general tokenizer/generator TOKAN (Habash, 2007) to generate untokenized surface form words. For more details, see Salloum and Habash (2011).

Phrase-based translation. Unlike the word-based translation techniques which map single DA words to single or multi-word MSA sequences, this technique uses hand-written multi-word transfer rules that map multi-word DA constructions to

single or multi-word MSA constructions. In the current system, there are 47 phrase-based transfer rules. Many of the word-based morphosyntactic transfer rules are re-used for phrase-based translation. Figure 1 shows an example of a phrase-based morphological translation of the two-word DA sequence *wmA rAHwlA* ‘And they did not go to her’. If these two words were spelled as a single word, *wmA rAHwlA*, we would still get the same result using the word-based translation technique only. Table 2 shows some rule categories along with selection and translation examples.

5.3 Language Modeling

The language model (LM) component uses the SRILM lattice-tool for weight assignment and n-best decoding (Stolcke, 2002). ELISSA comes with a default 5-gram LM file trained on ~200M unto-

DA source	(بـالحالـة هـاي) ¹ (ما حـيكتـبـلو) ² عـحيـط ³ (الـصـفـحـه الشـخـصـيه تـبعـو) ⁴ وـلا (بـدـن يـاه) ⁵ يـعـتلـن ⁶ كـومـيـنـات ⁷ (<i>bhAlHALħ hAy</i>) ¹ (<i>mA Hyktbwlw</i>) ² <i>ςHyT</i> ³ (<i>AlSfHh AlšxSyħ tbsw</i>) ⁴ <i>wlA</i> (<i>bdn yAh</i>) ⁵ <i>ybçtln</i> ⁶ <i>kwmyntAi</i> ⁷ <i>lĀnw</i> ⁸ <i>mAxbrhwn</i> ⁹ <i>AymtA</i> ¹⁰ (<i>rH yrwH</i>) ¹¹ <i>ςAlbl</i> ¹² .

Table 3: Revisiting our motivating example, but with ELISSA-based DA-to-MSA middle step. ELISSA’s output is Alif/Ya normalized. Parentheses are added for illustrative reasons to highlight how multi-word DA constructions are selected and translated. Superscript indices link the selected words and phrases with their MSA translations.

kenized Arabic words of Arabic Gigaword (Parker et al., 2009). Users can specify their own LM file and/or interpolate it with our default LM. This is useful for adapting ELISSA’s output to the Arabic side of the training data.

5.4 Revisiting our Motivating Example

We revisit our motivating example in Section 2 and show automatic MSA-pivoting through ELISSA. Table 3 is divided into two parts. The first part is copied from Table 1 for convenience. The second part shows ELISSA’s output on the dialectal sentence and its Google Translate translation. The produced MSA is not perfect, but is clearly an improvement over doing nothing as far as usability for MT into English.

6 Evaluation

In this section, we present two evaluations of ELISSA. The first is an extrinsic evaluation of ELISSA as part of MSA-pivoting for DA-to-English SMT. And the second is an intrinsic evaluation of the quality of ELISSA’s MSA output.

6.1 DA-English MT Evaluation

6.1.1 Experimental Setup

We use the open-source Moses toolkit (Koehn et al., 2007) to build a phrase-based SMT system trained on mostly MSA data (64M words on the Arabic side) obtained from several LDC corpora including some limited DA data. Our system uses

a standard phrase-based architecture. The parallel corpus is word-aligned using GIZA++ (Och and Ney, 2003). Phrase translations of up to 10 words are extracted in the Moses phrase table. The language model for our system is trained on the English side of the bitext augmented with English Gigaword (Graff and Cieri, 2003). We use a 5-gram language model with modified Kneser-Ney smoothing. Feature weights are tuned to maximize BLEU on the NIST MTEval 2006 test set using Minimum Error Rate Training (Och, 2003). This is only done on the baseline systems. The English data is tokenized using simple punctuation-based rules. The Arabic side is segmented according to the Arabic Treebank (ATB) tokenization scheme (Maamouri et al., 2004) using the MADA+TOKAN morphological analyzer and tokenizer v3.1 (Habash and Rambow, 2005; Roth et al., 2008). The Arabic text is also Alif/Ya normalized. MADA-produced Arabic lemmas are used for word alignment.

We use the same development (dev) and test sets used by Salloum and Habash (2011) (we will call them speech-dev and speech-test, respectively) and we compare to them in the next sections. We also evaluate on two web-crawled blind test sets: the Levantine test set presented in Zbib et al. (2012) (we will call it web-lev-test) and the Egyptian Dev-MT-v2 development data of the DARPA BOLT program (we will call it web-egy-test). The speech-dev set has 1,496 sentences with 32,047 untokenized Arabic words. The speech-test set has 1,568 sentences with

32,492 untokenized Arabic words. The web-level-test set has 2,728 sentences with 21,179 untokenized Arabic words. The web-egy-test set has 1,553 sentences with 21,495 untokenized Arabic words. The two speech test sets contain multi-dialect (e.g., Iraqi, Levantine, Gulf, and Egyptian) broadcast conversational (BC) segments (with three reference translations), and broadcast news (BN) segments (with only one reference, replicated three times). The web-egy-test has two references while the web-level-test has only one reference. Results are presented in terms of BLEU (Papineni et al., 2002). All evaluation results are case insensitive.

6.1.2 Results on the Development Set

We experimented with different method combinations in the selection and translation components in ELISSA. We use the term selection mode and translation mode to denote a certain combination of methods in selection or translation, respectively. Due to limited space, we only present the best selection mode variation experiments. Other selection modes were tried but they proved to be consistently lower than the rest. The ‘F2F+L2L; S2S’ word-based translation mode (using morphological transfer of features and lemmas along with surface form transfer) showed to be consistently better than other method combinations across all selection modes. In this paper we only use ‘F2F+L2L; S2S’ word-based translation mode. Phrase-based translation mode is used when phrase-based selection mode is used.

To rank paraphrases in the generated MSA lattice, we combine two 5-gram untokenized Arabic language models: one is trained on Arabic Gigaword data and the other is trained the Arabic side of our SMT training data. The use of the latter LM gave frequent dialectal phrases a higher chance to appear in ELISSA’s output; thus, making the output “more dialectal” but adapting it to our SMT input. Experiments showed that using both LMs is better than using each one alone.

In all the experiments, we run the DA sentence through ELISSA to generate a top-1 MSA translation, which we then tokenize through MADA before sending to the MSA-English SMT system. Our baseline is to not run ELISSA at all; instead, we send the DA sentence through MADA before applying the MSA-English MT system.

Table 4 summarizes the experiments and results

on the dev set. The rows of the table are the different systems (baseline and ELISSA’s experiments). All differences in BLEU scores from the baseline are statistically significant above the 95% level. Statistical significance is computed using paired bootstrap re-sampling (Koehn, 2004). The name of the system in ELISSA’s experiments denotes the combination of selection method. ELISSA’s experiments are grouped into three groups: simple selection, frequency-based selection, and phrase-based selection. Simple selection group consists of five systems: OOV, ADAM, OOV U ADAM, DICT, and OOV U ADAM U DICT. The OOV selection mode identifies the untokenized OOV words. In the ADAM selection mode, or the morphological selection mode, we use ADAM to identify dialectal words. Experiments showed that ADAM’s DI-AMSA mode (selecting words that have at least one dialectal analysis) is slightly better than ADAM’s DIAONLY mode (selecting words that have only dialectal analyses and no MSA ones). The OOV U ADAM selection mode is the union of the OOVs and ADAM selection modes. In DICT selection mode, we select dialectal words that exist in our DA-MSA dictionaries. The OOV U ADAM U DICT selection mode is the union of the OOVs, ADAM, and DICT selection modes. The results show that combining the output of OOV selection method and ADAM selection method is the best. DICT selection method hurts the performance of the system when used because dictionaries usually have frequent dialectal words that the SMT system already knows how to handle.

In the frequency-based selection group, we exclude from word selection all words with number of occurrences in the training data that is above a certain threshold. This threshold was determined empirically to be 50. The string ‘- (Freq \geq 50)’ means that all words with frequencies of 50 or more should not be selected. The results show that excluding frequent dialectal words improves the best simple selection system. It also shows that using DICT selection improves the best system if frequent words are excluded.

In the last system group, phrase+word-based selection, phrase-based selection is used to select phrases and add them on top of the best performers of the previous two groups. Phrase-based trans-

Test Set	speech-dev	
	BLEU	Diff.
Baseline	37.20	0.00
Select: OOV	37.75	0.55
Select: ADAM	37.88	0.68
Select: OOV U ADAM	37.89	0.69
Select: DICT	37.06	-0.14
Select: OOV U ADAM U DICT	37.53	0.33
Select: (OOV U ADAM) - (Freq >= 50)	37.96	0.76
Select: (OOV U ADAM U DICT) - (Freq >= 50)	38.00	0.80
Select: Phrase; (OOV U ADAM)	37.99	0.79
Select: Phrase; ((OOV U ADAM) - (Freq >= 50))	38.05	0.85
Select: Phrase; ((OOV U ADAM U DICT) - (Freq >= 50))	38.10	0.90

Table 4: Results for the speech-dev set in terms of BLEU. The ‘Diff.’ column shows result differences from the baseline. The rows of the table are the different systems (baseline and ELISSA’s experiments). The name of the system in ELISSA’s experiments denotes the combination of selection method. In all ELISSA’s experiments, all word-based translation methods are tried. Phrase-based translation methods are used when phrase-based selection is used (i.e., the last three rows). The best system is in bold.

lation is also added to word-based translation. Results show that selecting and translating phrases improve the three best performers of word-based selection. The best performer, shown in the last raw, suggests using phrase-based selection and restricted word-based selection. The restriction is to include OOV words and selected low frequency words that have at least one dialectal analysis or appear in our dialectal dictionaries. Comparing the best performer to the OOV selection mode system shows that translating low frequency in-vocabulary dialectal words and phrases to their MSA paraphrases can improve the English translation. This is a similar conclusion to our previous work in Salloum and Habash (2011).

6.1.3 Results on the Blind Test Sets

We run the system settings that performed best on the dev set along with the OOV selection mode system on the three blind test set. Results and their differences from the baseline are reported in Table 5. We see that OOV selection mode system always improves over the baseline for all test sets. Also, the best performer on the dev is the best performer for all test sets. The improvements of the best performer over the OOV selection mode system on all test sets confirm that translating low frequency in-vocabulary dialectal words and phrases to their MSA paraphrases can improve the English translation. Its improvements over the baseline for the three test sets are: 0.95% absolute BLEU (or 2.5% relative) for the speech-test, 1.41% absolute BLEU (or 15.4% rela-

tive) for the web-lev-test, and 0.61% absolute BLEU (or 3.2% relative) for the web-egy-test.

6.1.4 A Case Study

We next examine an example in some detail. Table 6 shows a dialectal sentence along with its ELISSA’s translation, English references, the output of the baseline system and the output of our best system. The example shows a dialectal word هالبلغ *hAlmbly* ‘this-amount/sum’, which is not translated by the baseline (although it appears in the training data, but quite infrequently such that all of its phrase table occurrences have restricted contexts, making it effectively an OOV). The dialectal proclitic + *hAl*+ ‘this-’ comes sometimes in the dialectal construction: ‘*hAl+NOUN DEM*’ (as in this example: هالبلغ *hAlmbly* *hðA* ‘this-amount/sum this’). ELISSA’s selection component captures this multi-word expression and its translation component produces the following paraphrases: هـا المـبلغ *hðA Almbly* ‘this amount/sum’ (*hðA* is used with masculine singular nouns), هذه المـبلغ *hðh Almbly* ‘this amount/sum’ (*hðh* is used with feminine singular or irrational plural nouns), and هـؤلاء المـبلغ *hŵIA Almbly* ‘these amount/sum’ (*hŵIA* is used with rational plural nouns). ELISSA’s language modeling component picks the first MSA paraphrase, which perfectly fits the context and satisfies the gender/number/rationality agreement (note that the word *Almbly* is an irrational masculine singular

Test Set	speech-test		web-lev-test		web-egy-test	
	BLEU	Diff.	BLEU	Diff.	BLEU	Diff.
Baseline	38.18	0.00	9.13	0.00	18.98	0.00
Select: OOV	38.76	0.58	9.65	0.62	19.19	0.21
Select: Phrase; ((OOV U ADAM U DICT) - (Freq >= 50))	39.13	0.95	10.54	1.41	19.59	0.61

Table 5: Results for the three blind test sets (table columns) in terms of BLEU. The ‘Diff.’ columns show result differences from the baselines. The rows of the table are the different systems (baselines and ELISSA’s experiments). The best systems are in bold.

noun). For more on Arabic morpho-syntactic agreement patterns, see Alkuhlani and Habash (2011). Finally, the best system translation for the selected phrase is ‘this sum’. We can see how both the accuracy and fluency of the sentence have improved.

DA sentence	fmA mA AtSwr hAlmblγ hðA ysny.
ELISSA’s output	fmA mA AtSwr hðA Almblγ ysny.
References	I don’t think this amount is I mean. So I do not I do not think this cost I mean. So I do not imagine this sum I mean
Baseline	So i don’t think hAlmblg this means.
Best system	So i don’t think this sum i mean.

Table 6: An example of handling dialectal words/phrases using ELISSA and its effect on the accuracy and fluency of the English translation. Words of interest are bolded.

6.2 DA-to-MSA Translation Quality

We conducted a manual error analysis comparing ELISSA’s input (the original dev set) to its output using our best system settings from the experiments above. Out of 708 affected sentences, we randomly selected 300 sentences (42%). Out of the 482 handled tokens, 449 (93.15%) tokens have good MSA translations, and 33 (6.85%) tokens have wrong MSA translations. Most of the wrong translations are due to spelling errors, proper nouns, and weak input sentence fluency (especially due to speech effect). This analysis clearly validates ELISSA’s MSA output. Of course, a correct MSA output can still be mistranslated by the MT system we used above if it is not in the vocabulary of the MT system.

7 Conclusion and Future Work

We presented ELISSA, a tool for DA-MSA translation. ELISSA employs a rule-based MT approach that relies on morphological analysis, transfer rules and dictionaries in addition to language models to produce MSA paraphrases of dialectal sentences.

Using ELISSA to produce MSA versions of dialectal sentences as part of an MSA-pivoting DA-to-English MT solution, improves BLEU scores on three blind test sets by: 0.95% absolute BLEU (or 2.5% relative) for a speech multi-dialect (Iraqi, Levantine, Gulf, Egyptian) test set, 1.41% absolute BLEU (or 15.4% relative) for a web-crawled Levantine test set, and 0.61% absolute BLEU (or 3.2% relative) for a web-crawled Egyptian test set. A manual error analysis of translated selected words shows that our system produces correct MSA translations over 93% of the time.

In the future, we plan to extend ELISSA’s coverage of phenomena in the handled dialects and to new dialects. We also plan to automatically learn additional rules from limited available data (DA-MSA or DA-English). We also would like to do additional MT experiments where we use ELISSA to preprocess the training data, comparable to experiments done by Sawaf (2010). We are interested in studying how our approach can be combined with solutions that simply add more dialectal training data since the two directions are complementary in that they address linguistic normalization and domain coverage. Finally, we look forward to experimenting with ELISSA as a preprocessing system for a variety of dialect NLP applications similar to Chiang et al. (2006)’s work on dialect parsing, for example.

ELISSA will be publicly available. Please contact the authors for more information.

What to do about bad language on the internet

Jacob Eisenstein

Georgia Institute of Technology

Abstract

The rise of social media has brought computational linguistics in ever-closer contact with *bad language*: text that defies our expectations about vocabulary, spelling, and syntax. This paper surveys the landscape of bad language, and offers a critical review of the NLP community’s response, which has largely followed two paths: normalization and domain adaptation. Each approach is evaluated in the context of theoretical and empirical work on computer-mediated communication. In addition, the paper presents a quantitative analysis of the lexical diversity of social media text, and its relationship to other corpora.

1 Introduction

As social media becomes an increasingly important application domain for natural language processing, we encounter language that is substantially different from many benchmark corpora. The following examples are all from the social media service Twitter:

- *Work on farm Fri. Burning piles of brush WindyFire got out of control. Thank God for good naber He help get undr control Pants-BurnLegWound.* (Senator Charles Grassley)
- *Boom! Ya ur website suxx bro*
(Sarah Silverman)
- *...dats why pluto is pluto it can neva b a star*
(Shaquille O’Neil)
- *michelle obama great. job. and. whit all my respect she. look. great. congrats. to. her.*
(Ozzie Guillen)

These examples are selected from celebrities (for privacy reasons), but they contain linguistic challenges that are endemic to the medium, including non-standard punctuation, capitalization, spelling, vocabulary, and syntax. The consequences for language technology are dire: a series of papers has detailed how state-of-the-art natural language processing (NLP) systems perform significantly worse on social media text. In part-of-speech tagging, the accuracy of the Stanford tagger (Toutanova et al., 2003) falls from 97% on Wall Street Journal text to 85% accuracy on Twitter (Gimpel et al., 2011). In named entity recognition, the CoNLL-trained Stanford recognizer achieves 44% F-measure (Ritter et al., 2011), down from 86% on the CoNLL test set (Finkel et al., 2005). In parsing, Foster et al. (2011) report double-digit decreases in accuracy for four different state-of-the-art parsers when applied to social media text.

The application of language technology to social media is potentially transformative, leveraging the knowledge and perspectives of millions of people. But to deliver on this potential, the problems at the core of the NLP pipeline must be addressed. A growing thread of research takes up this challenge, including a shared task and workshop on “parsing the web,” with new corpora which appear to sit somewhere between the Wall Street Journal and Twitter on the spectrum of bad language (Petrov and McDonald, 2012). But perhaps surprisingly, very little of this research has considered *why* social media language is so different. This review paper attempts to shed some light on this question, surveying a strong tradition of empirical and theoreti-

cal research on computer-mediated communication (CMC). I argue that the two main computational approaches to dealing with bad language — normalization and domain adaptation — are based on theories of social media language that are not descriptively accurate. I have worked and continue to work in both of these areas, so I make this argument not as a criticism of others, but in a spirit of self-reflection. It is hoped that a greater engagement with sociolinguistic and CMC research will lead to new, nuanced approaches to the challenge of bad language.

Why so much Twitter? Most of the examples in this paper will focus on Twitter, a microblogging service. Munro and Manning (2012) argue that Twitter has unfairly dominated recent research, at the expense of email and SMS text messages, which they found to be both linguistically distinct from Twitter and significantly more prevalent (in 2010). This matches earlier research arguing that email contained relatively little “neography,” compared with text messages and chat (Anis, 2007).

A crucial advantage for Twitter is that it is public by default, while SMS and email are private. This makes Twitter data less problematic from a privacy standpoint,¹ far easier to obtain, and more amenable to target applications such as large-scale mining of events (Sakaki et al., 2010; Benson et al., 2011) and opinions (Sauper et al., 2011). Similar argument could be made on behalf of other public social media, such as blog comments (Ali-Hasan and Adamic, 2007), forums, and chatrooms (Paolillo, 2001). The main advantage of Twitter over these media is convenience in gathering large datasets through a single streaming interface. More comparative evaluation is needed to determine linguistic similarities and differences between Twitter and these other media; Section 4 presents an evaluation of the lexical similarity between Twitter and political blogs.

2 A tour of bad language

While many NLP researchers and engineers have wrestled with the difficulties imposed by bad language, there has been relatively little consideration of *why* language in social media is so different from our other corpora. A survey of laypeo-

ple found that more than half of the respondents agreed with the following partial explanations for non-standard spelling on the internet: “people are unsure of the correct spellings,” “it’s faster,” “it’s become the norm,” and “people want to represent their own dialects and/or accents” (Jones, 2010). Let us now consider the evidence for these and other potential explanations.

2.1 Illiteracy

Some commentators have fixated on the proposal that the authors of non-standard language in social media are simply unaware or incapable of using more standard language (Thurlow, 2006). But empirical research suggests that many users of bad language are capable of using more traditional forms. Drouin and Davis (2009) find no significant differences in the literacy scores of individuals who do or do not use non-standard vocabulary in text messages. Tagliamonte and Denis (2008) review traces of instant messaging conversations among students, arguing that they “pick and choose ... from the entire stylistic repertoire of the language” in a way that would be impossible without skilled command of both formal and informal registers. While news text is usually more carefully composed and edited than much of the language in social media, there is little evidence that bad language results from an inability to speak anything else.

2.2 Length limits

In the case of Twitter, the limit of 140 characters for each message is frequently cited as an explanation for bad language (Finin et al., 2010). Does Twitter’s character limit cause users to prefer shorter words, such as *u* instead of *you*? If so, one might expect shortening to be used most frequently in messages that are near the 140-character limit. Using a dataset of one million English-language tweets (Bamman et al., 2012), I have computed the average length of messages containing both standard words and their non-standard alternatives, focusing on the top five non-standard shortenings identified by the automatic method of Gouws et al. (2011a). The shortening *ur* can substitute for both *your* and *you’re*. While *wit* and *bout* are also spellings for standard words, manual examination of one hundred randomly selected examples for each surface form revealed only one

¹boyd and Crawford (2012) note that “public by default” data still raises important ethical considerations.

standard	length	alternative	length
<i>your</i>	85.1 ± 0.4	<i>ur</i>	81.9 ± 0.6
<i>you're</i>	90.0 ± 0.1		
<i>with</i>	87.9 ± 0.3	<i>wit</i>	78.8 ± 0.7
<i>going</i>	82.7 ± 0.5	<i>goin</i>	72.2 ± 1.0
<i>know</i>	86.1 ± 0.4	<i>kno</i>	78.4 ± 1.0
<i>about</i>	88.9 ± 0.4	<i>bout</i>	74.5 ± 0.7

Table 1: Average length of messages containing standard forms and their shortenings

case in which the standard meaning was intended for *wit*, and none for *bout*.

The average message lengths are shown in Table 1. In all five cases, the non-standard form tends to be used in shorter messages — not in long messages near the 140 character limit. Moreover, this difference is substantially greater than the saving of one or two characters offered by shortened form. This is not consistent with the explanation that Twitter’s character limit is the primary factor driving the use of shortened forms. It is still possible that Twitter’s length limitations might indirectly cause word shortenings: for example, by legitimizing shortened forms or causing authors to develop a habit of preferring them. But factors other than the length limit must be recruited to explain why such conventions or habits apply only to some messages and not others.

2.3 Text input affordances

Text input affordances — whether standard keyboards or predictive entry on mobile devices — play a role in computer-mediated communication that is perhaps under-appreciated. Gouws et al. (2011b) investigate orthographic variation on Twitter, and find differences across devices: for example, that messages from iPhones include more contractions than messages from Blackberries, and that tweets sent from the web browser are more likely to drop vowels. While each affordance facilitates some writing styles and inhibits others, the affordances themselves are unevenly distributed across users. For example, older people may prefer standard keyboards, and wealthier people may be more likely to own iPhones. Affordances are a moving target: new devices and software are constantly becoming available, the software itself may adapt to the user’s in-

put, and the user may adapt to the software and device.

2.4 Pragmatics

Emoticons are frequently thought of as introducing an expressive, non-verbal component into written language, mirroring the role played by facial expressions in speech (Walther and D’Addario, 2001), but they can also be seen as playing a pragmatic function: marking an utterance as facetious, or demonstrating a non-confrontational, less invested stance (Dresner and Herring, 2010). In many cases, **phrasal abbreviations** like *lol* (*laugh out loud*), *lmao* (*laughing my ass off*), *smh* (*shake my head*), and *ikr* (*i know, right?*) play a similar role: *yea she dnt like me lol; lmao I’m playin son*. A key difference from emoticons is that abbreviations can act as constituents, as in *smh at your ignorance*. Another form of non-standard language is **expressive lengthening** (e.g., *coooolllllll*), found by Brody and Diakopoulos (2011) to indicate subjectivity and sentiment. In running dialogues — such as in online multiplayer games — the symbols * and ^ can play an explicit pragmatic function (Collister, 2011; Collister, 2012).

2.5 Social variables

A series of papers has documented the interactions between social media text and social variables such as age (Burger and Henderson, 2006; Argamon et al., 2007; Rosenthal and McKeown, 2011), gender (Burger et al., 2011; Rao et al., 2010), race (Eisenstein et al., 2011), and location (Eisenstein et al., 2010; Wing and Baldridge, 2011). From this literature, it is clear that many of the features that characterize bad language have strong associations with specific social variables. In some cases, these associations mirror linguistic variables known from speech — such as geographically-associated lexical items like *hella*, or transcriptions of phonological variables like “g-dropping” (Eisenstein et al., 2010). But in other cases, apparently new lexical items, such as the abbreviations *ctfu*, *lls*, and *af*, acquire surprisingly strong associations with geographical areas and demographic groups (Eisenstein et al., 2011).

A robust finding from the sociolinguistics literature is that non-standard forms that mark social vari-

ables, such as regional dialects, are often inhibited in formal registers (Labov, 1972). For example, while the Pittsburgh spoken dialect sometimes features the address term *yinz* (Johnstone et al., 2006), one would not expect to find many examples in financial reports. Other investigators have found that much of the content in Twitter concerns social events and self presentation (Ramage et al., 2010), which may encourage the use of less formal registers in which socially-marketed language is uninhibited.

The use of non-standard language is often seen as a form of *identity work*, signaling authenticity, solidarity, or resistance to norms imposed from above (Bucholtz and Hall, 2005). In spoken language, many of the linguistic variables that perform identity work are phonological — for example, Eckert (2000) showed how the northern cities vowel shift was used by a subset of suburban teenagers to index affiliation with Detroit. The emergence of new linguistic variables in social media suggests that this identity work is as necessary in social media as it is in spoken language. Some of these new variables are transcriptions of existing spoken language variables: like *finna*, which transcribes *fixing to*. Others — abbreviations like *ctfu* and emoticons — seem to be linguistic inventions created to meet the needs of social communication in a new medium. In an early study of variation in social media, Paolillo (1999) notes that code-switching between English and Hindi also performs this type of identity work.

Finally, it is an uncomfortable fact that the text in many of our most frequently-used corpora was written and edited predominantly by working-age white men. The Penn Treebank is composed of professionally-written news text from 1989, when minorities comprised 7.5% of the print journalism workforce; the proportion of women in the journalism workforce was first recorded in 1999, when it was 37% (American Society of Newspaper Editors, 1999). In contrast, Twitter users in the USA contain an equal proportion of men and women, and a higher proportion of young adults and minorities than in the population as a whole (Smith and Brewer, 2012). Such demographic differences are very likely to lead to differences in language (Green, 2002; Labov, 2001; Eckert and McConnell-Ginet, 2003).

Overall, the reasons for language diversity in social media are manifold, though some of the most

frequently cited explanations (illiteracy and length restrictions) do not hold up to scrutiny. The increasing prevalence of emoticons, phrasal abbreviations (*lol*, *ctfu*), and expressive lengthening may reflect the increasing use of written language for ephemeral social interaction, with the concomitant need for multiple channels through which to express multiple types of meaning. The fact many such neologisms are closely circumscribed in geography and demographics may reflect diffusion through social networks that are assortative on exactly these dimensions (Backstrom et al., 2010; Thelwall, 2009). But an additional consideration is that non-standard language is deliberately deployed in the performance of identity work and stancetaking. This seems a particularly salient explanation for the use of lexical variables that originate in spoken language (*jawn*, *hella*), and for the orthographic transcription of phonological variation (Eisenstein, 2013). Determining the role and relative importance of social network diffusion and identity work as factors in the diversification of social media language is an exciting direction for future research.

3 What can we do about it?

Having surveyed the landscape of bad language and its possible causes, let us now turn to the responses offered by the language technology research community.

3.1 Normalization

One approach to dealing with bad language is to turn it good: “normalizing” social media or SMS messages to better conform to the sort of language that our technology expects. Approaches to normalization include the noisy-channel model (Cook and Stevenson, 2009), string and distributional similarity (Han and Baldwin, 2011; Han et al., 2012), sequence labeling (Choudhury et al., 2007; Liu et al., 2011a), and machine translation (Aw et al., 2006). As this task has been the focus of substantial attention in recent years, labeled datasets have become available and accuracies have climbed.

That said, it is surprisingly difficult to find a precise definition of the normalization task. Writing before social media was a significant focus for NLP, Sproat et al. (2001) proposed to replace non-

standard words with “the contextually appropriate word or sequence of words.” In some cases, this seems clear enough: we can rewrite *dat's why pluto is pluto* with *that's why...* But it is not difficult to find cases that are less clear, putting would-be normalizers in a difficult position. The labeled dataset of Han and Baldwin (2011) addresses a more tractable subset of the normalization problem, annotating only token-to-token normalizations. Thus, *imma* — a transcription of *I'm gonna*, which in turn transcribes *I'm going to* — is not normalized in this dataset. Abbreviations like *LOL* and *WTF* are also not normalized, even when they are used to abbreviate syntactic constituents, as in *wtf is the matter with you?* Nor are words like *hella* and *jawn* normalized, since they have no obvious one-word transcription in standard English. These decisions no doubt help to solidify the reliability of the annotations, but they provide an overly optimistic impression of the ability of string edit distance and related similarity-based techniques to normalize bad language. The resulting gold standard annotations seem little more amenable to automated parsing and information extraction than the original text.

But if we critique normalization for not going far enough, we must also ask whether it goes too far. The logic of normalization presupposes that the “norm” can be identified unambiguously, and that there is a direct mapping from non-standard words to the elements in this normal set. On closer examination, the norm reveals itself to be slippery. Whose norm are we targeting? Should we normalize *flvr* to *flavor* or *flavour*? Where does the normal end and the abnormal begin? For example, Han and Baldwin normalize *ain* to *ain't*, but not all the way to *isn't*. While *ain't* is certainly well-known to speakers of Standard American English, it does not appear in the Penn Treebank and probably could not be used in the Wall Street Journal, except in quotation.

Normalization is often impossible without changing the meaning of the text. Should we normalize the final word of *ya ur website suxx bro* to *brother*? At the very least, this adds semantic ambiguity where there was none before (is she talking to her biological brother? or possibly to a monk?). Language variation does not arise from passing standard text through a noisy channel; it often serves a pragmatic and/or stancetaking (Du Bois, 2007) function. Elim-

inating variation would strip those additional layers of meaning from whatever propositional content might survive the normalization process. Sarah Silverman's *ya ur website suxx bro* can only be understood as a critique from a caricatured persona — the type of person who ends sentences with *bro*. Similarly, we can assume that Shaquille O'Neil is capable of writing *that's why Pluto is Pluto*, but that to do so would convey an undesirably didactic and authoritative stance towards the audience and topic.

This is not to deny that there is great potential value in research aimed at understanding orthographic variation through a combination of local context, string similarity, and related finite-state machinery. Given the productivity of orthographic substitutions in social media text, it is clear that language technology must be made more robust. Normalization may point the way towards such robustness, even if we do not build an explicit normalization component directly into the language processing pipeline. Another potential benefit of this research is to better understand the underlying orthographic processes that lead to the diversity of language in social media, how these processes diffuse over social networks, and how they impact comprehensibility for both the target and non-target audiences.

3.2 Domain adaptation

Rather than adapting text to fit our tools, we may instead adapt our tools to fit the text. A series of papers has followed the mold of “NLP for Twitter,” including part-of-speech tagging (Gimpel et al., 2011; Owoputi et al., 2013), named entity recognition (Finin et al., 2010; Ritter et al., 2011; Liu et al., 2011b), parsing (Foster et al., 2011), dialogue modeling (Ritter et al., 2010) and summarization (Sharifi et al., 2010). These papers adapt various parts of the natural language processing pipeline for social media text, and make use of a range of techniques:

- **preprocessing** to normalize expressive lengthening, and eliminate or group all hashtags, usernames, and URLs (Gimpel et al., 2011; Foster et al., 2011)
- **new labeled data**, enabling the application of semi-supervised learning (Finin et al., 2010; Gimpel et al., 2011; Ritter et al., 2011)

- **new annotation schemes** specifically customized for social media text (Gimpel et al., 2011)
- **self-training** on unlabeled social media text (Foster et al., 2011)
- **distributional features** to address the sparsity of bag-of-words features (Gimpel et al., 2011; Owoputi et al., 2013; Ritter et al., 2011)
- **joint normalization**, incorporated directly into downstream application (Liu et al., 2012)
- **distant supervision**, using named entity ontologies and topic models (Ritter et al., 2011)

Only a few of these techniques (normalization and new annotation systems) are specific to social media; the rest can found in other domain adaptation settings. Is domain adaptation appropriate for social media? Darling et al. (2012) argue that social media is not a coherent domain at all, and that a POS tagger for Twitter will not necessarily generalize to other social media. One can go further: Twitter itself is not a unified genre, it is composed of many different styles and registers, with widely varying expectations for the degree of standardness and dimensions of variation (Androutsopoulos, 2011). I am the co-author on a paper entitled “Part-of-speech tagging for Twitter,” but if we take this title literally, it is impossible on a trivial level: Twitter contains text in dozens or hundreds of languages, including many for which no POS tagger exists. Even within a single language — setting aside issues of code-switching (Paolillo, 1996) — Twitter and other social media can contain registers ranging from hashtag wordplay (Naaman et al., 2011) to the official pronouncements of the British Monarchy. And even if all good language is alike, bad language can be bad in many different ways — as Androutsopoulos (2011) notes when contrasting the types of variation encountered when “visiting a gamer forum” versus “joining the Twitter profile of a rap star.”

4 The lexical coherence of social media

The internal coherence of social media — and its relationship to other types of text — can be quantified in terms of the similarity of distributions over

bigrams. While there are many techniques for comparing word distributions, I apply the relatively simple method of counting out-of-vocabulary (OOV) bigrams. The relationship between OOV rate and domain adaptation has been explored by McClosky et al. (2010), who use it as a feature to predict how well a parser will perform when applied across domains.²

Specifically, the datasets A and B are compared by counting the number of bigram tokens in A that are unseen in B . The following corpora are compared:

- **Twitter-month**: randomly selected tweets from each month between January 2010 to October 2012 (Eisenstein et al., 2012).
- **Twitter-hour**: randomly selected tweets from each hour of the day, randomly sampled during the period from January 2010 to October 2012.
- **Twitter-#**: tweets in which the first token is a hashtag. The hashtag itself is not included in the bigram counts; see below for more details on which bigrams are included.
- **Twitter-@**: tweets in which the first token is a username. The username itself is not included in the bigram counts.
- **Penn Treebank**: sections 2-21
- **Infinite Jest**: the text of the 1996 novel by David Foster Wallace (Wallace, 2012). Consists of only 482,558 tokens.
- **Blog articles**: A randomly-sampled subset of the American political blog posts gathered by Yano et al. (2009).
- **Blog comments**: A randomly-selected subset of comments associated with the blog posts described above.

In all corpora, only fully alphabetic tokens are counted; thus, all hashtags and usernames are discarded. The Twitter text is tokenized using Tweet-

²A very recent study compares Twitter with other corpora, using a number of alternative metrics, such as the use of high and low frequency words, pronouns, and intensifiers (Hu et al., 2013). This is complementary to the present study, which focuses on the degree of difference in the lexical distributions of corpora gathered from various media.

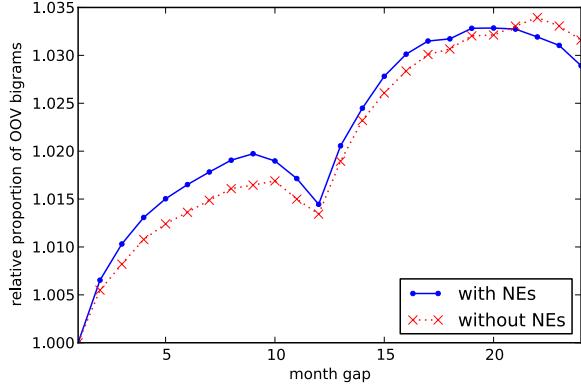

Figure 1: Lexical mismatch increases over time, as social media language evolves.

motif;³ the Penn Treebank data uses the gold standard tokenization; Infinite Jest and the blog data are tokenized using NLTK (Bird et al., 2009). All tokens are downcased, and sequences of three or more consecutive identical characters are reduced to three characters (e.g., *cooooo* → *coool*). All Twitter corpora are subject to the following filters: messages must be from the United States and should be written in English,⁴ they may not include hyperlinks (eliminating most marketing messages), they may not be retweets, and the author must not have more than 1,000 followers or follow more than 1,000 people. These criteria serve to eliminate text from celebrities, businesses, or automated bots.

Twitter over time Figure 1 shows how the proportion of out-of-vocabulary bigrams increases over time. It is possible that the core features of language are constant but the set of named entities that are mentioned changes over time. To control for this, the CMU Twitter Part-of-Speech tagger (Owoputi et al., 2013) was used to identify named entity mentions, and they were replaced with a special token.

³<https://github.com/brendano/tweetmotif>

⁴Approximate language detection was performed as follows. We first identify the 1000 most common words, then sort all *authors* by the proportion of these types that they used, and eliminate the bottom 10%. This filtering mechanism eliminates individuals who never write in English, but a small amount of foreign language still enters the dataset via code-switching authors. The effect of more advanced language detection methods (Bergsma et al., 2012) on these results may be considered in future work.

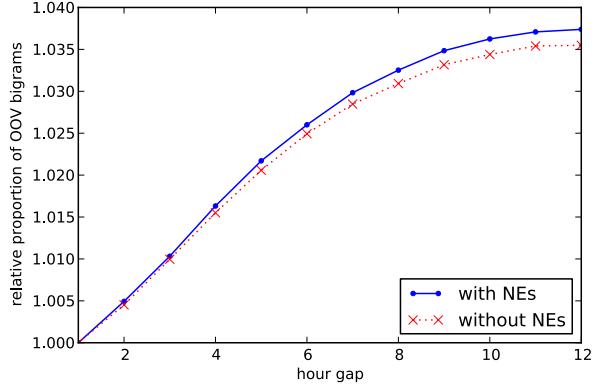

Figure 2: Different times of day have unique lexical signatures, reflecting differing topics and authors.

The OOV rate is standardized with respect to a one-month time gap, where it is 24.4% when named entities are included, and 21.3% when they are not. These rates reach maxima at 25.2% and 22.0% respectively, with dips at 12 and 24 months indicating cyclic yearly effects. While the proportion of OOV tokens is smaller when named entities are not included, the rate of growth is similar in each case. The steadily increasing rate of OOV bigrams suggests that we cannot annotate our way out of the bad language problem. An NLP system trained from data gathered in January 2010 will be increasingly outdated as time passes and social media language continues to evolve.

One need not wait months to see language change on Twitter: marked changes can be observed over the course of a single day (Golder and Macy, 2011). A quantitative comparison is shown in Figure 2. Here the OOV rate is standardized with respect to a one-hour gap, where it is 24.2% when named entities are included, and 21.1% when they are not. These rates rise monotonically as the time gap increases, peaking at 25.1% and 21.9% respectively. Such diurnal changes may reflect the diverse language of the different types of authors who post throughout the day.

Types of usage The **Twitter-#** and **Twitter-@** corpora are designed to capture the diversity of ways in which social media is used to communicate. **Twitter-#** contains tweets that begin with hashtags, and are thus more likely to be part of running jokes

or trending topics (Naaman et al., 2011). **Twitter-@** contains tweets that begin with usernames — an addressing mechanism that is used to maintain dialogue threads on the site. These datasets are compared with a set of randomly selected tweets from June 2011, and with several other corpora: Penn Treebank, the novel Infinite Jest, and text and comments from political blogs. There was no attempt to remove named entities from any of these corpora, as such a comparison would merely reflect the different accuracy levels of NER in each corpus.

The results are shown in Table 2. A few observations stand out. First, the Penn Treebank is the clear outlier: a PTB dictionary has by far the most OOV tokens for all three Twitter domains and Infinite Jest, although it is a better match for the blog corpora than Infinite Jest is. Second, the social media are fairly internally coherent: the Twitter datasets better match each other than any other corpus, with a maximum OOV rate of 33.4 for **Twitter-#** against **Twitter-@**, though this is significantly higher than the OOV rate of 27.8 between two separate generic Twitter samples drawn from the same month. Finally, the OOV rate increase between Twitter and blogs — also social media — is substantial. Contrary to expectations, the **Blog-body** corpus was no closer to the **PTB** standard than **Blog-comment**.

These results suggest that the Penn Treebank corpus is so distant from social media that there are indeed substantial gains to be reaped by adapting from news text towards generic Twitter or Blog target domains. The internal differences within these social media — at least as measured by the distinctions drawn in Table 2 — are much smaller than the differences between these corpora and the PTB standard. However, in the long run, the effectiveness of this approach will be limited, as it is clear from Figure 1 that social media is a moving target. Any static system that we build today, whether by manual annotation or automated adaptation, will see its performance decay over time.

5 What to do next

Language is shaped by a constant negotiation between processes that encourage change and linguistic diversity, and countervailing processes that enforce existing norms. The decision of the NLP com-

munity to focus so much effort on news text is eminently justified on practical grounds, but has unintended consequences not just for technology but for language itself. By developing software that works best for standard linguistic forms, we throw the weight of language technology behind those forms, and against variants that are preferred by disempowered groups. By adopting a model of “normalization,” we declare one version of language to be the norm, and all others to be outside that norm. By adopting a model of “domain adaptation,” we confuse a medium with a coherent domain. Adapting language technology towards the median Tweet can improve accuracy on average, but it is certain to leave many forms of language out.

Much of the current research on the relationship between social media language and metadata has the goal of using language to predict the metadata — *revealing* who is a woman or a man, who is from Oklahoma or New Jersey, and so on. This perspective on social variables and personal identity ignores the *local categories* that are often more linguistically salient (Eckert, 2008); worse, it strips individuals of any agency in using language as a resource to create and shape their identity (Coupland, 2007), and conceals the role that language plays in creating and perpetuating categories like gender (Bucholtz and Hall, 2005). An alternative possibility is to reverse the relationship between language and metadata, using metadata to achieve a more flexible and heterogeneous domain adaptation that is sensitive to the social factors that shape variation. Such a reversal would help language technology to move beyond false dichotomies between normal and abnormal text, source and target domains, and good and bad language.

Acknowledgments

This paper benefitted from discussions with David Bamman, Natalia Cecire, Micha Elsner, Sharon Goldwater, Scott Kiesling, Brendan O’Connor, Tyler Schnoebel, and Yi Yang. Many thanks to Brendan O’Connor and David Bamman for providing Twitter datasets, Tae Yano for the blog comment dataset, and Byron Wallace for the *Infinite Jest* dataset. Thanks also to the anonymous reviewers for their helpful feedback.

Minibatch and Parallelization for Online Large Margin Structured Learning

Abstract

Online learning algorithms such as perceptron and MIRA have become popular for many NLP tasks thanks to their simpler architecture and faster convergence over batch learning methods. However, while batch learning such as CRF is easily parallelizable, online learning is much harder to parallelize: previous efforts often witness a decrease in the converged accuracy, and the speedup is typically very small (~ 3) even with many (10+) processors. We instead present a much simpler architecture based on “mini-batches”, which is trivially parallelizable. We show that, unlike previous methods, minibatch learning (in serial mode) actually *improves* the converged accuracy for both perceptron and MIRA learning, and when combined with simple parallelization, minibatch leads to very significant speedups (up to 9x on 12 processors) on state-of-the-art parsing and tagging systems.

1 Introduction

Online structured learning algorithms such as the structured perceptron (Collins, 2002) and k -best MIRA (McDonald et al., 2005) have become more and more popular for many NLP tasks such as dependency parsing and part-of-speech tagging. This is because, compared to their batch learning counterparts, online learning methods offer faster convergence rates and better scalability to large datasets, while using much less memory and a much simpler architecture which only needs 1-best or k -best decoding. However, online learning for NLP typically involves expensive inference on each example for 10 or more passes over millions of examples, which often makes training too slow in practice; for example systems such as the popular (2nd-order) MST parser

(McDonald and Pereira, 2006) usually require the order of days to train on the Treebank on a commodity machine (McDonald et al., 2010).

There are mainly two ways to address this scalability problem. On one hand, researchers have been developing modified learning algorithms that allow inexact search (Collins and Roark, 2004; Huang et al., 2012). However, the learner still needs to loop over the whole training data (on the order of millions of sentences) many times. For example the best-performing method in Huang et al. (2012) still requires 5-6 hours to train a very fast parser.

On the other hand, with the increasing popularity of multicore and cluster computers, there is a growing interest in speeding up training via parallelization. While batch learning such as CRF (Lafferty et al., 2001) is often trivially parallelizable (Chu et al., 2007) since each update is a batch-aggregate of the update from each (independent) example, online learning is much harder to parallelize due to the dependency between examples, i.e., the update on the first example should in principle influence the decoding of all remaining examples. Thus if we decode and update the first and the 1000th examples in parallel, we lose their interactions which is one of the reasons for online learners’ fast convergence. This explains why previous work such as the iterative parameter mixing (IPM) method of McDonald et al. (2010) witnesses a decrease in the accuracies of parallelly-learned models, and the speedup is typically very small (about 3 in their experiments) even with 10+ processors.

We instead explore the idea of “minibatch” for online large-margin structured learning such as perceptron and MIRA. We argue that minibatch is advantageous in *both* serial and parallel settings.

First, for minibatch perceptron in the serial set-

ting, our intuition is that, although decoding is done independently within one minibatch, updates are done by averaging update vectors in batch, providing a “mixing effect” similar to “averaged parameters” of Collins (2002) which is also found in IPM (McDonald et al., 2010), and online EM (Liang and Klein, 2009).

Secondly, minibatch MIRA in the serial setting has an advantage that, different from previous methods such as SGD which simply sum up the updates from all examples in a minibatch, a minibatch MIRA update tries to simultaneously satisfy an aggregated set of constraints that are collected from multiple examples in the minibatch. Thus each minibatch MIRA update involves an optimization over many more constraints than in pure online MIRA, which could potentially lead to a better margin. In other words we can view MIRA as an online version or stepwise approximation of SVM, and minibatch MIRA can be seen as a better approximation as well as a middleground between pure MIRA and SVM.¹

More interestingly, the minibatch architecture is trivially parallelizable since the examples within each minibatch could be decoded in parallel on multiple processors (while the update is still done in serial). This is known as “synchronous minibatch” and has been explored by many researchers (Gimpel et al., 2010; Finkel et al., 2008), but all previous works focus on probabilistic models along with SGD or EM learning methods while our work is the first effort on large-margin methods.

We make the following contributions:

- Theoretically, we present a serial minibatch framework (Section 3) for online large-margin learning and prove the convergence theorems for minibatch perceptron and minibatch MIRA.
- Empirically, we show that serial minibatch could speed up convergence and improve the converged accuracy for both MIRA and perceptron on state-of-the-art dependency parsing and part-of-speech tagging systems.
- In addition, when combined with simple (synchronous) parallelization, minibatch MIRA

¹This is similar to Pegasos (Shalev-Shwartz et al., 2007) that applies subgradient descent over a minibatch. Pegasos becomes pure online when the minibatch size is 1.

Algorithm 1 Generic Online Learning.

Input: data $D = \{(x^{(t)}, y^{(t)})\}_{t=1}^n$ and feature map Φ
Output: weight vector \mathbf{w}

- 1: **repeat**
- 2: **for each** example (x, y) **in** D **do**
- 3: $C \leftarrow \text{FINDCONSTRAINTS}(x, y, \mathbf{w})$ \triangleright decoding
- 4: **if** $C \neq \emptyset$ **then** $\text{UPDATE}(\mathbf{w}, C)$
- 5: **until** converged

leads to very significant speedups (up to 9x on 12 processors) that are much higher than that of IPM (McDonald et al., 2010) on state-of-the-art parsing and tagging systems.

2 Online Learning: Perceptron and MIRA

We first present a unified framework for online large-margin learning, where perceptron and MIRA are two special cases. Shown in Algorithm 1, the online learner considers each input example (x, y) sequentially and performs two steps:

1. find the set C of violating constraints, and
2. update the weight vector \mathbf{w} according to C .

Here a triple $\langle x, y, z \rangle$ is said to be a “violating constraint” with respect to model \mathbf{w} if the incorrect label z scores higher than (or equal to) the correct label y in \mathbf{w} , i.e., $\mathbf{w} \cdot \Delta\Phi(\langle x, y, z \rangle) \leq 0$, where $\Delta\Phi(\langle x, y, z \rangle)$ is a short-hand notation for the update vector $\Phi(x, y) - \Phi(x, z)$ and Φ is the feature map (see Huang et al. (2012) for details). The subroutines FINDCONSTRAINTS and UPDATE are analogous to “APIs”, to be specified by specific instances of this online learning framework. For example, the structured perceptron algorithm of Collins (2002) is implemented in Algorithm 2 where FINDCONSTRAINTS returns a singleton constraint if the 1-best decoding result z (the highest scoring label according to the current model) is different from the true label y . Note that in the UPDATE function, C is always a singleton constraint for the perceptron, but we make it more general (as a set) to handle the batch update in the minibatch version in Section 3.

On the other hand, Algorith 3 presents the k -best MIRA Algorithm of McDonald et al. (2005) which generalizes multiclass MIRA (Crammer and Singer, 2003) for structured prediction. The decoder now

Algorithm 2 Perceptron (Collins, 2002).

```

1: function FINDCONSTRAINTS( $x, y, \mathbf{w}$ )
2:    $z \leftarrow \operatorname{argmax}_{s \in \mathcal{Y}(x)} \mathbf{w} \cdot \Phi(x, s)$      $\triangleright$  decoding
3:   if  $z \neq y$  then return  $\{\langle x, y, z \rangle\}$ 
4:   else return  $\emptyset$ 
5: procedure UPDATE( $\mathbf{w}, C$ )
6:    $\mathbf{w} \leftarrow \mathbf{w} + \frac{1}{|C|} \sum_{c \in C} \Delta\Phi(c)$      $\triangleright$  (batch) update

```

Algorithm 3 k -best MIRA (McDonald et al., 2005).

```

1: function FINDCONSTRAINTS( $x, y, \mathbf{w}$ )
2:    $Z \leftarrow k\text{-best}_{z \in \mathcal{Y}(x)} \mathbf{w} \cdot \Phi(x, z)$ 
3:    $Z \leftarrow \{z \in Z \mid z \neq y, \mathbf{w} \cdot \Delta\Phi(\langle x, y, z \rangle) \leq 0\}$ 
4:   return  $\{\langle x, y, z \rangle, \ell(y, z) \mid z \in Z\}$ 
5: procedure UPDATE( $\mathbf{w}, C$ )
6:    $\mathbf{w} \leftarrow \underset{\mathbf{w}' : \forall (c, \ell) \in C, \mathbf{w}' \cdot \Delta\Phi(c) \geq \ell}{\operatorname{argmin}} \|\mathbf{w}' - \mathbf{w}\|^2$ 

```

finds the k -best solutions Z first, and returns a set of violating constraints in Z . The update in MIRA is more interesting: it searches for the new model \mathbf{w}' with minimum change from the current model \mathbf{w} so that \mathbf{w}' corrects each violating constraint by a margin at least as large as the loss $\ell(y, z)$ of the incorrect label z .

Although not mentioned in the pseudocode, we also employ “averaged parameters” (Collins, 2002) for both perceptron and MIRA in all experiments.

3 Serial Minibatch

The idea of serial minibatch learning is extremely simple: divide the data into $\lceil n/m \rceil$ minibatches of size m , and do batch updates after decoding each minibatch (see Algorithm 4). The FINDCONSTRAINTS and UPDATE subroutines remain unchanged for both perceptron and MIRA, although it is important to note that a perceptron batch update uses the average of update vectors, not the sum, which simplifies the proof. This architecture is often called “synchronous minibatch” in the literature (Gimpel et al., 2010; Liang and Klein, 2009; Finkel et al., 2008). It could be viewed as a middleground between pure online learning and batch learning.

3.1 Convergence of Minibatch Perceptron

We denote $C(D)$ to be the set of all possible violating constraints in data D (cf. Huang et al. (2012)):

$$C(D) = \{\langle x, y, z \rangle \mid (x, y) \in D, z \in \mathcal{Y}(x) - \{y\}\}.$$

Algorithm 4 Serial Minibatch Online Learning.

```

Input: data  $D$ , feature map  $\Phi$ , and minibatch size  $m$ 
Output: weight vector  $\mathbf{w}$ 
1: Split  $D$  into  $\lceil n/m \rceil$  minibatches  $D_1 \dots D_{\lceil n/m \rceil}$ 
2: repeat
3:   for  $i \leftarrow 1 \dots \lceil n/m \rceil$  do     $\triangleright$  for each minibatch
4:      $C \leftarrow \cup_{(x,y) \in D_i} \text{FINDCONSTRAINTS}(x, y, \mathbf{w})$ 
5:     if  $C \neq \emptyset$  then UPDATE( $\mathbf{w}, C$ )     $\triangleright$  batch update
6:   until converged

```

A training set D is **separable** by feature map Φ with **margin** $\delta > 0$ if there exists a unit oracle vector \mathbf{u} with $\|\mathbf{u}\| = 1$ such that $\mathbf{u} \cdot \Delta\Phi(\langle x, y, z \rangle) \geq \delta$, for all $\langle x, y, z \rangle \in C(D)$. Furthermore, let radius $R \geq \|\Delta\Phi(\langle x, y, z \rangle)\|$ for all $\langle x, y, z \rangle \in C(D)$.

Theorem 1. *For a separable dataset D with margin δ and radius R , the minibatch perceptron algorithm (Algorithms 4 and 2) will terminate after t minibatch updates where $t \leq R^2/\delta^2$.*

Proof. Let \mathbf{w}^t be the weight vector **before** the t^{th} update; $\mathbf{w}^0 = \mathbf{0}$. Suppose the t^{th} update happens on the constraint set $C_t = \{c_1, c_2, \dots, c_a\}$ where $a = |C_t|$, and each $c_i = \langle x_i, y_i, z_i \rangle$. We convert them to the set of update vectors $\mathbf{v}_i = \Delta\Phi(c_i) = \Delta\Phi(\langle x_i, y_i, z_i \rangle)$ for all i . We know that:

1. $\mathbf{u} \cdot \mathbf{v}_i \geq \delta$ (margin on unit oracle vector)
2. $\mathbf{w}^t \cdot \mathbf{v}_i \leq 0$ (violation: z_i dominates y_i)
3. $\|\mathbf{v}_i\|^2 \leq R^2$ (radius)

Now the update looks like

$$\mathbf{w}^{t+1} = \mathbf{w}^t + \frac{1}{|C_t|} \sum_{c \in C_t} \Delta\Phi(c) = \mathbf{w}^t + \frac{1}{a} \sum_i \mathbf{v}_i. \quad (1)$$

We will bound $\|\mathbf{w}^{t+1}\|$ from two directions:

1. Dot product both sides of the update equation (1) with the unit oracle vector \mathbf{u} , we have

$$\begin{aligned} \mathbf{u} \cdot \mathbf{w}^{t+1} &= \mathbf{u} \cdot \mathbf{w}^t + \frac{1}{a} \sum_i \mathbf{u} \cdot \mathbf{v}_i \\ &\geq \mathbf{u} \cdot \mathbf{w}^t + \frac{1}{a} \sum_i \delta \quad (\text{margin}) \\ &= \mathbf{u} \cdot \mathbf{w}^t + \delta \quad (\sum_i = a) \\ &\geq t\delta \quad (\text{by induction}) \end{aligned}$$

Since for any two vectors \mathbf{a} and \mathbf{b} we have $\|\mathbf{a}\|\|\mathbf{b}\| \geq \mathbf{a} \cdot \mathbf{b}$, thus $\|\mathbf{u}\|\|\mathbf{w}^{t+1}\| \geq \mathbf{u} \cdot \mathbf{w}^{t+1} \geq t\delta$. As \mathbf{u} is a unit vector, we have $\|\mathbf{w}^{t+1}\| \geq t\delta$.

2. On the other hand, take the norm of both sides of Eq. (1):

$$\begin{aligned}
\|\mathbf{w}^{t+1}\|^2 &= \|\mathbf{w}^t + \frac{1}{a} \sum_i \mathbf{v}_i\|^2 \\
&= \|\mathbf{w}^t\|^2 + \left\| \sum_i \frac{1}{a} \mathbf{v}_i \right\|^2 + \frac{2}{a} \mathbf{w}^t \cdot \sum_i \mathbf{v}_i \\
&\leq \|\mathbf{w}^t\|^2 + \left\| \sum_i \frac{1}{a} \mathbf{v}_i \right\|^2 + 0 \quad (\text{violation}) \\
&\leq \|\mathbf{w}^t\|^2 + \sum_i \frac{1}{a} \|\mathbf{v}_i\|^2 \quad (\text{Jensen's}) \\
&\leq \|\mathbf{w}^t\|^2 + \sum_i \frac{1}{a} R^2 \quad (\text{radius}) \\
&= \|\mathbf{w}^t\|^2 + R^2 \quad (\sum_i = a) \\
&\leq tR^2 \quad (\text{by induction})
\end{aligned}$$

Combining the two bounds, we have

$$t^2\delta^2 \leq \|\mathbf{w}^{t+1}\|^2 \leq tR^2$$

thus the number of minibatch updates $t \leq R^2/\delta^2$. \square

Note that this bound is identical to that of pure online perceptron (Collins, 2002, Theorem 1) and is irrelevant to minibatch size m . The use of Jensen's inequality is inspired by McDonald et al. (2010).

3.2 Convergence of Minibatch MIRA

We also give a proof of convergence for MIRA with relaxation.² We present the optimization problem in the UPDATE function of Algorithm 3 as a quadratic program (QP) with slack variable ξ :

$$\begin{aligned}
\mathbf{w}^{t+1} &\leftarrow \underset{\mathbf{w}^{t+1}}{\operatorname{argmin}} \|\mathbf{w}^{t+1} - \mathbf{w}^t\|^2 + \xi \\
\text{s.t. } \mathbf{w}^{t+1} \cdot \mathbf{v}_i &\geq \ell_i - \xi, \text{ for all } (c_i, \ell_i) \in C_t
\end{aligned}$$

where $\mathbf{v}_i = \Delta\Phi(c_i)$ is the update vector for constraint c_i . Consider the Lagrangian:

$$\begin{aligned}
\mathcal{L} &= \|\mathbf{w}^{t+1} - \mathbf{w}^t\|^2 + \xi + \sum_{i=1}^{|C_t|} \eta_i (\ell_i - \mathbf{w}^t \cdot \mathbf{v}_i - \xi) \\
\eta_i &\geq 0, \text{ for } 1 \leq i \leq |C_t|.
\end{aligned}$$

²Actually this relaxation is *not* necessary for the convergence proof. We employ it here solely to make the proof shorter. It is *not* used in the experiments either.

Set the partial derivatives to 0 with respect to \mathbf{w}' and ξ we have:

$$\mathbf{w}' = \mathbf{w} + \sum_i \eta_i \mathbf{v}_i \quad (2)$$

$$\sum_i \eta_i = 1 \quad (3)$$

This result suggests that the weight change can always be represented by a linear combination of the update vectors (i.e. normal vectors of the constraint hyperplanes), with the linear coefficients sum to 1.

Theorem 2 (convergence of minibatch MIRA). *For a separable dataset D with margin δ and radius R , the minibatch MIRA algorithm (Algorithm 4 and 3) will make t updates where $t \leq R^2/\delta^2$.*

Proof. 1. Dot product both sides of Equation 2 with unit oracle vector \mathbf{u} :

$$\begin{aligned}
\mathbf{u} \cdot \mathbf{w}^{t+1} &= \mathbf{u} \cdot \mathbf{w}^t + \sum_i \eta_i \mathbf{u} \cdot \mathbf{v}_i \\
&\geq \mathbf{u} \cdot \mathbf{w}^t + \sum_i \eta_i \delta \quad (\text{margin}) \\
&= \mathbf{u} \cdot \mathbf{w}^t + \delta \quad (\text{Eq. 3}) \\
&= t\delta \quad (\text{by induction})
\end{aligned}$$

2. On the other hand

$$\begin{aligned}
\|\mathbf{w}^{t+1}\|^2 &= \|\mathbf{w}^t + \sum_i \eta_i \mathbf{v}_i\|^2 \\
&= \|\mathbf{w}^t\|^2 + \left\| \sum_i \eta_i \mathbf{v}_i \right\|^2 + 2 \mathbf{w}^t \cdot \sum_i \eta_i \mathbf{v}_i \\
&\leq \|\mathbf{w}^t\|^2 + \left\| \sum_i \eta_i \mathbf{v}_i \right\|^2 + 0 \quad (\text{violation}) \\
&\leq \|\mathbf{w}^t\|^2 + \sum_i \eta_i \mathbf{v}_i^2 \quad (\text{Jensen's}) \\
&\leq \|\mathbf{w}^t\|^2 + \sum_i \eta_i R^2 \quad (\text{radius}) \\
&= \|\mathbf{w}^t\|^2 + R^2 \quad (\text{Eq. 3}) \\
&\leq tR^2 \quad (\text{by induction})
\end{aligned}$$

From the two bounds we have:

$$t^2\delta^2 \leq \|\mathbf{w}^{t+1}\|^2 \leq tR^2$$

thus within at most $t \leq R^2/\delta^2$ minibatch updates MIRA will converge. \square

4 Parallelized Minibatch

The key insight into parallelization is that the calculation of constraints (i.e. decoding) for each example within a minibatch is completely independent of

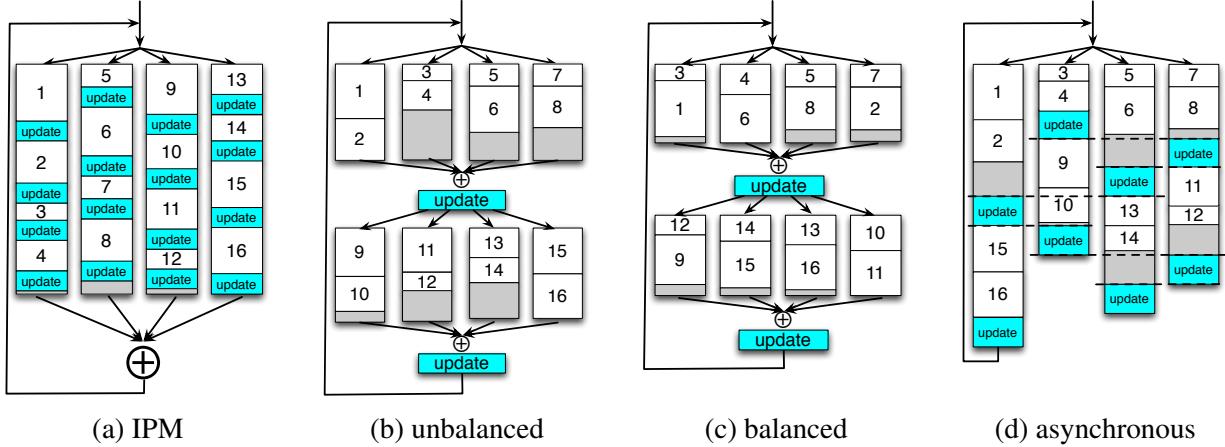

Figure 1: Comparison of various methods for parallelizing online learning (number of processors $p = 4$). (a) iterative parameter mixing (McDonald et al., 2010). (b) unbalanced minibatch parallelization (minibatch size $m = 8$). (c) minibatch parallelization after load-balancing (within each minibatch). (d) asynchronous minibatch parallelization (Gimpel et al., 2010) (not implemented here). Each numbered box denotes the decoding of one example, and \oplus denotes an aggregate operation, i.e., the merging of constraints after each minibatch or the mixing of weights after each iteration in IPM. Each gray shaded box denotes time wasted due to synchronization in (a)-(c) or blocking in (d). Note that in (d) at most one update can happen concurrently, making it substantially harder to implement than (a)-(c).

Algorithm 5 Parallized Minibatch Online Learning.

Input: D , Φ , minibatch size m , and # of processors p
 Output: weight vector \mathbf{w}
 Split D into $\lceil n/m \rceil$ minibatches $D_1 \dots D_{\lceil n/m \rceil}$
 Split each D_i into m/p groups $D_{i,1} \dots D_{i,m/p}$
repeat
 for $i \leftarrow 1 \dots \lceil n/m \rceil$ **do** \triangleright for each minibatch
 for $j \leftarrow 1 \dots m/p$ **in parallel do**
 $C_j \leftarrow \cup_{(x,y) \in D_{i,j}} \text{FINDCONSTRAINTS}(x, y, \mathbf{w})$
 $C \leftarrow \cup_j C_j$ \triangleright in serial
 if $C \neq \emptyset$ **then** $\text{UPDATE}(\mathbf{w}, C)$ \triangleright in serial
until converged

other examples in the same batch. Thus we can easily distribute decoding for different examples in the same minibatch to different processors.

Shown in Algorithm 5, for each minibatch D_i , we split D_i into groups of equal size, and assign each group to a processor to decode. After all processors finish, we collect all constraints and do an update based on the union of all constraints. Figure 1 (b) illustrates minibatch parallelization, with comparison to iterative parameter mixing (IPM) of McDonald et al. (2010) (see Figure 1 (a)).

This synchronous parallelization framework should provide significant speedups over the serial

mode. However, in each minibatch, inevitably, some processors will end up waiting for others to finish, especially when the lengths of sentences vary substantially (see the shaded area in Figure 1 (b)).

To alleviate this problem, we propose “**per-minibatch load-balancing**”, which rearranges the sentences within each minibatch based on their lengths (which correlate with their decoding times) so that the total workload on each processor is balanced (Figure 1c). It is important to note that this shuffling does **not** affect learning at all thanks to the independence of each example within a minibatch. Basically, we put the shortest and longest sentences into the first thread, the second shortest and second longest into the second thread, etc. Although this is not necessarily optimal scheduling, it works well in practice. As long as decoding time is linear in the length of sentence (as in incremental parsing or tagging), we expect a much smaller variance in processing time on each processor in one minibatch, which is confirmed in the experiments (see Figure 8).³

³In IPM, however, the waiting time is negligible, since the workload on each processor is almost balanced, analogous to a huge minibatch (Fig. 1a). Furthermore, shuffling *does* affect learning here since each thread in IPM is a pure online learner. So our IPM implementation does *not* use load-balancing.

5 Experiments

We conduct experiments on two typical structured prediction problems: incremental dependency parsing and part-of-speech tagging; both are done on state-of-the-art baseline. We also compare our parallelized minibatch algorithm with the iterative parameter mixing (IPM) method of McDonald et al. (2010). We perform our experiments on a commodity 64-bit Dell Precision T7600 workstation with two 3.1GHz 8-core CPUs (16 processors in total) and 64GB RAM. We use Python 2.7’s multiprocessing module in all experiments.⁴

5.1 Dependency Parsing with MIRA

We base our experiments on our dynamic programming incremental dependency parser (Huang and Sagae, 2010).⁵ Following Huang et al. (2012), we use max-violation update and beam size $b = 8$. We evaluate on the standard Penn Treebank (PTB) using the standard split: Sections 02-21 for training, and Section 22 as the held-out set (which is indeed the test-set in this setting, following McDonald et al. (2010) and Gimpel et al. (2010)). We then extend it to employ 1-best MIRA learning. As stated in Section 2, MIRA separates the gold label y from the incorrect label z with a margin at least as large as the loss $\ell(y, z)$. Here in incremental dependency parsing we define the loss function between a gold tree y and an incorrect *partial* tree z as the number of incorrect edges in z , plus the number of correct edges in y which are already ruled out by z . This MIRA extension results in slightly higher accuracy of 92.36, which we will use as the pure online learning baseline in the comparisons below.

5.1.1 Serial Minibatch

We first run minibatch in the serial mode with varying minibatch size of 4, 16, 24, 32, and 48 (see Figure 2). We can make the following observations. First, except for the largest minibatch size of 48, minibatch learning generally improves the accuracy

⁴We turn off garbage-collection in worker processes otherwise their running times will be highly unbalanced. We also admit that Python is not the best choice for parallelization, e.g., asynchronous minibatch (Gimpel et al., 2010) requires “shared memory” not found in the current Python (see also Sec. 6).

⁵Available at <http://acl.cs.qc.edu/>. The version with minibatch parallelization will be available there soon.

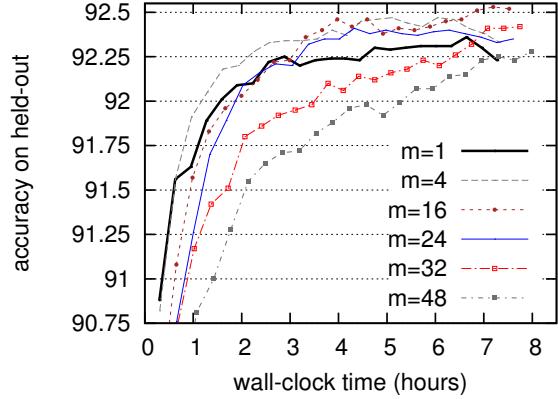

Figure 2: Minibatch with various minibatch sizes ($m = 4, 16, 24, 32, 48$) for parsing with MIRA, compared to pure MIRA ($m = 1$). All curves are on a single CPU.

of the converged model, which is explained by our intuition that optimization with a larger constraint set could improve the margin. In particular, $m = 16$ achieves the highest accuracy of 92.53, which is a 0.27 improvement over the baseline.

Secondly, minibatch learning can reach high levels of accuracy faster than the baseline can. For example, minibatch of size 4 can reach 92.35 in 3.5 hours, and minibatch of size 24 in 3.7 hours, while the pure online baseline needs 6.9 hours. In other words, just minibatch alone in serial mode can already speed up learning. This is also explained by the intuition of better optimization above, and contributes significantly to the final speedup of parallelized minibatch.

Lastly, larger minibatch sizes slow down the convergence, with $m = 4$ converging the fastest and $m = 48$ the slowest. This can be explained by the trade-off between the relative strengths from online learning and batch update: with larger batch sizes, we lose the dependencies between examples within the same minibatch.

Although larger minibatches slow down convergence, they actually offer better potential for parallelization since the number of processors p has to be smaller than minibatch size m (in fact, p should divide m). For example, $m = 24$ can work with 2, 3, 4, 6, 8, or 12 processors while $m = 4$ can only work with 2 or 4 and the speed up of 12 processors could easily make up for the slightly slower convergence

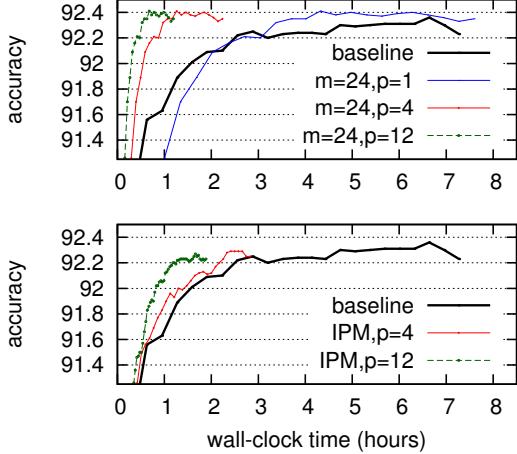

Figure 3: Parallelized minibatch is much faster than iterative parameter mixing. Top: minibatch of size 24 using 4 and 12 processors offers significant speedups over the serial minibatch and pure online baselines. Bottom: IPM with the same processors offers very small speedups.

rate. So there seems to be a “sweetspot” of minibatch sizes, similar to the tipping point observed in McDonald et al. (2010) when adding more processors starts to hurt convergence.

5.1.2 Parallelized Minibatch vs. IPM

In the following experiments we use minibatch size of $m = 24$ and run it in parallel mode on various numbers of processors ($p = 2 \sim 12$). Figure 3 (top) shows that 4 and 12 processors lead to very significant speedups over the serial minibatch and pure online baselines. For example, it takes the 12 processors only 0.66 hours to reach an accuracy of 92.35, which takes the pure online MIRA 6.9 hours, amounting to an impressive speedup of 10.5.

We compare our minibatch parallelization with the iterative parameter mixing (IPM) of McDonald et al. (2010). Figure 3 (bottom) shows that IPM not only offers much smaller speedups, but also converges lower, and this drop in accuracy worsens with more processors.

Figure 4 gives a detailed analysis of speedups. Here we perform both extrinsic and intrinsic comparisons. In the former, we care about the time to reach a given accuracy; in this plot we use 92.27 which is the converged accuracy of IPM on 12 processors. We choose it since it is the lowest accu-

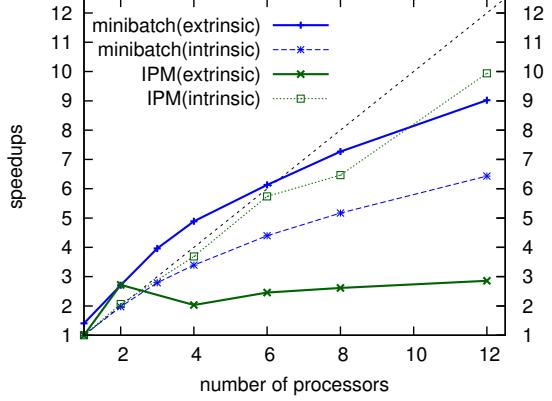

Figure 4: Speedups of minibatch parallelization vs. IPM on 1 to 12 processors (parsing with MIRA). Extrinsic comparisons use “the time to reach an accuracy of 92.27” for speed calculations, 92.27 being the converged accuracy of IPM using 12 processors. Intrinsic comparisons use average time per iteration regardless of accuracy.

racy among all converged models; choosing a higher accuracy would reveal even larger speedups for our methods. This figure shows that our method offers superlinear speedups with small number of processors (1 to 6), and almost linear speedups with large number of processors (8 and 12). Note that even $p = 1$ offers a speedup of 1.5 thanks to serial minibatch’s faster convergence; in other words, within the 9 fold speed-up at $p = 12$, parallelization contributes about 6 and minibatch about 1.5. By contrast, IPM only offers an almost constant speedup of around 3, which is consistent with the findings of McDonald et al. (2010) (both of their experiments show a speedup of around 3).

We also try to understand where the speedup comes from. For that purpose we study **intrinsic speedup**, which is about the speed regardless of accuracy (see Figure 4). For our minibatch method, intrinsic speedup is the average time per iteration of a parallel run over the serial minibatch baseline. This answers the questions such as “how CPU-efficient is our parallelization” or “how much CPU time is wasted”. We can see that with small number of processors (2 to 4), the **efficiency**, defined as S_p/p where S_p is the intrinsic speedup for p processors, is almost 100% (ideal linear speedup), but with more processors it decreases to around 50% with $p = 12$, meaning about half of CPU time is

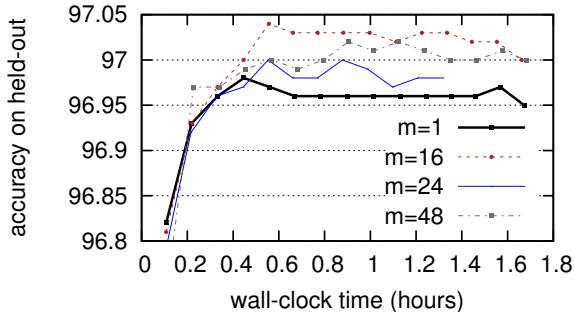

Figure 5: Minibatch learning for tagging with perceptron ($m = 16, 24, 32$) compared with baseline ($m = 1$) for tagging with perceptron. All curves are on single CPU.

wasted. This wasting is due to two sources: first, the load-balancing problem worsens with more processors, and secondly, the update procedure still runs in serial mode with $p - 1$ processors sleeping.

5.2 Part-of-Speech Tagging with Perceptron

Part-of-speech tagging is usually considered as a simpler task compared to dependency parsing. Here we show that using minibatch can also bring better accuracies and speedups for part-of-speech tagging.

We implement a part-of-speech tagger with averaged perceptron. Following the standard splitting of Penn Treebank (Collins, 2002), we use Sections 00–18 for training and Sections 19–21 as held-out. Our implementation provides an accuracy of 96.98 with beam size 8.

First we run the tagger on a single processor with minibatch sizes 8, 16, 24, and 32. As in Figure 5, we observe similar convergence acceleration and higher accuracies with minibatch. In particular, minibatch of size $m = 16$ provides the highest accuracy of 97.04, giving an improvement of 0.06. This improvement is smaller than what we observe in MIRA learning for dependency parsing experiments, which can be partly explained by the fast convergence of the tagger, and that perceptron does not involve optimization in the updates.

Then we choose minibatch of size 24 to investigate the parallelization performance. As Figure 6 (top) shows, with 12 processors our method takes only 0.10 hours to converge to an accuracy of 97.00, compared to the baseline of 96.98 with 0.45 hours. We also compare our method with IPM as in Fig-

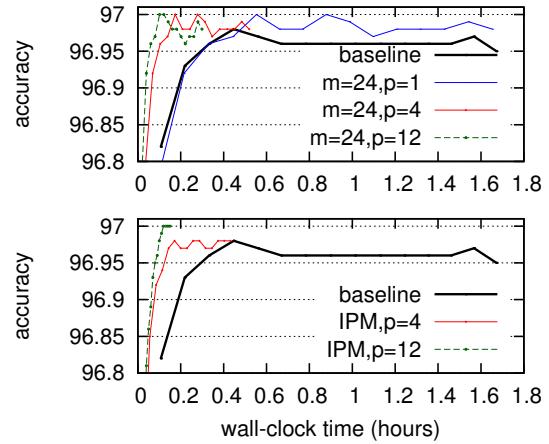

Figure 6: Parallelized minibatch is faster than iterative parameter mixing (on tagging with perceptron). Top: minibatch of size 24 using 4 and 12 processors offers significant speedups over the baselines. Bottom: IPM with the same 4 and 12 processors offers slightly smaller speedups. Note that IPM with 4 processors converges lower than other parallelization curves.

ure 6 (bottom). Again, our method converges faster and better than IPM, but this time the differences are much smaller than those in parsing.

Figure 7 uses 96.97 as a criteria to evaluate the extrinsic speedups given by our method and IPM. Again we choose this number because it is the lowest accuracy all learners can reach. As the figure suggests, although our method does not have a higher pure parallelization speedup (intrinsic speedup), it still outperforms IPM.

We are interested in the reason why tagging benefits less from minibatch and parallelization compared to parsing. Further investigation reveals that in tagging the working load of different processors are more unbalanced than in parsing. Figure 8 shows that, when p is small, waiting time is negligible, but when $p = 12$, tagging wastes about 40% of CPU cycles and parser about 30%. By contrast, there is almost no waiting time in IPM and the intrinsic speedup for IPM is almost linear. The communication overhead is not included in this figure, but by comparing it to the speedups (Figures 4 and 7), we conclude that the communication overhead is about 10% for both parsing and tagging at $p = 12$.

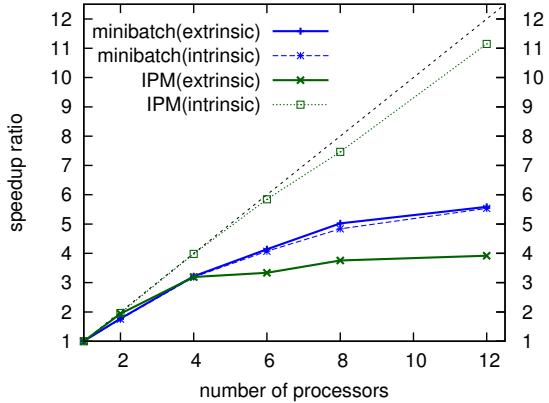

Figure 7: Speedups of minibatch parallelization and IPM on 1 to 12 processors (tagging with perceptron). Extrinsic speedup uses “the time to reach an accuracy of 96.97” as the criterion to measure speed. Intrinsic speedup measures the pure parallelization speedup. IPM has an almost linear intrinsic speedup but a near constant extrinsic speedup of about 3 to 4.

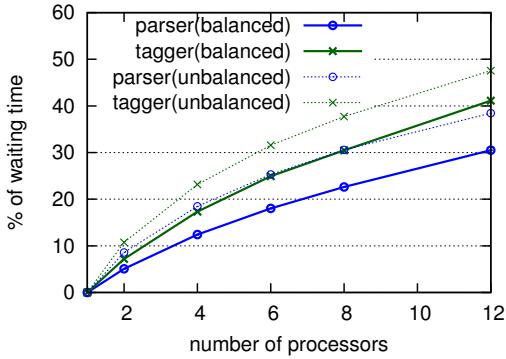

Figure 8: Percentage of time wasted due to synchronization (waiting for other processors to finish) (minibatch $m = 24$), which corresponds to the gray blocks in Figure 1 (b-c). The number of sentences assigned to each processor decreases with more processors, which worsens the unbalance. Our load-balancing strategy (Figure 1 (c)) alleviates this problem effectively. The communication overhead and update time are **not** included.

6 Related Work and Discussions

Besides synchronous minibatch and iterative parameter mixing (IPM) discussed above, there is another method of asynchronous minibatch parallelization (Zinkevich et al., 2009; Gimpel et al., 2010; Chiang, 2012), as in Figure 1. The key advantage of asynchronous over synchronous minibatch is that the former allows processors to remain near-constant use,

while the latter wastes a significant amount of time when some processors finish earlier than others in a minibatch, as found in our experiments. Gimpel et al. (2010) show significant speedups of asynchronous parallelization over synchronous minibatch on SGD and EM methods, and Chiang (2012) finds asynchronous parallelization to be much faster than IPM on MIRA for machine translation. However, asynchronous is significantly more complicated to implement, which involves locking when one processor makes an update (see Fig. 1 (d)), and (in languages like Python) message-passing to other processors after update. Whether this added complexity is worthwhile on large-margin learning is an open question.

7 Conclusions and Future Work

We have presented a simple minibatch parallelization paradigm to speed up large-margin structured learning algorithms such as (averaged) perceptron and MIRA. Minibatch has an advantage in both serial and parallel settings, and our experiments confirmed that a minibatch size of around 16 or 24 leads to a significant speedups over the pure online baseline, and when combined with parallelization, leads to almost linear speedups for MIRA, and very significant speedups for perceptron. These speedups are significantly higher than those of iterative parameter mixing of McDonald et al. (2010) which were almost constant (3~4) in both our and their own experiments regardless of the number of processors.

One of the limitations of this work is that although decoding is done in parallel, update is still done in serial and in MIRA the quadratic optimization step (Hildreth algorithm (Hildreth, 1957)) scales super-linearly with the number of constraints. This prevents us from using very large minibatches. For future work, we would like to explore parallelized quadratic optimization and larger minibatch sizes, and eventually apply it to machine translation.

Abstract

We consider the problem of part-of-speech tagging for informal, online conversational text. We systematically evaluate the use of large-scale unsupervised word clustering and new lexical features to improve tagging accuracy. With these features, our system achieves state-of-the-art tagging results on both Twitter and IRC POS tagging tasks; Twitter tagging is improved from 90% to 93% accuracy (more than 3% absolute). Qualitative analysis of these word clusters yields insights about NLP and linguistic phenomena in this genre. Additionally, we contribute the first POS annotation guidelines for such text and release a new dataset of English language tweets annotated using these guidelines. Tagging software, annotation guidelines, and large-scale word clusters are available at:

<http://www.ark.cs.cmu.edu/TweetNLP>
This paper describes release 0.3 of the “CMU Twitter Part-of-Speech Tagger” and annotated data.

1 Introduction

Online conversational text, typified by microblogs, chat, and text messages,¹ is a challenge for natural language processing. Unlike the highly edited genres that conventional NLP tools have been developed for, conversational text contains many non-standard lexical items and syntactic patterns. These are the result of unintentional errors, dialectal variation, conversational ellipsis, topic diversity, and creative use of language and orthography (Eisenstein, 2013). An example is shown in Fig. 1. As a result of this widespread variation, standard modeling assumptions that depend on lexical, syntactic, and orthographic regularity are inappropriate. There

ikr	smh	he	asked	fir	yo	last

Figure 1: Automatically tagged tweet showing nonstandard orthography, capitalization, and abbreviation. Ignoring the interjections and abbreviations, it glosses as *He asked for your last name so he can add you on Facebook*. The tagset is defined in Appendix A. Refer to Fig. 2 for word clusters corresponding to some of these words.

is preliminary work on social media part-of-speech (POS) tagging (Gimpel et al., 2011), named entity recognition (Ritter et al., 2011; Liu et al., 2011), and parsing (Foster et al., 2011), but accuracy rates are still significantly lower than traditional well-edited genres like newswire. Even web text parsing, which is a comparatively easier genre than social media, lags behind newspaper text (Petrov and McDonald, 2012), as does speech transcript parsing (McClosky et al., 2010).

To tackle the challenge of novel words and constructions, we create a new Twitter part-of-speech tagger—building on previous work by Gimpel et al. (2011)—that includes new large-scale distributional features. This leads to state-of-the-art results in POS tagging for both Twitter and Internet Relay Chat (IRC) text. We also annotated a new dataset of tweets with POS tags, improved the annotations in the previous dataset from Gimpel et al., and developed annotation guidelines for manual POS tagging of tweets. We release all of these resources to the research community:

- an open-source part-of-speech tagger for online conversational text (§2);
- unsupervised Twitter word clusters (§3);
- an improved emoticon detector for conversational text (§4);

¹Also referred to as *computer-mediated communication*.

- POS annotation guidelines (§5.1); and
- a new dataset of 547 manually POS-annotated tweets (§5).

2 MEMM Tagger

Our tagging model is a first-order maximum entropy Markov model (MEMM), a discriminative sequence model for which training and decoding are extremely efficient (Ratnaparkhi, 1996; McCallum et al., 2000).² The probability of a tag y_t is conditioned on the input sequence \mathbf{x} and the tag to its left y_{t-1} , and is parameterized by a multiclass logistic regression:

$$p(y_t = k \mid y_{t-1}, \mathbf{x}, t; \boldsymbol{\beta}) \propto \exp\left(\beta_{y_{t-1}, k}^{(trans)} + \sum_j \beta_{j, k}^{(obs)} f_j(\mathbf{x}, t)\right)$$

We use transition features for every pair of labels, and extract base observation features from token t and neighboring tokens, and conjoin them against all $K = 25$ possible outputs in our coarse tagset (Appendix A). Our feature sets will be discussed below in detail.

Decoding. For experiments reported in this paper, we use the $O(|\mathbf{x}|K^2)$ Viterbi algorithm for prediction; K is the number of tags. This exactly maximizes $p(\mathbf{y} \mid \mathbf{x})$, but the MEMM also naturally allows a faster $O(|\mathbf{x}|K)$ left-to-right greedy decoding:

```
for  $t = 1 \dots |\mathbf{x}|$ :
     $\hat{y}_t \leftarrow \arg \max_k p(y_t = k \mid \hat{y}_{t-1}, \mathbf{x}, t; \boldsymbol{\beta})$ 
```

which we find is 3 times faster and yields similar accuracy as Viterbi (an insignificant accuracy decrease of less than 0.1% absolute on the DAILY547 test set discussed below). Speed is paramount for social media analysis applications—which often require the processing of millions to billions of messages—so we make greedy decoding the default in the released software.

²Although when compared to CRFs, MEMMs theoretically suffer from the “label bias” problem (Lafferty et al., 2001), our system substantially outperforms the CRF-based taggers of previous work; and when comparing to Gimpel et al. system with similar feature sets, we observed little difference in accuracy. This is consistent with conventional wisdom that the quality of lexical features is much more important than the parametric form of the sequence model, at least in our setting: part-of-speech tagging with a small labeled training set.

This greedy tagger runs at 800 tweets/sec. (10,000 tokens/sec.) on a single CPU core, about 40 times faster than Gimpel et al.’s system. The tokenizer by itself (§4) runs at 3,500 tweets/sec.³

Training and regularization. During training, the MEMM log-likelihood for a tagged tweet $\langle \mathbf{x}, \mathbf{y} \rangle$ is the sum over the observed token tags y_t , each conditional on the tweet being tagged and the observed previous tag (with a start symbol before the first token in \mathbf{x}),

$$\ell(\mathbf{x}, \mathbf{y}, \boldsymbol{\beta}) = \sum_{t=1}^{|\mathbf{x}|} \log p(y_t \mid y_{t-1}, \mathbf{x}, t; \boldsymbol{\beta}).$$

We optimize the parameters $\boldsymbol{\beta}$ with OWL-QN, an L_1 -capable variant of L-BFGS (Andrew and Gao, 2007; Liu and Nocedal, 1989) to minimize the regularized objective

$$\arg \min_{\boldsymbol{\beta}} -\frac{1}{N} \sum_{\langle \mathbf{x}, \mathbf{y} \rangle} \ell(\mathbf{x}, \mathbf{y}, \boldsymbol{\beta}) + R(\boldsymbol{\beta})$$

where N is the number of tokens in the corpus and the sum ranges over all tagged tweets $\langle \mathbf{x}, \mathbf{y} \rangle$ in the training data. We use elastic net regularization (Zou and Hastie, 2005), which is a linear combination of L_1 and L_2 penalties; here j indexes over all features:

$$R(\boldsymbol{\beta}) = \lambda_1 \sum_j |\beta_j| + \frac{1}{2} \lambda_2 \sum_j \beta_j^2$$

Using even a very small L_1 penalty eliminates many irrelevant or noisy features.

3 Unsupervised Word Clusters

Our POS tagger can make use of any number of possibly overlapping features. While we have only a small amount of hand-labeled data for training, we also have access to billions of tokens of *unlabeled* conversational text from the web. Previous work has shown that unlabeled text can be used to induce unsupervised word clusters which can improve the performance of many supervised NLP tasks (Koo et al., 2008; Turian et al., 2010; Täckström et al., 2012, *inter alia*). We use a similar approach here to improve tagging performance for online conversational text. We also make our induced clusters publicly available in the hope that they will be useful for other NLP tasks in this genre.

Figure 2: Example word clusters (HMM classes): we list the most probable words, starting with the most probable, in descending order. Boldfaced words appear in the example tweet (Figure 1). The binary strings are root-to-leaf paths through the binary cluster tree. For example usage, see e.g. search.twitter.com, bing.com/social and urbandictionary.com.

3.1 Clustering Method

We obtained hierarchical word clusters via Brown clustering (Brown et al., 1992) on a large set of unlabeled tweets.⁴ The algorithm partitions words into a base set of 1,000 clusters, and induces a hierarchy among those 1,000 clusters with a series of greedy agglomerative merges that heuristically optimize the likelihood of a hidden Markov model with a one-class-per-lexical-type constraint. Not only does Brown clustering produce effective features for discriminative models, but its variants are better unsupervised POS taggers than some models developed nearly 20 years later; see comparisons in Blunsom and Cohn (2011). The algorithm is attractive for our purposes since it scales to large amounts of data.

When training on tweets drawn from a single day, we observed time-specific biases (e.g., numerical dates appearing in the same cluster as the word *tonight*), so we assembled our unlabeled data from a random sample of 100,000 tweets per day from September 10, 2008 to August 14, 2012, and filtered out non-English tweets (about 60% of the sample) using `langid.py` (Lui and Baldwin, 2012).⁵ Each tweet was processed with our to-

kenizer and lowercased. We normalized all mentions to $\langle @MENTION \rangle$ and URLs/email addresses to their domains (e.g. <http://bit.ly/dP8rR8> $\Rightarrow \langle URL-bit.ly \rangle$). In an effort to reduce spam, we removed duplicated tweet texts (this also removes retweets) before word clustering. This normalization and cleaning resulted in 56 million unique tweets (847 million tokens). We set the clustering software’s count threshold to only cluster words appearing 40 or more times, yielding 216,856 word types, which took 42 hours to cluster on a single CPU.

3.2 Cluster Examples

Fig. 2 shows example clusters. Some of the challenging words in the example tweet (Fig. 1) are highlighted. The term *lololol* (an extension of *lol* for “laughing out loud”) is grouped with a large number of laughter acronyms (A1: “laughing my (fucking) ass off,” “cracking the fuck up”). Since expressions of laughter are so prevalent on Twitter, the algorithm creates another laughter cluster (A1’s sibling A2), that tends to have onomatopoeic, non-acronym variants (e.g., *haha*). The acronym *ikr* (“I know, right?”) is grouped with expressive variations of “yes” and “no” (A4). Note that A1–A4 are grouped in a fairly specific subtree; and indeed, in this message *ikr* and

⁴As implemented by Liang (2005), v. 1.3: <https://github.com/percyliang/brown-cluster>

⁵<https://github.com/saffsd/langid.py>

lololol are both tagged as interjections.

smh (“shaking my head,” indicating disapproval) seems related, though is always tagged in the annotated data as a miscellaneous abbreviation (G); the difference between acronyms that are interjections versus other acronyms may be complicated. Here, *smh* is in a related but distinct subtree from the above expressions (A5); its usage in this example is slightly different from its more common usage, which it shares with the other words in its cluster: message-ending expressions of commentary or emotional reaction, sometimes as a metacomment on the author’s message; e.g., *Maybe you could get a guy to date you if you actually respected yourself #smh* or *There is really NO reason why other girls should send my boyfriend a goodmorning text #justsaying*.

We observe many variants of categories traditionally considered closed-class, including pronouns (B: *u* = “you”) and prepositions (C: *fir* = “for”).

There is also evidence of grammatical categories specific to conversational genres of English; clusters E1–E2 demonstrate variations of single-word contractions for “going to” and “trying to,” some of which have more complicated semantics.⁶

Finally, the HMM learns about orthographic variants, even though it treats all words as opaque symbols; cluster F consists almost entirely of variants of “so,” their frequencies monotonically decreasing in the number of vowel repetitions—a phenomenon called “expressive lengthening” or “affective lengthening” (Brody and Diakopoulos, 2011; Schnoebelen, 2012). This suggests a future direction to jointly model class sequence and orthographic information (Clark, 2003; Smith and Eisner, 2005; Blunsom and Cohn, 2011).

We have built an HTML viewer to browse these and numerous other interesting examples.⁷

3.3 Emoticons and Emoji

We use the term *emoticon* to mean a face or icon constructed with traditional alphabetic or punctua-

⁶One coauthor, a native speaker of the Texan English dialect, notes “finna” (short for “fixing to”, cluster E1) may be an immediate future auxiliary, indicating an immediate future tense that is present in many languages (though not in standard English). To illustrate: “She finna go” approximately means “She will go,” but sooner, in the sense of “She is about to go.”

⁷http://www.ark.cs.cmu.edu/TweetNLP/cluster_viewer.html

tion symbols, and *emoji* to mean symbols rendered in software as small pictures, in line with the text.

Since our tokenizer is careful to preserve emoticons and other symbols (see §4), they are clustered just like other words. Similar emoticons are clustered together (G1–G4), including separate clusters of happy [[:) =) ^_ ^]], sad/disappointed [[: / :(-_- </3]], love [[xoxo . .]] and winking [[;) (^_-)]] emoticons. The clusters are not perfectly aligned with our POS annotation guidelines; for example, the “sad” emoticon cluster included emotion-bearing terms that our guidelines define as non-emoticons, such as *#ugh*, *#tear*, and *#fml* (“fuck my life”), though these seem potentially useful for sentiment analysis.

One difficult task is classifying different types of symbols in tweets: our annotation guidelines differentiate between emoticons, punctuation, and garbage (apparently non-meaningful symbols or tokenization errors). Several Unicode character ranges are reserved for emoji-style symbols (including the three Unicode hearts in G4); however, depending on the user’s software, characters in these ranges might be rendered differently or not at all. We have found instances where the clustering algorithm groups proprietary iOS emoji symbols along with normal emoticons; for example, the character U+E056, which is interpreted on iOS as a smiling face, is in the same G2 cluster as smiley face emoticons. The symbol U+E12F, which represents a picture of a bag of money, is grouped with the words *cash* and *money*.

3.4 Cluster-Based Features

Since Brown clusters are hierarchical in a binary tree, each word is associated with a tree path represented as a bitstring with length ≤ 16 ; we use prefixes of the bitstring as features (for all prefix lengths $\in \{2, 4, 6, \dots, 16\}$). This allows sharing of statistical strength between similar clusters. Using prefix features of hierarchical clusters in this way was similarly found to be effective for named-entity recognition (Turian et al., 2010) and Twitter POS tagging (Ritter et al., 2011).

When checking to see if a word is associated with a cluster, the tagger first normalizes the word using the same techniques as described in §3.1, then creates a priority list of fuzzy match transformations

of the word by removing repeated punctuation and repeated characters. If the normalized word is not in a cluster, the tagger considers the fuzzy matches. Although only about 3% of the tokens in the development set (§6) did not appear in a clustering, this method resulted in a relative error decrease of 18% among such word tokens.

3.5 Other Lexical Features

Besides unsupervised word clusters, there are two other sets of features that contain generalized lexical class information. We use the tag dictionary feature from Gimpel et al., which adds a feature for a word’s most frequent part-of-speech tag.⁸ This can be viewed as a feature-based domain adaptation method, since it gives lexical type-level information for standard English words, which the model learns to map between PTB tags to the desired output tags. Second, since the lack of consistent capitalization conventions on Twitter makes it especially difficult to recognize names—Gimpel et al. and Foster et al. (2011) found relatively low accuracy on proper nouns—we added a token-level name list feature, which fires on (non-function) words from names from several sources: Freebase lists of celebrities and video games (Google, 2012), the Moby Words list of US Locations,⁹ and lists of male, female, family, and proper names from Mark Kantrowitz’s name corpus.¹⁰

4 Tokenization and Emoticon Detection

Word segmentation on Twitter is challenging due to the lack of orthographic conventions; in particular, punctuation, emoticons, URLs, and other symbols may have no whitespace separation from textual

⁸Frequencies came from the *Wall Street Journal* and Brown corpus sections of the Penn Treebank. If a word has multiple PTB tags, each tag is a feature with value for the frequency rank; e.g. for three different tags in the PTB, this feature gives a value of 1 for the most frequent tag, 2/3 for the second, etc. Coarse versions of the PTB tags are used (Petrov et al., 2011). While 88% of words in the dictionary have only one tag, using rank information seemed to give a small but consistent gain over only using the most common tag, or using binary features conjoined with rank as in Gimpel et al.

⁹<http://icon.shef.ac.uk/Moby/mwords.html>

¹⁰<http://www.cs.cmu.edu/afs/cs/project/ai-repository/ai/areas/nlp/corpora/names/0.html>

words (e.g. *no:-d, yes* should parse as four tokens), and internally may contain alphanumeric symbols that could be mistaken for words: a naive *split(/[^a-zA-Z0-9]+/)* tokenizer thinks the words “p” and “d” are among the top 100 most common words on Twitter, due to misanalysis of :*p* and :*d*. Traditional Penn Treebank–style tokenizers are hardly better, often breaking a string of punctuation characters into a single token per character.

We rewrote `twokenize` (O’Connor et al., 2010), a rule-based tokenizer, emoticon, and URL detector, for use in the tagger. Emoticons are especially challenging, since they are open-class and productive. We revise O’Connor et al.’s regular expression grammar that describes possible emoticons, adding a grammar of horizontal emoticons (e.g. -_-), known as “Eastern-style,”¹¹ though we observe high usage in English-speaking Twitter (Fig. 2, G2–G3). We also add a number of other improvements to the patterns. Because this system was used as preprocessing for the word clustering experiment in §3, we were able to infer the emoticon clusters in Fig. 2. Furthermore, whether a token matches the emoticon pattern is also used as a feature in the tagger (§2).

URL recognition is also difficult, since the *http://* is often dropped, resulting in protocol-less URLs like *about.me*. We add recognition patterns for these by using a list of top-level and country domains.

5 Annotated Dataset

Gimpel et al. (2011) provided a dataset of POS-tagged tweets consisting almost entirely of tweets sampled from one particular day (October 27, 2010). We were concerned about overfitting to time-specific phenomena; for example, a substantial fraction of the messages are about a basketball game happening that day.

We created a new test set of 547 tweets for evaluation. The test set consists of one random English tweet from every day between January 1, 2011 and June 30, 2012. In order for a tweet to be considered English, it had to contain at least one English word other than a URL, emoticon, or at-mention. We noticed biases in the outputs of `langid.py`, so we instead selected these messages completely manu-

¹¹http://en.wikipedia.org/wiki/List_of_emoticons

ally (going through a random sample of one day’s messages until an English message was found).

5.1 Annotation Methodology

Gimpel et al. provided a tagset for Twitter (shown in Appendix A), which we used unmodified. The original annotation guidelines were not published, but in this work we recorded the rules governing tagging decisions and made further revisions while annotating the new data.¹² Some of our guidelines reiterate or modify rules made by Penn Treebank annotators, while others treat specific phenomena found on Twitter (refer to the next section).

Our tweets were annotated by two annotators who attempted to match the choices made in Gimpel et al.’s dataset. The annotators also consulted the POS annotations in the Penn Treebank (Marcus et al., 1993) as an additional reference. Differences were reconciled by a third annotator in discussion with all annotators.¹³ During this process, an inconsistency was found in Gimpel et al.’s data, which we corrected (concerning the tagging of *this/that*, a change to 100 labels, 0.4%). The new version of Gimpel et al.’s data (called OCT27), as well as the newer messages (called DAILY547), are both included in our data release.

5.2 Compounds in Penn Treebank vs. Twitter

Ritter et al. (2011) annotated tweets using an augmented version of the PTB tagset and presumably followed the PTB annotation guidelines. We wrote new guidelines because the PTB conventions are inappropriate for Twitter in several ways, as shown in the design of Gimpel et al.’s tagset. Importantly, “compound” tags (e.g., nominal+verbal and nominal+possessive) are used because tokenization is difficult or seemingly impossible for the nonstandard word forms that are commonplace in conversational text.

For example, the PTB tokenization splits contractions containing apostrophes: *I’m* ⇒ *I/PRP ’m/VBP*. But conversational text often contains variants that resist a single PTB tag (like *im*), or even challenge traditional English grammatical categories

¹²The annotation guidelines are available online at <http://www.ark.cs.cmu.edu/TweetNLP/>

¹³Annotators are coauthors of this paper.

(like *imma* or *umma*, which both mean “I am going to”). One strategy would be to analyze these forms into a PTB-style tokenization, as discussed in Forsyth (2007), who proposes to analyze *doncha* as *do/VBP ncha/PRP*, but notes it would be difficult. We think this is impossible to handle in the rule-based framework used by English tokenizers, given the huge (and possibly growing) number of large compounds like *imma*, *gonna*, *w/that*, etc. These are not rare: the word clustering algorithm discovers hundreds of such words as statistically coherent classes (e.g. clusters E1 and E2 in Fig. 2); and the word *imma* is the 962nd most common word in our unlabeled corpus, more frequent than *cat* or *near*.

We do not attempt to do Twitter “normalization” into traditional written English (Han and Baldwin, 2011), which we view as a lossy translation task. In fact, many of Twitter’s unique linguistic phenomena are due not only to its informal nature, but also a set of authors that heavily skews towards younger ages and minorities, with heavy usage of dialects that are different than the standard American English most often seen in NLP datasets (Eisenstein, 2013; Eisenstein et al., 2011). For example, we suspect that *imma* may implicate tense and aspect markers from African-American Vernacular English.¹⁴ Trying to impose PTB-style tokenization on Twitter is linguistically inappropriate: should the lexico-syntactic behavior of casual conversational chatter by young minorities be straightjacketed into the stylistic conventions of the 1980s *Wall Street Journal*? Instead, we would like to directly analyze the syntax of online conversational text on its own terms.

Thus, we choose to leave these word forms untokenized and use compound tags, viewing compositional multiword analysis as challenging future work.¹⁵ We believe that our strategy is sufficient for many applications, such as chunking or named entity recognition; many applications such as sentiment analysis (Turney, 2002; Pang and Lee, 2008, §4.2.3), open information extraction (Carlson et al., 2010; Fader et al., 2011), and information retrieval (Allan and Raghavan, 2002) use POS

¹⁴See “Tense and aspect” examples in http://en.wikipedia.org/wiki/African_American_Vernacular_English

¹⁵For example, *wtf* has compositional behavior in “Wtf just happened??”, but only debatably so in “Huh wtf”.

Table 1: Annotated datasets: number of messages, tokens, tagset, and date range. More information in §5, §6.3, and §6.2.

patterns that seem quite compatible with our approach. More complex downstream processing like parsing is an interesting challenge, since contraction parsing on traditional text is probably a benefit to current parsers. We believe that any PTB-trained tool requires substantial retraining and adaptation for Twitter due to the huge genre and stylistic differences (Foster et al., 2011); thus tokenization conventions are a relatively minor concern. Our simple-to-annotate conventions make it easier to produce new training data.

6 Experiments

We are primarily concerned with performance on our annotated datasets described in §5 (Oct27, DAILY547), though for comparison to previous work we also test on other corpora (RITTERTW in §6.2, NPSCHAT in §6.3). The annotated datasets are listed in Table 1.

6.1 Main Experiments

We use Oct27 to refer to the entire dataset described in Gimpel et al.; it is split into training, development, and test portions (Oct27TRAIN, Oct27DEV, Oct27TEST). We use DAILY547 as an additional test set. Neither Oct27TEST nor DAILY547 were extensively evaluated against until final ablation testing when writing this paper.

The total number of features is 3.7 million, all of which are used under pure L_2 regularization; but only 60,000 are selected by elastic net regularization with $(\lambda_1, \lambda_2) = (0.25, 2)$, which achieves nearly the same (but no better) accuracy as pure L_2 ,¹⁶ and we use it for all experiments. We observed that it was

¹⁶We conducted a grid search for the regularizer values on part of DAILY547, and many regularizer values give the best or nearly the best results. We suspect a different setup would have yielded similar results.

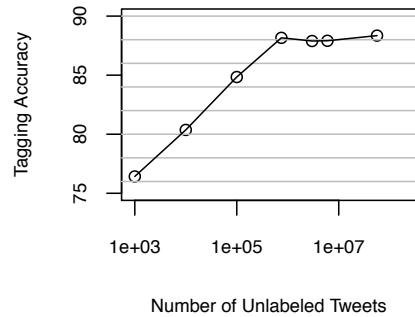

Figure 3: OCT27 development set accuracy using only clusters as features.

Model	In dict.	Out of dict.
Full	93.4	85.0
No clusters	92.0 (-1.4)	79.3 (-5.7)
Total tokens	4,808	1,394

Table 3: DAILY547 accuracies (%) for tokens in and out of a traditional dictionary, for models reported in rows 1 and 3 of Table 2.

possible to get radically smaller models with only a slight degradation in performance: (4, 0.06) has 0.5% worse accuracy but uses only 1,632 features, a small enough number to browse through manually.

First, we evaluate on the new test set, training on all of Oct27. Due to DAILY547’s statistical representativeness, we believe this gives the best view of the tagger’s accuracy on English Twitter text. The full tagger attains **93.2%** accuracy (final row of Table 2).

To facilitate comparisons with previous work, we ran a series of experiments training only on Oct27’s training and development sets, then report test results on both Oct27TEST and all of DAILY547, shown in Table 2. Our tagger achieves substantially higher accuracy than Gimpel et al. (2011).¹⁷

Feature ablation. A number of ablation tests indicate the word clusters are a very strong source of lexical knowledge. When dropping the tag dictionaries and name lists, the word clusters maintain most of the accuracy (row 2). If we drop the clusters and rely only on tag dictionaries and namelists, accuracy decreases significantly (row 3). In fact, we can remove *all* observation features except for word clusters—no word features, orthographic fea-

¹⁷These numbers differ slightly from those reported by Gimpel et al., due to the corrections we made to the Oct27 data, noted in Section 5.1. We retrained and evaluated their tagger (version 0.2) on our corrected dataset.

Model trained on all OCT27		93.2		8

Table 2: Tagging accuracies (%) in ablation experiments. OCT27TEST and DAILY547 95% confidence intervals are roughly $\pm 0.7\%$. Our final tagger uses all features and also trains on OCT27TEST, achieving 93.2% on DAILY547.

tures, affix n -grams, capitalization, emoticon patterns, etc.—and the accuracy is in fact still better than the previous work (row 4).¹⁸

We also wanted to know whether to keep the tag dictionary and name list features, but the splits reported in Fig. 2 did not show statistically significant differences; so to better discriminate between ablations, we created a lopsided train/test split of all data with a much larger test portion (26,974 tokens), having greater statistical power (tighter confidence intervals of $\pm 0.3\%$).¹⁹ The full system got 90.8% while the no-tag dictionary, no-namelists ablation had 90.0%, a statistically significant difference. Therefore we retain these features.

Compared to the tagger in Gimpel et al., most of our feature changes are in the new lexical features described in §3.5.²⁰ We do not reuse the other lexical features from the previous work, including a phonetic normalizer (Metaphone), a name list consisting of words that are frequently capitalized, and distributional features trained on a much smaller unlabeled corpus; they are all worse than our new lexical features described here. (We did include, however, a variant of the tag dictionary feature that uses phonetic normalization for lookup; it seemed to yield a small improvement.)

¹⁸Furthermore, when evaluating the clusters as *unsupervised* (hard) POS tags, we obtain a many-to-one accuracy of 89.2% on DAILY547. Before computing this, we lowercased the text to match the clusters and removed tokens tagged as URLs and at-mentions.

¹⁹Reported confidence intervals in this paper are 95% binomial normal approximation intervals for the proportion of correctly tagged tokens: $\pm 1.96 \sqrt{p(1-p)/n_{tokens}} \lesssim 1/\sqrt{n}$.

²⁰Details on the exact feature set are available in a technical report (Owoputi et al., 2012), also available on the website.

Non-traditional words. The word clusters are especially helpful with words that do not appear in traditional dictionaries. We constructed a dictionary by lowercasing the union of the *ispell* ‘American’, ‘British’, and ‘English’ dictionaries, plus the standard Unix *words* file from Webster’s Second International dictionary, totalling 260,985 word types. After excluding tokens defined by the gold standard as punctuation, URLs, at-mentions, or emoticons,²¹ 22% of DAILY547’s tokens do not appear in this dictionary. Without clusters, they are very difficult to classify (only 79.2% accuracy), but adding clusters generates a 5.7 point improvement—much larger than the effect on in-dictionary tokens (Table 3).

Varying the amount of unlabeled data. A tagger that only uses word clusters achieves an accuracy of 88.6% on the OCT27 development set.²² We created several clusterings with different numbers of unlabeled tweets, keeping the number of clusters constant at 800. As shown in Fig. 3, there was initially a logarithmic relationship between number of tweets and accuracy, but accuracy (and lexical coverage) levels out after 750,000 tweets. We use the largest clustering (56 million tweets and 1,000 clusters) as the default for the released tagger.

6.2 Evaluation on RITTERTW

Ritter et al. (2011) annotated a corpus of 787 tweets²³ with a single annotator, using the PTB

²¹We retain hashtags since by our guidelines a #-prefixed token is ambiguous between a hashtag and a normal word, e.g. #1 or going #home.

²²The only observation features are the word clusters of a token and its immediate neighbors.

tagset plus several Twitter-specific tags, referred to in Table 1 as RITTERTW. Linguistic concerns notwithstanding (§5.2), for a controlled comparison, we train and test our system on this data with the same 4-fold cross-validation setup they used, attaining 90.0% ($\pm 0.5\%$) accuracy. Ritter et al.’s CRF-based tagger had 85.3% accuracy, and their best tagger, trained on a concatenation of PTB, IRC, and Twitter, achieved 88.3% (Table 4).

6.3 IRC: Evaluation on NPSCHAT

IRC is another medium of online conversational text, with similar emoticons, misspellings, abbreviations and acronyms as Twitter data. We evaluate our tagger on the NPS Chat Corpus (Forsyth and Martell, 2007),²⁴ a PTB-part-of-speech annotated dataset of Internet Relay Chat (IRC) room messages from 2006.

First, we compare to a tagger in the same setup as experiments on this data in Forsyth (2007), training on 90% of the data and testing on 10%; we average results across 10-fold cross-validation.²⁵ The full tagger model achieved 93.4% ($\pm 0.3\%$) accuracy, significantly improving over the best result they report, 90.8% accuracy with a tagger trained on a mix of several POS-annotated corpora.

We also perform the ablation experiments on this corpus, with a slightly different experimental setup: we first filter out system messages then split data

²⁴Release 1.0: <http://faculty.nps.edu/cmartell/NPSChat.htm>

²⁵Forsyth actually used 30 different 90/10 random splits; we prefer cross-validation because the same test data is never repeated, thus allowing straightforward confidence estimation of accuracy from the number of tokens (via binomial sample variance, footnote 19). In all cases, the models are trained on the same amount of data (90%).

into 5,067 training and 2,868 test messages. Results show a similar pattern as the Twitter data (see final column of Table 2). Thus the Twitter word clusters are also useful for language in the medium of text chat rooms; we suspect these clusters will be applicable for deeper syntactic and semantic analysis in other online conversational text mediums, such as text messages and instant messages.

7 Conclusion

We have constructed a state-of-the-art part-of-speech tagger for the online conversational text genres of Twitter and IRC, and have publicly released our new evaluation data, annotation guidelines, open-source tagger, and word clusters at <http://www.ark.cs.cmu.edu/TweetNLP>.

Abstract

We describe a new self-learning framework for parser lexicalisation that requires only a plain-text corpus of in-domain text. The method first creates augmented versions of dependency graphs by applying a series of modifications designed to directly capture higher-order lexical path dependencies. Scores are assigned to each edge in the graph using statistics from an automatically parsed background corpus. As bilexical dependencies are sparse, a novel directed distributional word similarity measure is used to smooth edge score estimates. Edge scores are then combined into graph scores and used for reranking the top- n analyses found by the unlexicalised parser. The approach achieves significant improvements on WSJ and biomedical text over the unlexicalised baseline parser, which is originally trained on a subset of the Brown corpus.

1 Introduction

Most parsers exploit supervised machine learning methods and a syntactically annotated dataset (i.e. treebank), incorporating a wide range of features in the training process to deliver competitive performance. The use of lexically-conditioned features, such as relations between lemmas or word forms, is often critical when choosing the correct syntactic analysis in ambiguous contexts. However, utilising such features leads the parser to learn information that is often specific to the domain and/or genre of the training data. Several experiments have demonstrated that many lexical features learnt in

one domain provide little if any benefit when parsing text from different domains and genres (Sekine, 1997; Gildea, 2001). Furthermore, manual creation of in-domain treebanks is an expensive and time-consuming process, which can only be performed by experts with sufficient linguistic and domain knowledge.

In contrast, unlexicalised parsers avoid using lexical information and select a syntactic analysis using only more general features, such as POS tags. While they cannot be expected to achieve optimal performance when trained and tested in a single domain, unlexicalised parsers can be surprisingly competitive with their lexicalised counterparts (Klein and Manning, 2003; Petrov et al., 2006). In this work, instead of trying to adapt a lexicalised parser to new domains, we explore how bilexical features can be integrated effectively with any unlexicalised parser. As our novel self-learning framework requires only a large unannotated corpus, lexical features can be easily tuned to a specific domain or genre by selecting a suitable dataset. In addition, we describe a graph expansion process that captures selected bilexical relations which improve performance but would otherwise require sparse higher-order dependency path feature types in most approaches to dependency parsing. As many bilexical features will still be sparse, we also develop an approach to estimating confidence scores for dependency relations using a directional distributional word similarity measure. The final framework integrates easily with any unlexicalised (and therefore potentially less domain/genre-biased) parser capable of returning ranked dependency analyses.

2 Background

We hypothesise that a large corpus will often contain examples of dependency relations in non-ambiguous contexts, and these will mostly be correctly parsed by an unlexicalised parser. Lexical statistics derived from the corpus can then be used to select the correct parse in a more difficult context. For example, consider the following sentences:

- (1) a. Government projects interest researchers
- b. Government raises interest rates
- c. Government projects receive funding
- d. Interest rates are increasing

Noun-verb ambiguities over *projects* and *interest* might erroneously result in the unlexicalised parser returning similar dependency graphs for both *a* and *b*. However, sentences *c* and *d* contain less ambiguous instances of the same phrases and can provide clues to correctly parsing the first two examples. In a large in-domain corpus we are likely to find more cases of *researchers* being the object for *interest* and fewer cases where it is the object of *project*. In contrast, *rates* is more likely to have *interest* as a modifier than as a head in an object relation. Exploiting this lexical information, we can assign the correct derivation to each of the more ambiguous sentences.

Similar intuitions have been used to motivate the acquisition of bilexical features from background corpora for improving parser accuracy. However, previous work has focused on including these statistics as auxiliary features during supervised training. For example, van Noord (2007) incorporated bilexical preferences as features via self-training to improve the Alpino parser for Dutch. Plank and van Noord (2008) investigated the application of auxiliary distributions for domain adaptation. They incorporated information from both in-domain and out-of-domain sources into their maximum entropy model and found that the out-of-domain auxiliary distributions did not contribute to parsing accuracy in the target domain. Zhou et al. (2011) extracted n-gram counts from Google queries and a large corpus to improve the MSTParser. In contrast to previous work, we refer to our approach as self-learning because it differs from self-training by utilising statistics found using an initial parse ranking model to

create a *separate* unsupervised reranking component, without retraining the baseline unlexicalised model.

We formulate our self-learning framework as a reranking process that assigns new scores to the top- n ranked analyses found by the original parser. Parse reranking has been successfully used in previous work as a method of including a wider range of features to rescore a smaller selection of highly-ranked candidate parses. Collins (2000) was one of the first to propose supervised reranking as an additional step to increase parser accuracy and achieved 1.55% accuracy improvement for his parser. Charniak and Johnson (2005) utilise a discriminative reranker and show a 1.3% improvement for the Charniak parser. McClosky et al. (2006) extend their work by adding new features and further increase the performance by 0.3%. Ng et al. (2010) implemented a discriminative maximum entropy reranker for the C&C parser and showed a 0.23% improvement over the baseline. Bansal and Klein (2011) discriminatively rerank derivations from the Berkeley unlexicalised parser (Petrov et al., 2006) demonstrating that lexical features derived from the Google n-gram corpus improve accuracy even when used in conjunction with other reranking features. They have all treated reranking as a supervised task and trained a discriminative classifier using parse tree features and annotated in-domain data. In contrast, our reranker only uses statistics from an unlabelled source and requires no manual annotation or training of the reranking component. As we utilise an unlexicalised parser, our baseline performance on WSJ text is lower compared to some fully-lexicalised parsers. However, an unlexicalised parser is also likely to be less biased to domains or genres manifested in the text used to train its original ranking model. This may allow the reranker to adapt it to a new domain and/or genre more effectively.

3 Reordering dependency graphs

For our experiments, we make use of the unlexicalised RASP parser (Briscoe et al., 2006) as the baseline system. For every sentence s the parser returns a list of dependency graphs G_s , ranked by the log probability of the associated derivation in the structural ranking model. Our goal is to reorder this

list to improve ranking accuracy and, most importantly, to improve the quality of the highest-ranked dependency graph. This is done by assigning a confidence score to every graph $g_{s,r} \in G_s$ where r is the rank of g_s for sentence s . The method treats each sentence independently, therefore we can omit the sentence identifiers and refer to $g_{s,r}$ as g_r .

We first calculate confidence scores for all the individual edges and then combine them into an overall score for the dependency graph. In the following sections, we describe a series of graph modifications that incorporates selected higher-order dependency path relations, without introducing unwanted noise or complexity into the reranker. Next, we outline different approaches for calculating and smoothing the confidence scores for blexical relations. Finally, we describe methods for combining together these scores and calculating an overall score for a dependency graph. We make publically available all the code developed for performing these steps in the parse reranking system.¹

3.1 Graph modifications

For every dependency graph g_r the graph expansion procedure creates a modified representation g'_r which contains a wider range of blexical relations. The motivation for this graph expansion step is similar to that motivating the move from first-order to higher-order dependency path feature types (e.g., Carreras (2007)). However, compared to using all n th-order paths, these rules are chosen to maximise the utility and minimise the sparsity of the resulting blexical features. In addition, the cascading nature of the expansion steps means in some cases the expansion captures useful 3rd and 4th order dependencies. Similar approaches to graph modifications have been successfully used for several NLP tasks (van Noord, 2007; Arora et al., 2010).

For any edge e we also use notation (rel, w_1, w_2) , referring to an edge from w_1 to w_2 with the label rel . We perform the following modifications on every dependency graph:

1. **Normalising lemmas.** All lemmas are converted to lowercase. Numerical lemmas are replaced with more generic tags to reduce sparsity.

¹www.marekrei.com/projects/lexicalisation

2. **Bypassing conjunctions.** For every edge pair (rel_1, w_1, w_2) and (rel_2, w_2, w_3) where w_2 is tagged as a conjunction, we create an additional edge (rel_1, w_1, w_3) . This bypasses the conjunction node and creates direct edges between the head and dependents of the conjunctive lemma.
3. **Bypassing prepositions.** For every edge pair (rel_1, w_1, w_2) and (rel_2, w_2, w_3) where w_2 is tagged as a preposition, we create an additional edge (rel_3, w_1, w_3) . $rel_3 = rel_1 + \text{'-prep'}$, where ‘-prep’ is added as a marker to indicate that the relation originally contained a preposition.
4. **Bypassing verbs.** For every edge pair (rel_1, w_1, w_2) and (rel_2, w_1, w_3) where w_1 is tagged as a verb, w_2 and w_3 are both tagged as open-class lemmas, rel_1 starts with a subject relation, and rel_2 starts with an object relation, we create an additional edge (rel_3, w_2, w_3) where $rel_3 = rel_1 + \text{'-' + rel}_2$. This creates an additional edge between the subject and the object, with the new edge label containing both of the original labels.
5. **Duplicating nodes.** For every existing node in the graph, containing the lemma and POS for each token ($lemma_pos$), we create a parallel node without the POS information ($lemma$). Then, for each existing edge, we create three corresponding edges, interconnecting the parallel nodes to each other and the original graph. This allows the reranker to exploit both specific and more generic instantiations of each lemma.

Figure 1 illustrates the graph modification process. It is important to note that each of these modifications gets applied in the order that they are described above. For example, when creating edges for bypassing verbs, the new edges for prepositions and conjunctions have already been created and also participate in this step. We performed ablation tests on the development data and verified that each of these modifications contributes positively to the final performance.

3.2 Edge scoring methods

We start the scoring process by assigning individual confidence scores to every blexical relation in the

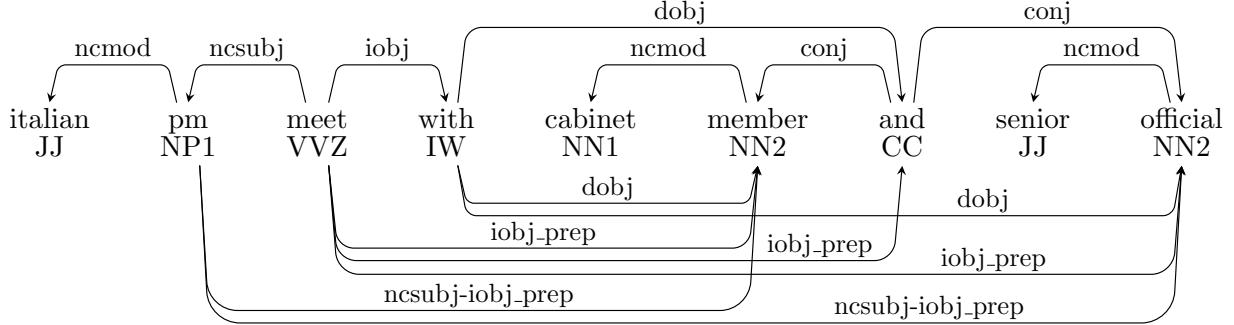

Figure 1: Modified graph for the sentence ‘*Italian PM meets with Cabinet members and senior officials*’ after steps 1-4. Edges above the text are created by the parser, edges below the text are automatically created using the operations described in Section 3.1. The 5th step will create 9 new nodes and 45 additional edges (not shown).

modified graph. In this section we give an overview of some possible strategies for performing this task.

The parser returns a ranked list of graphs and this can be used to derive an edge score without requiring any additional information. We estimate that the likelihood of a parse being the best possible parse for a given sentence is roughly inversely proportional to the rank that it is assigned by the parser. These values can be summed for all graphs that contain a specific edge, normalised to approximate a probability. We then calculate the score for edge e as the Reciprocal Edge Score (RES) – the probability of e belonging to the best possible parse:

$$\text{RES}(e) = \frac{\sum_{r=1}^R [\frac{1}{r} \times \text{contains}(g'_r, e)]}{\sum_{r=1}^R \frac{1}{r}}$$

where R is the total number of parses for a sentence, and $\text{contains}(g'_r, e)$ returns 1 if graph g'_r contains edge e , and 0 otherwise. The value is normalised, so that an edge which is found in all parses will have a score of 1.0, but occurrences at higher ranks will have a considerably larger contribution.

The score of an edge can also be assigned by estimating the probability of that edge using a parsed reference corpus. van Noord (2007) improved overall parsing performance in a supervised self-training framework using feature weights based on pointwise mutual information:

$$I(e) = \log \frac{P(\text{rel}, w_1, w_2)}{P(\text{rel}, w_1, *) \times P(*, *, w_2)}$$

where $P(\text{rel}, w_1, w_2)$ is the probability of seeing an edge from w_1 to w_2 with label rel , $P(\text{rel}, w_1, *)$ is

the probability of seeing an edge from w_1 to any node with label rel , and $P(*, *, w_2)$ is the probability of seeing any type of edge linking to w_2 . Plank and van Noord (2008) used the same approach for semi-supervised domain adaptation but were not able to achieve similar performance benefits. In our implementation we omit the logarithm in the equation, as this improves performance and avoids problems with $\log(0)$ for unseen edges.

$I(e)$ compares the probability of the complete edge to the probabilities of partially specified edges, but it assumes that w_2 will have an incoming relation, and that w_1 will have an outgoing relation of type rel to some unknown node. These assumptions may or may not be true – given the input sentence, we have observed w_1 and w_2 but do not know what relations they are involved in. Therefore, we create a more general version of the measure that compares the probability of the complete edge to the individual probabilities of the two lemmas – the Conditional Edge Score (CES_1):

$$\text{CES}_1(e) = \frac{P(\text{rel}, w_1, w_2)}{P(w_1) \times P(w_2)}$$

where $P(w_1)$ is the probability of seeing w_1 in text, estimated from a background corpus using maximum likelihood.

Finally, we know that w_1 and w_2 are in a sentence together but cannot assume that there is a dependency relation between them. However, we can choose to think of each sentence as a fully connected graph, with an edge going from every lemma to every other lemma in the same sentence. If there exists

$$\text{ECES}_1(\text{rel}, w_1, w_2) = \frac{1}{2} \times \left(\frac{\sum_{c_1 \in C_1} \text{sim}(c_1, w_1) \times \frac{P(\text{rel}, c_1, w_2)}{P(c_1) \times P(w_2)}}{\sum_{c_1 \in C_1} \text{sim}(c_1, w_1)} + \frac{\sum_{c_2 \in C_2} \text{sim}(c_2, w_2) \times \frac{P(\text{rel}, w_1, c_2)}{P(w_1) \times P(c_2)}}{\sum_{c_2 \in C_2} \text{sim}(c_2, w_2)} \right)$$

$$\text{ECES}_2(\text{rel}, w_1, w_2) = \frac{1}{2} \times \left(\frac{\sum_{c_1 \in C_1} \text{sim}(c_1, w_1) \times \frac{P(\text{rel}, c_1, w_2)}{P(*, c_1, w_2)}}{\sum_{c_1 \in C_1} \text{sim}(c_1, w_1)} + \frac{\sum_{c_2 \in C_2} \text{sim}(c_2, w_2) \times \frac{P(\text{rel}, w_1, c_2)}{P(*, w_1, c_2)}}{\sum_{c_2 \in C_2} \text{sim}(c_2, w_2)} \right)$$

Figure 2: Expanded edge score calculation methods using the list of distributionally similar lemmas

no genuine relation between the lemmas, the edge is simply considered a *null* edge. We can then find the conditional probability of the relation type given the two lemmas:

$$\text{CES}_2(e) = \frac{P(\text{rel}, w_1, w_2)}{P(*, w_1, w_2)}$$

where $P(\text{rel}, w_1, w_2)$ is the probability of the fully-specified relation, and $P(*, w_1, w_2)$ is the probability of there being an edge of any type from w_1 to w_2 , including a *null* edge. Using fully connected graphs, the latter is equivalent to the probability of w_1 and w_2 appearing in a sentence together, which again can be calculated from the background corpus.

3.3 Smoothing edge scores

Apart from RES, all the scoring methods from the previous section rely on correctly estimating the probability of the fully-specified edge, $P(\text{rel}, w_1, w_2)$. Even in a large background corpus these triples will be very sparse, and it can be useful to find approximate methods for estimating the edge scores.

Using smoothing techniques derived from work on language modelling, we could back-off to a more general version of the relation. For example, if *(dobj, read, publication)* is not frequent enough, the value could be approximated using the probabilities of *(dobj, read, *)* and *(dobj, *, publication)*. However, this can lead to unexpected results due to compositionality – while *(dobj, read, *)* and *(dobj, *, rugby)* can be fairly common, *(dobj, read, rugby)* is an unlikely relation.

Instead, we can consider looking at other lemmas which are similar to the rare lemmas in the relation. If *(dobj, read, publication)* is infrequent in the data, the system might predict that *book* is a reasonable substitute for *publication* and use *(dobj, read, book)*

to estimate the original probability.

Given that we have a reliable way of finding likely substitutes for a given lemma, we can create expanded versions of CES₁ and CES₂, as shown in Figure 2. C_1 is the list of substitute lemmas for w_1 , and sim(c_1, w_1) is a measure showing how similar c_1 is to w_1 . The methods iterate over the list of substitutes and calculate the CES score for each of the modified relations. The values are then combined by using the similarity score as a weight – more similar lemmas will have a higher contribution to the final result. This is done for both the head and the dependent in the original relation, and the scores are then normalised and averaged.

Experiments with a wide variety of distributional word similarity measures revealed that *WeightedCosine* (Rei, 2013), a directional similarity measure designed to better capture hyponymy relations, performed best. Hyponyms are more specific versions of a word and normally include the general properties of the hypernym, making them well-suited for lexical substitution. The *WeightedCosine* measure incorporates an additional directional weight into the standard cosine similarity, assigning different importance to individual features for the hyponymy relation. We retain the 10 most distributionally similar putative hyponyms for each lemma and substitute them in the relation. The original lemma is also included with similarity 1.0, thereby assigning it the highest weight. The lemma vectors are built from the same vector space model that is used for calculating edge probabilities, which includes all the graph modifications described in Section 3.1.

3.4 Combining edge scores

While the CES and ECES measures calculate confidence scores for bilexical relations using statistics from a large background corpus, they do not include any knowledge about grammar, syntax, or the con-

$$\text{CMB}_1(e) = \sqrt[3]{\text{RES}(e) * \text{CES}_1(e) * \text{CES}_2(e)}$$

$$\text{CMB}_2(e) = \sqrt[3]{\text{RES}(e) * \text{ECES}_1(e) * \text{ECES}_2(e)}$$

Figure 3: Edge score combination methods

text in a specific sentence. In contrast, the RES score implicitly includes some of this information, as it is calculated based on the original parser ranking. In order to take advantage of both information sources, we combine these scores into CMB_1 and CMB_2 , as shown in Figure 3.

3.5 Graph scoring

Every edge in graph g'_r is assigned a score indicating the reranker’s confidence in that edge belonging to the best parse. We investigated different strategies for combining these values together into a confidence score for the whole graph. The simplest solution is to sum together individual edge scores, but this would lead to always preferring graphs that have a larger number of edges. Interestingly, averaging the edge scores does not produce good results either because it is biased towards smaller graph fragments containing only highly-confident edges.

We created a new scoring method which prefers graphs that cover all the nodes, but does not create bias for a higher number of edges. For every node in the graph, it finds the average score of all edges which have that node as a dependent. These scores are then averaged again over all nodes:

$$\text{NScore}(n) = \frac{\sum_{e \in E_g} \text{EdgeScore}(e) \times \text{isDep}(e, n)}{\sum_{e \in E_g} \text{isDep}(e, n)}$$

$$\text{GraphScore}(g) = \frac{\sum_{n \in N_g} \text{NScore}(n)}{|N_g|}$$

where g is the graph being scored, $n \in N_g$ is a node in graph g , $e \in E_g$ is an edge in graph g , $\text{isDep}(e, n)$ is a function returning 1.0 if n is the dependent in edge e , and 0.0 otherwise. $\text{NScore}(n)$ is set to 0 if the node does not appear as a dependent in any edges. We found this metric performs well, as it prefers graphs that connect together many nodes without simply rewarding a larger number of edges.

While the score calculation is done using the modified graph g'_r , the resulting score is directly assigned to the corresponding original graph g_r , and

the reordering of the original dependency graphs is used for evaluation.

4 Experiments

4.1 Evaluation methods

In order to evaluate how much the reranker improves the highest-ranked dependency graph, we calculate the microaveraged precision, recall and F-score over all dependencies from the top-ranking parses for the test set. Following the official RASP evaluation (Briscoe et al., 2006) we employ the hierarchical edge matching scheme which aggregates counts up the dependency relation subsumption hierarchy and thus rewards the parser for making more fine-grained distinctions.² Statistical significance of the change in F-score is calculated by using the Approximate Randomisation Test (Noreen, 1989; Cohen, 1995) with 10^6 iterations.

We also wish to measure how well the reranker does at the overall task of ordering dependency graphs. For this we make use of an oracle that creates the perfect ranking for a set of graphs by calculating their individual F-scores; this ideal ranking is then compared to the output of our system. Spearman’s rank correlation coefficient between the two rankings is calculated for each sentence and then averaged over all sentences. If the scores for all of the returned analyses are equal, this coefficient cannot be calculated and is set to 0.

4.2 DepBank

We evaluated our self-learning framework using the DepBank/GR reannotation (Briscoe and Carroll, 2006) of the PARC 700 Dependency Bank (King et al., 2003). The dataset is provided with the open-source RASP distribution³ and has been used for evaluating different parsers, including RASP (Briscoe and Carroll, 2006; Watson et al., 2007) and

²Slight changes in the performance of the baseline parser compared to previous publications are due to using a more recent version of the parser and minor corrections to the gold standard annotation.

³ilexir.co.uk/2012/open-source-rasp-3-1/

C&C (Clark and Curran, 2007). It contains 700 sentences, randomly chosen from section 23 of the WSJ Penn Treebank (Marcus et al., 1993), divided into development (140 sentences) and test data (560 sentences). We made use of the development data to experiment with a wider selection of edge and graph scoring methods, and report the final results on the test data.

For reranking we collect up to 1000 top-ranked analyses for each sentence. The actual number of analyses that the RASP parser outputs depends on the sentence and can be smaller. As the parser first constructs parse trees and converts them to dependency graphs, several parse trees may result in identical graphs; we remove any duplicates to obtain a ranking of unique dependency graphs.

Our approach relies on a large unannotated corpus of in-domain text, and for this we used the BLLIP corpus containing 50M words of in-domain WSJ articles. Our version of this corpus excludes texts that are found in the Penn Treebank, thereby also excluding the section that we use for evaluation.

The baseline system is the unlexicalised RASP parser with default settings. In order to construct the upper bound, we use an oracle to calculate the F-score for each dependency graph individually, and then create the best possible ranking using these scores.

Table 1 contains evaluation results on the DepBank/GR test set. The baseline system achieves 76.41% F-score on the test data, with 32.70% average correlation. I and RES scoring methods give comparable results, with RES improving correlation by 9.56%. The CES and ECES scores all make use of corpus-based statistics and all significantly improve over the baseline system, with absolute increases in F-score of more than 2% for the fully-connected edge score variants.

Finally, we combine the RES score with the corpus-based methods and the fully-connected CMB₂ variant again delivers the best overall results. The final F-score is 79.21%, an absolute improvement of 2.8%, corresponding to 33.65% relative error reduction with respect to the upper bound. Correlation is also increased by 16.32%; this means the methods not only improve the chances of finding the best dependency graph, but also manage to create a better overall ranking. The F-scores for all the

corpus-based scoring methods are statistically significant when compared to the baseline ($p < 0.05$).

By using our self-learning framework, we were able to significantly improve the original unlexicalised parser. To put the overall result in a wider perspective, Clark and Curran (2007) achieve an F-score of 81.86% on the DepBank/GR test sentences using the C&C lexicalised parser, trained on 40,000 manually-treebanked sentences from the WSJ. The unlexicalised RASP parser, using a manually-developed grammar and a parse ranking component trained on 4,000 partially-bracketed unlabelled sentences from a domain/genre balanced subset of Brown (Watson et al., 2007), achieves an F-score of 76.41% on the same test set. The method introduced here improves this to 79.21% F-score without using any further manually-annotated data, closing more than half of the gap between the performance of a fully-supervised in-domain parser and a more weakly-supervised more domain-neutral one.

We also performed an additional detailed analysis of the results and found that, with the exception of the auxiliary dependency relation, the reranking process was able to improve the F-score of all other individual dependency types. Complements and modifiers are attached with much higher accuracy, resulting in 3.34% and 3.15% increase in the corresponding F-scores. The non-clausal modifier relation (*nc-mod*), which is the most frequent label in the dataset, increases by 3.16%.

4.3 Genia

One advantage of our reranking framework is that it does not rely on any domain-dependent manually annotated resources. Therefore, we are interested in seeing how it performs on text from a completely different domain and genre.

The GENIA-GR dataset (Tateisi et al., 2008) is a collection of 492 sentences taken from biomedical research papers in the GENIA corpus (Kim et al., 2003). The sentences have been manually annotated with dependency-based grammatical relations identical to those output by the RASP parser. However, it does not contain dependencies for all tokens and many multi-word phrases are treated as single units. For example, the tokens ‘*intracellular redox status*’ are annotated as one node with label *intracellular_redox_status*. We retain this annotation and

	DepBank/GR				GENIA-GR			
	Prec	Rec	F	ρ	Prec	Rec	F	ρ
Baseline	77.91	74.97	76.41	32.70	79.91	78.86	79.38	36.54
Upper Bound	86.74	82.82	84.73	75.36	86.33	84.71	85.51	78.66
I	77.77	75.00	76.36	33.32	77.18	76.21	76.69	30.23
RES	78.13	74.94	76.50	42.26	80.06	78.89	79.47	47.52
CES₁	79.68	76.40	<u>78.01</u>	41.95	78.64	77.50	78.07	36.06
CES₂	80.48	77.28	<u>78.85</u>	48.43	79.92	78.92	79.42	43.09
ECES₁	79.96	76.68	<u>78.29</u>	42.41	79.09	78.11	78.60	38.02
ECES₂	80.71	77.52	<u>79.08</u>	49.05	79.84	78.95	79.39	43.64
CMB₁	80.64	77.31	<u>78.94</u>	48.25	80.60	79.51	80.05	44.96
CMB₂	80.88	77.60	79.21	49.02	80.69	79.64	80.16	46.24

Table 1: Performance of different edge scoring methods on the test data. For each measure we report precision, recall, F-score, and average Spearman’s correlation (ρ). The highest results for each measure are marked in bold. The underlined F-scores are significantly better compared to the baseline.

allow the unlexicalised parser to treat these nodes as atomic unseen words during POS tagging and parsing. However, we use the last lemma in each multi-word phrase for calculating the edge score statistics.

In order to initialise our parse reranking framework, we also need a background corpus that closely matches the evaluation domain. The annotated sentences in GENIA-GR were chosen from abstracts that are labelled with the MeSH term ‘*NF-kappa B*’. Following this method, we created our background corpus by extracting 7,100 full-text articles (1.6M sentences) from the PubMed Central Open Access collection, containing any of the following terms with any capitalisation: ‘*nf-kappa b*’, ‘*nf-kappab*’, ‘*nf kappa b*’, ‘*nf-kappa.b*’, ‘*nf-kb*’, ‘*nf-κb*’. Since we retain all texts from matching documents, this keyword search acts as a broad indicator that the sentences contain topics which correspond to the evaluation dataset. This focussed corpus was then parsed with the unlexicalised parser and used to create a statistical model for the reranking system, following the same methods as described in Sections 3 and 4.2.

Table 1 also contains the results for experiments in the biomedical domain. The first thing to notice is that while the upper bound for the unlexicalised parser is similar to that for the DepBank experiments in Section 4.2, the baseline results are considerably higher. This is largely due to the nature of the dataset – since many complicated multi-word phrases are treated as single nodes, the parser is not evaluated on edges within these nodes. In addition, treating these

nodes as unseen words eliminates many incorrect derivations that would otherwise split the phrases. This results in a naturally higher baseline of 79.38%, and also makes it more difficult to further improve the performance.

The edge scoring methods I, CES₁ and ECES₁ deliver F-scores lower than the baseline in this experiment. RES, CES₂ and ECES₂ yield a modest improvement in both F-score and Spearman’s correlation. Finally, the combination methods again give the best performance, with CMB₂ delivering an F-score of 80.16%, an absolute increase of 0.78%, which is statistically significant ($p < 0.05$). The experiment shows that our self-learning framework works on very different domains, and it can be used to significantly increase the accuracy of an unlexicalised parser without requiring any annotated data.

5 Conclusion

We developed a new self-learning framework for dependency graph reranking that requires only a plain-text corpus from a suitable domain. We automatically parse this corpus and use the highest ranked analyses to estimate maximum likelihood probabilities for bilexical relations. Every dependency graph is first modified to incorporate additional edges that model selected higher-order dependency path relationships. Each edge in the graph is then assigned a confidence score based on statistics from the background corpus and ranking preferences from the un-

lexicalised parser. We also described a novel method for smoothing these scores using directional distributional similarity measures. Finally, the edge scores are combined into an overall graph score by first averaging them over individual nodes.

As the method requires no annotated data, it can be easily adapted to different domains and genres. Our experiments showed that the reranking process significantly improved performance on both WSJ and biomedical data.

Abstract

Advances in sentiment analysis have enabled extraction of user relations implied in online textual exchanges such as forum posts. However, recent studies in this direction only consider direct relation extraction from text. As user interactions can be sparse in online discussions, we propose to apply collaborative filtering through probabilistic matrix factorization to generalize and improve the opinion matrices extracted from forum posts. Experiments with two tasks show that the learned latent factor representation can give good performance on a relation polarity prediction task and improve the performance of a subgroup detection task.

1 Introduction

The fast growth of the social Web has led to a large amount of interest in online social network analysis. Most existing work on social network analysis relies on explicit links among users such as undirected friendship relations (Liben-Nowell and Kleinberg, 2003), directed following relations (Hopcroft et al., 2011) and trust/distrust relations (Leskovec et al., 2010). However, besides these explicit social relations, the various kinds of interactions between online users often suggest other implicit relations. In particular, in online discussion forums, users interact through textual posts and these exchanged texts often reveal whether two users are friends or foes, or whether two users share the same viewpoint towards a given issue.

To uncover such implicit relations requires text analysis and particularly sentiment analysis. Re-

cently, Hassan et al. (2012) studied predicting the polarity of user interactions in online discussions based on textual exchanges. They found that the automatically predicted signed relations had an accuracy above 80%. The extracted signed network was further used to detect ideological subgroups. This is a piece of pioneering work that extracts online social relations based on text analysis.

In this paper, we further extend the idea of mining social relations from online forum posts by incorporating collaborative filtering. Our work is motivated by the observation that direct textual exchanges between users are sparse. For example, in the data set we use, only around 13% of user-user pairs have direct interactions. Collaborative filtering is a commonly used technique in recommender systems to predict missing ratings. The key assumption is that if two people have the same opinion on an item *A*, they are likely to also have the same opinion on a different item *B*. In online discussion forums, users express their opinions about each other as well as the various aspects of the topic under discussion, but not every user comments on every aspect or every other user. Collaborative filtering allows us to identify users with the same opinion even if they have not directly interacted with each other or commented on any common aspect.

Our method starts with extracting opinions on users and topic aspects from online posts using sentiment analysis. The results are two matrices indicating the sentiment polarity scores between pairs of users and pairs of a user and an aspect. To incorporate collaborative filtering, we choose probabilistic matrix factorization (PMF) (Salakhutdinov

and Mnih, 2008), a technique that has been successfully applied for collaborative filtering-based recommendation problems. PMF automatically discovers a low-rank representation for both users and items based on observed rating data. In our problem, the predicted sentiment polarity scores are treated as rating data, and the results of PMF are low-rank vectors representing each user in online discussions.

We evaluate our method on two tasks. The first is to predict the polarity of interactions between two users not from their own textual exchanges but from their interactions with other users or comments on topic aspects. The second is to use the latent vectors to group users based on viewpoints. We find that the latent factor representation can produce good prediction results for the first task and improve the clustering results of the second task compared with a number of baselines, showing the effectiveness of collaborative filtering for mining social relations from online discussions.

2 Related Work

Our work is closely related to recent studies on detecting subgroups from online discussions (Abu-Jbara et al., 2012; Dasigi et al., 2012; Hassan et al., 2012). Abu-Jbara et al. (2012) proposed to build discussant attitude profiles (DAP) from online posts and use these profiles to cluster users into subgroups. A DAP is a vector that contains the attitudes of a discussant towards other discussants and a set of opinion targets. We also extract opinions of users towards other users and opinion targets from posts, which are similar to DAPs. The difference is that we further apply probabilistic matrix factorization to derive a low-rank representation from the raw opinion scores. Our comparison with DAP-based clustering shows that probabilistic matrix factorization can improve subgroup detection. Hassan et al. (2012) proposed to predict the polarity of interactions between users based on their textual exchanges. They defined a set of interaction features using sentiment analysis and applied supervised learning for polarity prediction. In comparison, our work is unsupervised, that is, we do not use any ground truth of interaction polarity for training.

Probabilistic matrix factorization was proposed by Salakhutdinov and Mnih (2008) as a collabor-

ative filtering method for recommender systems. It has attracted much attention and been extended by Ma et al. (2008) and Wang and Blei (2011). In particular, Ma et al. (2008) proposed a SocRec model that combines social network information with rating data using the PMF framework to perform social recommendation. Our model bears similarity to SocRec in that we also consider two types of interactions, i.e. user-user interactions and user-aspect interactions. However, different from Ma et al. (2008), we predict both the user-user and user-aspect scores from textual posts using sentiment analysis, and the user-user opinion polarity scores are symmetric.

Part of our method uses sentiment analysis to extract opinions from text. This is built on top of a large body of existing work on opinion extraction, e.g. Choi et al. (2006) and Wu et al. (2009). As the sentiment analysis component is not our main contribution, we do not review existing work along this direction in detail here. Interested readers can refer to Pang and Lee (2008).

The idea of incorporating sentiment analysis into collaborative filtering algorithms has been explored by Kawamae (2011), Moshfeghi et al. (2011) and Leung et al. (2011). While their work also combines sentiment analysis with collaborative filtering, the purpose is to improve the accuracy of item recommendation. In contrast, we borrow the idea and technique of collaborative filtering to improve user relation mining from online text.

3 Method Overview

In this section, we provide an overview of our method. We first introduce some concepts.

User: We use *user* to refer to a discussant in an online discussion. Each user has an online ID, which can be used by other users to refer to him/her in a post. Users are both opinion holders and opinion targets. For example, User 1 below expresses a negative opinion towards another user in the following snippet.

User 1: Actually, I have to disagree with you.

Aspect: We use *topic aspect* or *aspect* to refer to an opinion target that is related to the topic under discussion. For example, when debating about whether one should vote for Obama, people may express

opinions on targets such as “President Obama” and “Republican party,” as shown in the following snippets. These aspects are all related to Obama’s presidential campaign. As we will explain later, the aspects we consider are named entities and frequent noun phrases.

User 2: Americans should vote for President Obama because he picks good corporations as winners.

User 3: I simply point out how absolutely terrible the Republican party is.

Polarity Score: A sentiment polarity score is a real number between 0 and 1, where 0 indicates a completely negative opinion and 1 indicates a completely positive opinion.

User-User Opinion Matrix: The opinions extracted from posts between users are represented by a user-user opinion matrix S , where entry $s_{i,j}$ is a polarity score between the i -th user and the j -th user. We assume that the polarity scores are symmetric.

User-Aspect Opinion Matrix: The opinions held by different users on the various topic aspects are represented by a user-aspect opinion matrix R , where entry $r_{i,k}$ is a polarity score indicating the i -th user’s opinion towards the k -th aspect.

Given the matrices S and R , we perform probabilistic matrix factorization to derive a low-rank vector representation for users and aspects such that if the polarity score between two users or a user and an aspect is high, the dot product between the corresponding two vectors is also high.

In Section 4, we will explain in detail how we identify topic aspects from a discussion thread and how we obtain polarity scores from posts. In Section 5, we will present the details of our probabilistic matrix factorization model.

4 Construction of Opinion Matrices

The opinion matrices are constructed from a single forum thread discussing some controversial topic.

4.1 Aspect Identification

As we have pointed out, there are two kinds of opinion targets, namely users and aspects. Users are clearly defined and can often be identified in posts by their IDs or second person pronouns. For aspects, however, there is not a pre-defined set. We observe that these topic aspects are usually named entities

or noun phrases frequently mentioned. We therefore use the OpenNLP toolkit¹ to perform chunking and obtain noun phrases and the Standford NER tagger² to identify named entities from the posts.

Some of the candidate aspect phrases identified above actually refer to the same actual aspect, e.g. “Obama voter,” “Obama voters” and “the Obama voter.” We remove stop words from each candidate phrase and use the WordNet by Miller (1995) to obtain the lemma of each word such that we can normalize the candidate aspect phrases to some extent.

Finally, to select salient aspects for a given discussion topic, we count the number of times each candidate aspect has been expressed a positive or negative opinion on by all users, and select those candidate aspects which have opinion expressions from at least M users. We set M to 2 in our experiments. Figure 1 shows the top salient aspects for the thread on “Will you vote for Obama?” We acknowledge there are still duplicate aspects in the results like “Republican Party” and “GOP”. To normalize these aspects, some additional information such as Wikipedia entries and Google snippets may be considered. We will study this problem in our future work.

4.2 Opinion Expression Identification

Our next step is to identify candidate opinion expressions. This problem has been studied in Hu and Liu (2004), Popescu and Etzioni (2005), and Hassan and Radev (2010). Based on previous work, we do the following. We first combine three popular sentiment lexicons to form a single sentiment lexicon: the lexicon used in Hu and Liu (2004), MPQA Subjectivity Lexicon by Wilson et al. (2005) and SentiWordNet by Baccianella et al. (2010). Our final sentiment lexicon contains 15,322 negative expressions and 10,144 positive expressions. We then identify candidate opinion expressions by searching for occurrences of words in this lexicon in the posts.

4.3 Opinion Relation Extraction

Given a post that contains an aspect and an opinion expression, we still need to determine whether the opinion expression is used to describe the aspect. This is a relation extraction problem. We use a supervised learning approach based on dependency

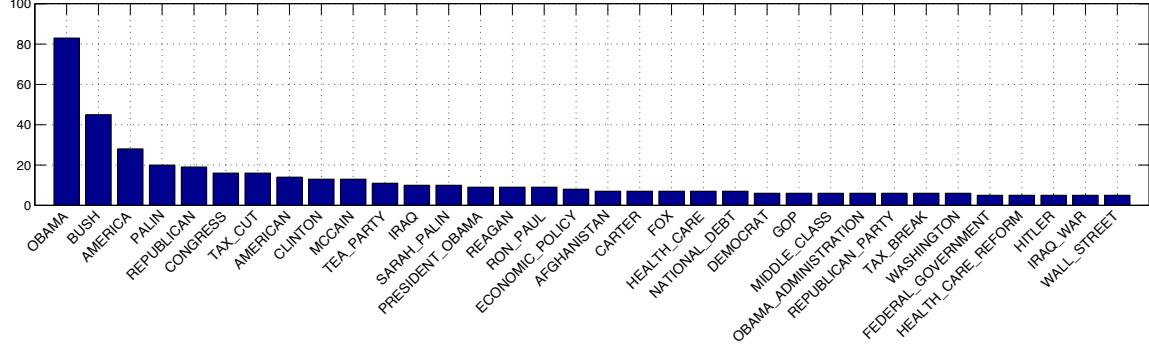

Figure 1: Salient aspects and number of users who express opinions on them in the thread “Will you vote for Obama?”

ID	Dependency path rule	Example
R1	$ADJ_{OP} \leftarrow amod \leftarrow N_{TR}$	I simply point out how <i>terrible</i> REPUBLICAN PARTY is.
R2	$ADJ_{OP} \rightarrow nsubj \rightarrow N_{TR}$	BUSH is even more <i>reasonable</i> for tax hike than Obama.
R3	$V_{OP} \rightarrow dobj \rightarrow N_{TR}$	I would never <i>support</i> OBAMA.
R4	$V_{OP} \rightarrow prep_* \rightarrow N_{TR}$	I'll <i>vote</i> for OBAMA.
R5	$V_{OP} \rightarrow nsubjpass \rightarrow N_{TR}$	DEMOCRATIC PARTY are ultimately <i>corrupted</i> by love of money.
R6	$N_{OP} \leftarrow dobj \leftarrow V \rightarrow nsubj \rightarrow N_{TR}$	PAKISTAN is increasing terrorist <i>threat</i> .
R7	$ADJ_{OP} \leftarrow amod \leftarrow N \rightarrow nsubj \rightarrow N_{TR}$	OBAMA was a <i>top</i> scorer for occidental college.
R8	$ADV_{OP} \leftarrow advmod \leftarrow V \rightarrow nsubj \rightarrow N_{TR}$	OBAMA is <i>smarter</i> than people.

Table 1: Examples of frequent dependency path rules in our training data. OP and TR refer to the opinion and the target. The opinion words are in italic and the aspect words are in uppercase.

paths. Previous work by Mintz et al. (2009), and Qiu et al. (2009) has shown that the shortest path between a candidate opinion aspect and a candidate opinion expression in the dependency parse tree can be effective in extracting opinion relations. We use the Stanford Parser from Klein and Manning (2003) to obtain the dependency parse trees for each sentence in the posts and then get the dependency paths between each pair of candidate aspect and opinion expression. We use dependency relations and POS tags of nodes along the path to represent a dependency path. Given a set of training sentences (we use the one from Wu et al. (2009)), we can get a set of dependency path rules based on their frequencies in the training data. Table 1 shows the frequent dependency path rules in our training data.

When a pair of aspect and opinion expression is identified to be related, we use the polarity of the opinion expression to label the relation. Finally, given a pair of users, we use the percentage of positive interactions between them over all subjective interactions (i.e. interactions with either positive or negative opinions) as extracted from their exchanged posts as the sentiment polarity score between the

two users, regardless of the reply-to direction of the posts. Similarly, given a user and an aspect, we also use the percentage of positive opinion relations extracted as the sentiment polarity score between them. Thus the user-user opinion matrix and the user-aspect opinion matrix are constructed. If there is no subjective interaction detected between two users or between a user and an aspect, the corresponding entry in the matrix is left empty. We will see later that empty entries in the matrices are not used in the probabilistic matrix factorization step.

5 Probabilistic Matrix Factorization

As we have pointed out earlier, a problem with the matrices extracted as described in Section 4 is that the matrices are sparse, i.e. many entries are empty. For the data set we use, we find that around 87% of entries in the user-user opinion matrix and around 90% of entries in the user-aspect opinion matrix are empty. In this section, we describe how we use Probabilistic Matrix Factorization (PMF) to represent users and aspects in a latent factor space and thus generalize the user preferences.

Our model is almost a direct application of proba-

bilistic matrix factorization from Salakhutdinov and Mnih (2008), originally proposed for recommender systems. The main difference is that the user-user opinion polarity scores are symmetric. Our model is also similar to the one used by Ma et al. (2008). We describe our model as follows.

We assume that there are K latent factors with which both users and aspects can be represented. Let $u_i \in \mathbb{R}^K$ denote the vector in the latent factor space for the i -th user, and a_k the vector for the k -th aspect.

Recall that the opinions extracted from posts between users are represented by a user-user opinion matrix S , and the opinions held by different users on the various topic aspects are represented by a user-aspect opinion matrix R . We assume that the polarity scores $s_{i,j}$ between the i -th and the j -th users and $r_{i,k}$ between the i -th user and the k -th aspect in the two matrices S and R are generated in the following way:

$$\begin{aligned} p(s_{i,j}|u_i, u_j, \sigma_1^2) &= \mathcal{N}(s_{i,j}|g(u_i^T u_j), \sigma_1^2), \\ p(r_{i,k}|u_i, a_k, \sigma_2^2) &= \mathcal{N}(r_{i,k}|g(u_i^T a_k), \sigma_2^2), \end{aligned}$$

where σ_1^2 and σ_2^2 are variance parameters, $g(\cdot)$ the logistic function, and $\mathcal{N}(\cdot|\mu, \sigma^2)$ is the normal distribution with mean μ and variance σ^2 .

We can see that with this generative assumption, if two users are similar in terms of their dot product in the latent factor space, then they are more likely to have positive interactions as extracted from their textual exchanges. Similarly, if a user and an aspect are similar, then the user is more likely to express a positive opinion on the aspect in his/her posts. The latent factors can therefore encode user preferences and similarity between two users in the latent factor space reflects whether they share similar viewpoints.

We also place the following prior over u_i and a_k :

$$\begin{aligned} p(u_i|\sigma_U^2) &= \mathcal{N}(u_i|\vec{0}, \sigma_U^2 \mathbf{I}), \\ p(a_k|\sigma_A^2) &= \mathcal{N}(a_k|\vec{0}, \sigma_A^2 \mathbf{I}), \end{aligned}$$

where σ_U^2 and σ_A^2 are two variance parameters for users and aspects, respectively, and \mathbf{I} is the identity matrix.

Figure 2 shows the plate notation for the generative model.

Let \mathcal{U} be a $K \times U$ matrix containing the vectors u_i for all U users, and \mathcal{A} be an $K \times A$ matrix containing

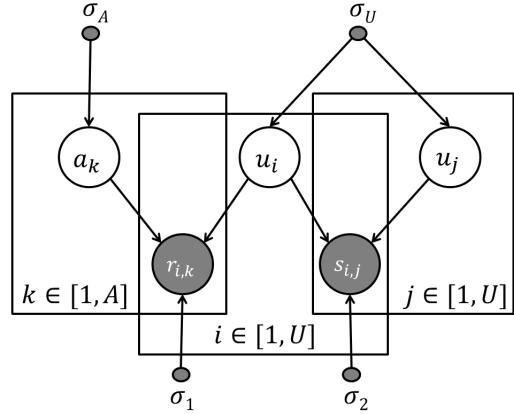

Figure 2: Probabilistic matrix factorization model on opinion matrices.

the vectors a_k for all A aspects. To automatically learn \mathcal{U} and \mathcal{A} , we minimize the following objective function:

$$\begin{aligned} &\mathcal{L}(\mathcal{U}, \mathcal{A}, \mathcal{S}, \mathcal{R}) \\ &= \frac{1}{2} \sum_{i=1}^U \sum_{k=1}^A \mathbb{I}(r_{i,k})(r_{i,k} - g(u_i^T a_k))^2 \\ &+ \frac{\lambda_1}{2} \sum_{i=1}^U \sum_{j=1}^U \mathbb{I}(s_{i,j})(s_{i,j} - g(u_i^T u_j))^2 \\ &+ \frac{\lambda_U}{2} \|\mathcal{U}\|_F^2 + \frac{\lambda_A}{2} \|\mathcal{A}\|_F^2, \end{aligned} \quad (1)$$

where $\lambda = \frac{\sigma_1^2}{\sigma_2^2}$, $\lambda_U = \frac{\sigma_1^2}{\sigma_U^2}$, and $\lambda_A = \frac{\sigma_1^2}{\sigma_A^2}$, $\mathbb{I}(s)$ is an indicator function which equals 1 when s is not empty and otherwise 0.

To optimize the objective function above, we can perform gradient descent on \mathcal{U} and \mathcal{A} to find a local optimum point. The derivation is similar to Ma et al. (2008).

Degenerate Versions of the Model

We refer to the complete model described above as PMF-UOM (PMF model based on User Opinion Matrices). PMF-UOM has the following two degenerate versions by considering either only the user-user opinion matrix or only the user-aspect opinion matrix.

PMF-UU: In this degenerate version of the model, we use only the user-user opinion matrix to learn the latent factor representation. Specifically, the objective function is modified such that we drop the sum

of the square errors involving R and the regularizer on \mathcal{A} .

PMF-UA: In this degenerate version of the model, we use only the user-aspect opinion matrix to learn the latent factor representation. Specifically, the objective function is modified such that we drop the sum of the square errors involving S .

6 Experiments

In this section, we present our experiments that evaluate our model.

6.1 Data Set and Experiment Settings

The data set we use comes from Abu-Jbara et al. (2012) and Hassan et al. (2012). The data set contains a set of discussion threads collected from two political forums (Createdebate³ and Politicalforum⁴) and one Wikipedia discussion session. We randomly select 6 threads from the original data set to evaluate our model. Some details of the data we use are listed in Table 2.

ID	topic	#sides	#sentences	#users
DS1	Vote for Obama	2	12492	197
DS2	Abortion Banned	6	3844	70
DS3	Profile Muslims	4	2167	69
DS4	England and USA	6	2030	62
DS5	Tax Cuts	2	1193	26
DS6	Political Spectrum	7	1130	50

Table 2: Some statistics of the data sets.

In our experiments, for the PMF-based methods, we set the number of latent factors to be 10 as we do not observe big difference when vary the latent factor size from 10 to 50. For the other parameters, we select the optimal setting for each thread based on the average of 50 runs. λ_U is chosen from $\{0.1, 0.01\}$, λ_A from $\{0.01, 0.001\}$ and λ from $\{1, 0.1\}$.

6.2 Relation Polarity Prediction

The first task we use to evaluate our model is to predict the polarity of interactions between two users. Different from Hassan et al. (2012), however, we are not using this task to evaluate the accuracy of sentiment analysis from text. Our experimental setting is completely different in that we do not make

use of the text exchanges between the two users but instead use their interactions with other users or aspects. The purpose is to test the effectiveness of collaborative filtering.

Experimental Setting: The experiments are set up in the following way. Given a pair of users i and j who have directly exchanged posts, i.e. $s_{i,j}$ is not empty, we first hide the value of $s_{i,j}$ in the matrix S . Let the altered matrix be $S_{-(i,j)}$. We then use $S_{-(i,j)}$ instead of S in the learning process as described in Section 5 to learn the latent factor representation. Let \hat{u}_i and \hat{u}_j denote the learned latent vectors for user i and user j . We predict the polarity of relation between i and j as follows:

$$\hat{s}_{i,j} = \begin{cases} 1 & \text{if } g(\hat{u}_i^T \hat{u}_j) > 0.5, \\ 0 & \text{otherwise,} \end{cases}$$

where $g(\cdot)$ is the logistic function to convert the dot product into a value between 0 and 1.

To judge the quality of the predicted polarity $\hat{s}_{i,j}$, we could compare it with $s_{i,j}$. But since $s_{i,j}$ itself is predicted from the textual exchanges between i and j , it is not the ground truth. Instead, we ask two human annotators to assign the true polarity label for user i and user j by reading the textual exchanges between them and judging whether they are friends or foes in the discussion thread. The annotators are asked to assign a score of 0 (indicating a negative relation), 0.5 (indicating a neutral relation) or 1 (indicating a positive relation). The lowest agreement score based on Cohen's kappa coefficient among the 6 threads we use is 0.56, showing fair to good agreement. As ground truth, we set the final polarity score to 1 if the average score of the two annotators is larger than 0.5 and 0 otherwise.

We compare the PMF-based methods with two majority baselines: MBL-0 always predicts negative relations for all the user pairs (assuming most relations are negative) and MBL-1 always predicts positive relations (assuming most relations are positive).

We use *MAE* (mean absolute error) and *RMSE* (root mean square error) as defined below as performance metrics:

$$MAE = \frac{\sum_{i,j} |\hat{s}_{i,j} - l_{i,j}|}{N},$$

$$RMSE = \sqrt{\frac{\sum_{i,j} (\hat{s}_{i,j} - l_{i,j})^2}{N}},$$

³www.createdebate.com

⁴www.politicalforum.com

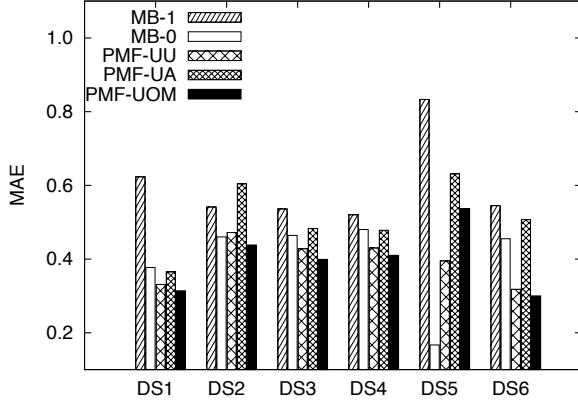

Figure 3: Comparing all the methods in terms of MAE.

where N is the total number of user pairs we test, and $l_{i,j}$ is the ground truth polarity score between user i and user j .

Results: We show the results of our model and of PMF-UU and PMF-UA in terms of MAE in Figure 3 and RMSE in Figure 4. The MAE values range between 0.31 and 0.44 except for DS5, which has a higher error rate of 0.53. The results show that even without knowing the textual exchanges between two users, from their interactions with other users and/or with topic aspects, we can still infer the polarity of their relation with decent accuracy most of the time.

The results also show the comparison between our model and the competing methods. We can see that overall the complete model (PMF-UOM) performs better than the two degenerate models (PMF-UU and PMF-UA). The differences are statistically significant at the 5% level without considering DS5, as indicated by a 2-tailed paired t-test. Comparing to the majority baselines, our model significantly outperforms MBL-1 at 1% significance level while outperforms MBL-0 on all the data sets except DS5. A close examinations shows DS5 has very unbalanced relations (around 83% of relations are negative). Except for the unbalanced data set, our model has reasonably good performance.

6.3 Subgroup Detection

The second task we study is the problem of detecting ideological subgroups from discussion threads. The original data set has been labeled with the ground truth for this problem, that is, for each thread the

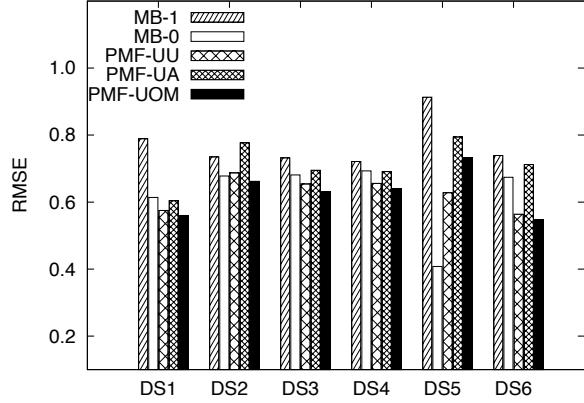

Figure 4: Comparing all the methods in terms of RMSE.

number of viewpoints is known and the viewpoint held by each user is labeled. A subgroup is defined as a set of users holding the same viewpoint.

Experimental Setting: Through this second experiment, we would like to verify the hypothesis that using the learned latent factor representation \mathcal{U} for users, we can better detect subgroups than directly using the opinion matrices S and R . For all the methods we compare, we first construct a feature vector representation for each user. We then apply K -means clustering to group users. The number of clusters is set to be the true number of viewpoints for each thread. The different methods are described below:

- **PMF-based methods:** We simply use the learned latent vectors \hat{u}_i after optimizing the objective function as the feature vectors to represent each user.
- **BL-1:** This is our own implementation to simulate the method by Abu-Jbara et al. (2012). Here each user is represented by a $(3 \times (U + A))$ -dimensional vector, where U is the number of users and A is the number of aspects, i.e. $(U + A)$ is the total number of opinion targets. For each opinion target, there are 3 dimensions in the feature vector, corresponding to the number of positive, neutral and negative opinion expressions towards the target from the online posts.
- **BL-2:** BL-2 is similar to BL-1 except that we only use a $(U + A)$ -dimensional vector to repre-

sent each user. Here for each opinion target, we directly use the corresponding sentiment polarity score $s_{i,j}$ or $r_{i,j}$ from the matrix S or R . For empty entries in S and R , we use a score of 0.5.

We use *Purity* (the higher the better), *Entropy* (the lower the better) and *Rand Index* (the higher the better) to evaluate the performance of subgroup detection (Manning et al., 2008). We further use *Accuracy* obtained by choosing the best alignment of clusters with the ground truth class labels and computing the percentage of users that are “classified” correctly.

Results: We first give an overview of the performance of all the methods on the task. We show the average performance of the methods on all the data sets in Figure 5. Overall, our model has a better performance than all the competing methods.

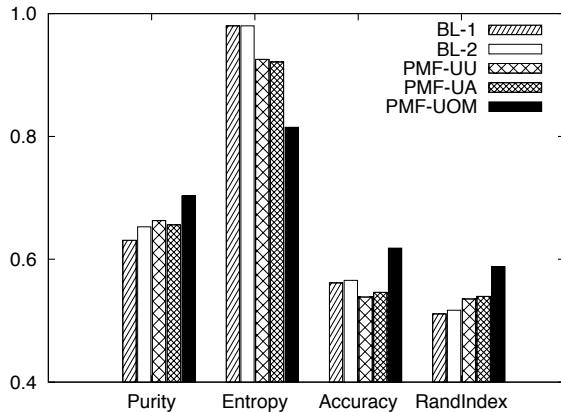

Figure 5: An overview of the average performance of all the methods on the 6 threads.

We present all the results in Table 3. We perform 2-tailed paired t-test on the results. We find that PMF-UOM outperforms all the other methods in terms of RandIndex at 5% significance level and outperforms other methods in terms of Purity and Entropy at 10% significance level. Furthermore, the PMF-UOM model outperforms its degenerative models PMF-UU and PMF-UA at 10% significance level in terms of all the measures.

We observe that PMF-UOM achieves the best performance in terms of all the measures for almost all threads. In particular, comparison with BL-1 and BL-2 shows that collaborative filtering can generalize the user preferences and help better group the users based on their viewpoints. The fact that

PMF-UOM outperforms both PMF-UU and PMF-UA shows that it is important to consider both user-user interactions and user-aspect interactions.

The Effects of Cluster Size: To test the effect of the number of clusters on the experiment result, we vary the number of clusters from 2 to 10 in all methods. We find that all methods tend to achieve better results when the number of clusters equals the ground truth cluster size. Overall, our method PMF-UOM shows a better performance than the other four methods when the number of clusters changes, which indicates the robustness of our method.

	BL-1	BL-2	PMF-UU	PMF-UA	PMF-UOM
DS1	<i>P</i>	0.61	0.61	0.61	0.62
	<i>E</i>	0.96	0.96	0.94	0.95

7 Conclusions

In this paper, we studied how to use probabilistic matrix factorization, a common technique for collaborative filtering, to improve relation mining from online discussion forums. We first applied sentiment analysis to extract user-user opinions and user-aspect opinions from forum posts. The extracted opinions form two opinion matrices. We then applied probabilistic matrix factorization using these

two matrices to discover a low-rank latent factor space which aims to better generalize the users' underlying preferences and indicate user similarities based on their viewpoints. Using a data set with 6 discussion threads, we showed that the learned latent vectors can be used to predict the polarity of user relations well without using the users' direct interaction data, demonstrating the effectiveness of collaborative filtering. We further found that for the task of subgroup detection, the latent vectors gave better performance than using the directly extracted opinion data, again showing that collaborative filtering through probabilistic matrix factorization can help address the sparseness problem in the extracted opinion matrices and help improve relation mining.

Our current work mainly focuses on the user opinion matrices. As future work, we would like to explore how to incorporate textual contents without opinionated expressions. One possible way is to consider the combination of matrix factorization and topic modeling as studied by Wang and Blei (2011) where we can use topic modeling to study textual contents.

Focused training sets to reduce noise in NER feature models

Amber McKenzie

Computer Science and Engineering Department

University of South Carolina

mckenzie.amber@gmail.com

Abstract

Feature and context aggregation play a large role in current NER systems, allowing significant opportunities for research into optimizing these features to cater to different domains. This work strives to reduce the noise introduced into aggregated features from disparate and generic training data in order to allow for contextual features that more closely model the entities in the target data. The proposed approach trains models based on only a part of the training set that is more similar to the target domain. To this end, models are trained for an existing NER system using the top documents from the training set that are similar to the target document in order to demonstrate that this technique can be applied to improve any pre-built NER system. Initial results show an improvement over the University of Illinois NE tagger with a weighted average F1 score of 91.67 compared to the Illinois tagger's score of 91.32. This research serves as a proof-of-concept for future planned work to cluster the training documents to produce a number of more focused models from a given training set, thereby reducing noise and extracting a more representative feature set.

1 Introduction

Though research in the area of named entity recognition (NER) is fairly extensive, current state-of-the-art solutions are generic, succeeding only for domains similar to their training data, and still fail to adequately provide functionality that is adaptable to a broad range of domains (Tkachenko and Simanovsky, 2012). This leaves room for improvement in designing a system that can more easily adapt to previously unseen data. In particular, the increasingly popular feature set produced by feature and context aggregation provides many opportunities for different types of optimization

given the strong correlation between the training input and the feature values that are produced. This is due to the fact that aggregation looks at features at a document or corpus level, rather than at the token level, and therefore will be sensitive to changes in the training set. This research looks to exploit this aspect of feature and context aggregation by identifying portions of a training set that are more similar to the target data and will thus provide feature values that are likely more representative of the entities within that data.

Rather than train a model with a full training set, this approach extracts portions of the training data that are most similar to the target data and trains a model using only those documents. This initial work tailors a model to a given target document to demonstrate that less, but more appropriate, training data is preferable to a full generic training set.

Similar to that of Dalton et al. (2011), in which they use passage retrieval to expand their feature set, cosine similarity is used to retrieve documents containing similar entity instances in an effort to achieve a more relevant feature set that will result in more likely output label predictions. However, the proposed approach conducts document similarity above the tagger level, without modifying the underlying tagging system. This allows for domain adaptation improvements using any available NER tagger. This approach is able to be implemented with any pre-existing NER tagger in order to improve the performance of the tagger for out-of-domain data. Initial results show an improvement over the standard NE tagger from the University of Illinois at Urbana-Champaign using a smaller training set and no additional external data sources.

2 Related work

Feature aggregation refers to collecting feature information from across a document or document set, rather than simply taking the information from a particular word instance. With feature aggrega-

tion, researchers strive to expand the context used to predict the classification of a given token. Much of the recent work on features for NER has been related to aggregation of some sort in an effort to widen model coverage, decrease human interaction in the feature generation process, and increase detection and classification accuracy. Many systems incorporating feature aggregation have seen performance improvements over other nearly state-of-the-art systems.

The global features discussed by Chieu and Ng (2003) represent context aggregation in that they extract features about the word in multiple instances within a document. Krishnan and Manning (2006) introduce a two-stage approach to feature aggregation layering two CRFs in which the second uses the output of the first as features, aggregated over both documents and the entire corpus.

Ratinov and Roth (2009) use a similar implementation for their work, substituting relative frequencies of tags within a 1000 token window for the majority tags used by Krishnan and Manning. They refer to the information gathered from aggregation as non-local features and categorize the different approaches as context aggregation, two-stage prediction aggregation and extended prediction history. In an effort not to treat all tokens in a text similarly, which they assert is the case with context aggregation and two-stage prediction, Ratinov and Roth developed an approach for non-local feature generation based on extended prediction history. Their approach is based on the idea that named entities are easier to spot at the beginning of texts where they are first introduced. They keep track of all label assignments for the token in the last 1000 words and use that probability information as a prediction history feature for the token.

Huang and Yates (2009) present their feature aggregation approaches in the form of smoothing of the dataset. Their goal for smoothing is the same as for aggregation in that they strive to extend the usefulness of the model by sharing information about multiple contexts for a token in order to provide more information about words that are rarely, or never, seen in training. In experimentation, the authors found that their smoothing approach improved performance on rare words, out-of-domain text, and smaller training sets.

Dalton et al. (2011) take an external knowledge approach to context aggregation. Using an information retrieval method called Pseudo-Relevance

Feedback (PRF), they query for relevant passages in an external data set using the context for the target token. Given that they searched for the context that the entity occurs in, it is assumed that the top returned passages all contain instances of the entity with the same label. They then aggregate the features for this token across a number of the top retrieved documents and induce features based on this information. Their approach is compared with the Stanford and Illinois NER systems and found that their aggregated features improved performance over those systems.

Apart from the body of work attempting to incorporate external data sources, such as Wikipedia, to augment training data, approaches for domain adaptation for NER focus on either adapting features to fit the domain or searching for more abstract features that can span multiple domains (Zhang and Johnson, 2003; Huang and Yates, 2009; Lin and Wu, 2009). This is largely due to the assumption that a domain-specific, tagged training set will not be available for most target domains.

This research expands on previous work by providing a more informative training set that is a closer representation of the features contained in the target documents. Further, the proposed system does not require external knowledge sources or additional tagged data to augment the utilized training set. The modifications that are made are implemented above the tagger level allowing for any existing tagger to be used without need to alter the underlying source code.

3 NER approach

Feature aggregation has become an integral part of building an NER prediction model. Because aggregating the context of every named entity across an entire training set can be fairly computationally expensive and introduces significant noise into the features due to the many contexts in which an entity may occur, many researchers have chosen instead to conduct local aggregation, such as across a document, or with a certain window of tokens that may span several documents. The NER tagger produced by the University of Illinois at Urbana-Champaign, one of the best performing systems on the CoNLL 2003 data set, uses a 1000 token window across which to take their global context aggregation (Ratinov and Roth, 2009). By choosing 1000 tokens, the researchers hope to be able to

capture a large enough example set to provide a robust feature value while maintaining a reasonable computation time. However, this method leaves the choice of context to chance: determined by how the documents are organized within the training set. A better option would be to choose the context that best represents the entities to be tagged. To that end, this work serves to provide a more useful and informative training set from which to pull context information.

The hypothesis explored in this work is that the context aggregation feature would prove more useful if the training data were more specific to the target entities. For this research, documents from the training set were compiled based on their similarity to the target document. These documents were then used to train a model for the Illinois NE tagger. In this way we strive to reduce the noise present in the context aggregation feature as a result of the generic contexts found in a large, often heterogeneous, training set and produce feature values that are more representative of the target entities, thus producing more reliable output labels.

3.1 Methodology

For an initial proof-of-concept test, vectors were created for all test (not the development set) and training documents in the CoNLL-2003 shared task data. This corpus was chosen due to the previous NER research using this corpus and the results available using the LBJ tagger. Also, it has been noted that the test and training sets within the corpus are not as similar in nature as are the development and training sets (Ratinov and Roth, 2009). The training set contains 946 documents, while the test set contains 231. For each test document, a specified number of the top documents from the training set most similar to that test document was collected. For this initial work, a simple cosine similarity measure was used. These top similar documents were used as a training set for the LBJ tagger, and the test document was then tagged using the resultant model. The system was tested by pulling the top 20, 50, 100, and 300 similar training documents to train the models. The performance of this customized model is compared to that of the standard, two-phase LBJ tagger trained on the full CoNLL '03 training set.

3.2 Results

For this research, because each test document is tagged using a different model, we chose to measure our performance on a per-document basis, rather than the standard overall measure for the entire test set.¹ This performance is compared to that achieved by the standard LBJ tagger on the same document. Figure 1 shows how many documents were tagged more accurately using the proposed system compared to the LBJ tagger.

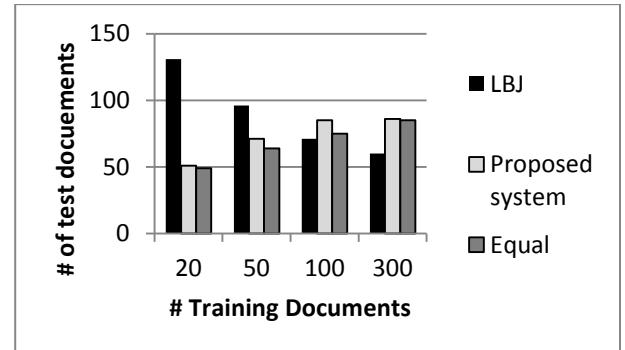

Figure 1 – Results showing the number of documents for which each system performed better or for which they had equal F1 scores.

Further, Figure 2 displays the average percentage better and worse in terms of F1 score for each training document size. In contrast to Figure 1, Figure 2 demonstrates the average difference in F1 scores between the LBJ tagger trained on the entire training set and the proposed system trained on varying numbers of training documents. These numbers indicate that there exists an optimal balance that can achieve the dual advantages of having a smaller, more relevant training set while also maintaining enough data to ensure enough features to accurately predict NER labels.

The overall aggregated difference is also provided as a more global view of performance achievements. This measurement is calculated by multiplying the F1 score of a given document by the number of entity tokens contained in that document, summing these calculations, and then dividing by the total number of entity tokens across the test dataset. These results reveal an improvement over the Illinois tagger for the 300 document train-

¹ The Illinois NE tagger only provides performance information in the form of percentages and does not give enough information to calculate an overall F1 score for the test set using the CoNLL eval script.

ing set with a weighted average F1 score of 91.67 compared to the Illinois score of 91.32.

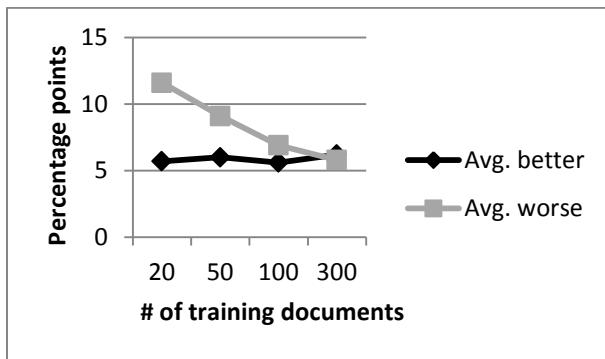

Figure 2 – Average percentage points better and worse in the F1 score that the proposed system achieved compared to the standard LBJ tagger for models trained with the top 20, 50, 100, and 300 similar documents.

These initial results demonstrate that an available training set can be easily tailored to better serve the needs of a target data set that differs from the training set and showed improvements on an existing competitive NER system by modifying the training data set used to build the prediction model. By identifying a smaller, relevant training set, the sequence tagging model is better equipped to accurately predict output labels for target data that does not closely align with the training documents.

4 Future work

Given the computational expense of training a model for each individual document to be tagged, improvements must be made to the approach to transform it into a viable long-term NER solution. The next logical step in this research will be to cluster the training documents and train models based on those clusters. Subsequently, the test documents can be clustered to the training set clusters and be tagged using the appropriate model for that cluster set. Alternatively, the test set could be initially clustered, with the training set then fit to those clusters. Tests must be conducted to determine which option produces the best prediction accuracy levels. Once a viable clustering methodology has been developed, further testing will be conducted to compare it with some of the best current techniques (e.g. the work of Dalton et. al 2011) to provide a more comprehensive evaluation.

The results presented here were achieved using baseline document representation and document similarity techniques. Significant work remains for experimentation to determine which alternative methodologies will result in the optimal NER performance. Not only could different clustering algorithms be employed, but an investigation into which type of clustering, in particular linear or hierarchical, is better suited for NER would be prudent. Also, further work will test the validity of this approach for successful domain adaptation by demonstrating that it is extensible to other data sets.

5 Summary

This research has implications in the NER domain adaptation space as it demonstrates that fewer training documents are required as long as they are sufficiently similar to the targeted test set. This methodology could potentially allow for better utilization of existing, freely-available (possibly generic) training sets by extracting portions of the training set that are more similar to the target data. It also allows for existing NER systems to be better adapted to domain-specific data without modification for feature augmentation or the inclusion of additional external data sources. The opportunities for continuing this trend of research are numerous, and initial results illustrate significant promise given the relative simplicity of the execution compared with its achievement.

Abstract

Language can describe our visual world at many levels, including not only what is literally there but also the sentiment that it invokes. In this paper, we study visual language, both literal and sentimental, that describes the overall appearance and style of virtual characters. Sentimental properties, including labels such as “youthful” or “country western,” must be inferred from descriptions of the more literal properties, such as facial features and clothing selection. We present a new dataset, collected to describe Xbox avatars, as well as models for learning the relationships between these avatars and their literal and sentimental descriptions. In a series of experiments, we demonstrate that such learned models can be used for a range of tasks, including predicting sentimental words and using them to rank and build avatars. Together, these results demonstrate that sentimental language provides a concise (though noisy) means of specifying low-level visual properties.

1 Introduction

Language can describe varied aspects of our visual world, including not only what is literally there but also the social, cultural, and emotional sentiment it invokes. Recently, there has been a growing effort to study *literal* language that describes directly observable properties, such as object color, shape, or

This is a light tan young man with short and trim haircut. He has straight eyebrows and large brown eyes. He has a neat and trim appearance.

State of mind: angry, upset, determined. Likes: country western, rodeo. Occupation: cowboy, wrangler, horse trainer. Overall: youthful, cowboy.

Figure 1: (A) Literal avatar descriptions and (B) sentimental descriptions of four avatar properties, including possible occupations and interests.

category (Farhadi et al., 2009; Mitchell et al., 2010; Matuszek et al., 2012). Here, we add a focus on *sentimental* visual language, which compactly describes more subjective properties such as if a person looks determined, if a resume looks professional, or if a restaurant looks romantic. Such models enable many new applications, such as text editors that automatically select properties including font, color, or text alignment to best match high level descriptions such as “professional” or “artistic.”

In this paper, we study visual language, both literal and sentimental, that describes the overall appearance and style of virtual characters, like those in Figure 1. We use literal language as feature norms, a tool used for studying semantic information in cognitive science (Mcrae et al., 2005). Literal words, such as “black” or “hat,” are annotated for objects to indicate how people perceive visual properties. Such feature norms provide our gold-standard visual detectors, and allow us to focus on learning to model sentimental language, such as “youthful” or “goth.”

We introduce a new corpus of descriptions of Xbox avatars created by actual gamers. Each avatar is specified by 19 attributes, including clothing and body type, allowing for more than 10^{20} possibilities. Using Amazon Mechanical Turk,¹ we collected literal and sentimental descriptions of complete avatars and many of their component parts, such as the cowboy hat in Figure 1(B). In all, there are over 100K descriptions. To demonstrate potential for learning, we also report an A/B test which shows that native speakers can use sentimental descriptions to distinguish the labeled avatars from random distractors. This new data will enable study of the relationships between the co-occurring literal and sentimental text in a rich visual setting.²

We describe models for three tasks: (i) classifying when words match avatars, (ii) ranking avatars given a description, and (iii) constructing avatars to match a description. Each model includes literal part descriptions as feature norms, enabling us to learn which literal and sentinel word pairs best predict complete avatars.

Experiments demonstrate the potential for jointly modeling literal and sentimental visual descriptions on our new dataset. The approach outperforms several baselines and learns varied relationships between the sentimental and literal descriptions. For example, in one experiment “nerdy student” is predictive of an avatar with features indicating its shirt is “plaid” and glasses are “large” and faces that are not “bearded.” We also show that individual sentimental words can be predicted but that multiple avatars can match a single sentimental description. Finally, we use our model to build complete avatars

and show that we can accurately predict the sentimental terms annotators ascribe to them.

2 Related Work

To the best of our knowledge, our focus on learning to understand visual sentiment descriptions is novel. However, visual sentiment has been studied from other perspectives. Jrgensen (1998) provides examples which show that visual descriptions communicate social status and story information in addition to literal object and properties. Tousch et al. (2012) draw the distinction between “of-ness” (objective and concrete) and “about-ness” (subjective and abstract) in image retrieval, and observe that many image queries are abstract (for example, images about freedom). Finally, in descriptions of people undergoing emotional distress, Fussell and Moss (1998) show that literal descriptions co-occur frequently with sentimental ones.

There has been significant work on more literal aspects of grounded language understanding, both visual and non-visual. The Words-Eye project (Coyne and Sproat, 2001) generates 3D scenes from literal paragraph-length descriptions. Generating literal textual descriptions of visual scenes has also been studied, including both captions (Kulkarni et al., 2011; Yang et al., 2011; Feng and Lapata, 2010) and descriptions (Farhadi et al., 2010). Furthermore, Chen and Dolan (2011) collected literal descriptions of videos with the goal of learning paraphrases while Zitnick and Parikh (2013) describe a corpus of descriptions for clip art that supports the discovery of semantic elements of visual scenes.

There has also been significant recent work on automatically recovering visual attributes, both absolute (Farhadi et al., 2009) and relative (Kovashka et al., 2012), a challenge that we avoid having to solve with our use of feature norms (Mcrae et al., 2005).

Grounded language understanding has also received significant attention, where the goal is to learn to understand situated non-visual language use. For example, there has been work on learning to execute instructions (Branavan et al., 2009; Chen and Mooney, 2011; Artzi and Zettlemoyer, 2013), provide sports commentary (Chen et al., 2010), understand high level strategy guides to improve game

play (Branavan et al., 2011; Eisenstein et al., 2009), and understand referring expression (Matuszek et al., 2012).

Finally, our work is similar in spirit to sentiment analysis (Pang et al., 2002), emotion detection from images and speech (Zeng et al., 2009), and metaphor understanding (Shutova, 2010a; Shutova, 2010b). However, we focus on more general visual context.

3 Data Collection

We gathered a large number of natural language descriptions from Mechanical Turk (MTurk). They include: (1) literal descriptions of specific facial features, clothing or accessories and (2) high level subjective descriptions of human-generated avatars.³

Literal Descriptions We showed annotators a single image of clothing, a facial feature or an accessory and asked them to produce short descriptions. Figure 2 shows the distribution over object types. We restricted descriptions to be between 3 and 15 words. In all, we collected 33.2K descriptions and had on average 7 words per descriptions. The example annotations with highlighted overlapping patterns are in Table 1.

Sentimental Descriptions We also collected 1913 gamer-created avatars from the web. The avatars were filtered to contain only items from the set of 665 for which we gathered literal descriptions. The gender distribution is 95% male.

³(2) also has phrases describing emotional reactions. We also collected (3) multilingual literal, (4) relative literal and (5) comprehensive full-body descriptions. We do not use this data, but it will be included in the public release.

LITERAL DESCRIPTIONS

full-sleeved	executive	blue	shirt
blue	, long-sleeved	button-up	shirt
mens	blue	button	dress shirt with dark blue stripes
multi-blue	striped	long-sleeve	button-up
			dress shirt with cuffs and breast pocket

Table 1: Literal descriptions of shirt in Figure 2.

To gather high level sentimental descriptions, annotators were presented with an image of an avatar and asked to list phrases in response to the follow different aspects:

- State of mind of the avatar.
- Things the avatar might care about.
- What the avatar might do for a living.
- Overall appearance of the avatar.

6144 unique vocabulary items occurred in these descriptions, but only 1179 occurred more than 10 times. Figure 1 (B) shows an avatar and its corresponding sentimental descriptions.

Quality Control All annotations in our dataset are produced by non-expert annotators. We relied on manual spot checks to limit poor annotations. Over time, we developed a trusted crowd of annotators who produced only high quality annotations during the earliest stage of data collection.

4 Feasibility

Our hypothesis is that sentimental language does not uniquely identify an avatar, but instead summarizes or otherwise describes its overall look. In general, there is a trade off between concise and precise descriptions. For example, given a single word you might be able to generally describe the overall look of an avatar, but a long, detailed, literal description would be required to completely specify their appearance.

To demonstrate that the sentimental descriptions we collected are precise enough to be predictive of appearance, we conducted an experiment that prompts people to judge when avatars match descriptions. We created an A/B test where we show English speakers two avatars and one sentimental description. They were asked to select which avatar is better matched by the description and how difficult they felt, on a scale from 1 to 4, it was to judge. For 100 randomly selected descriptions, we

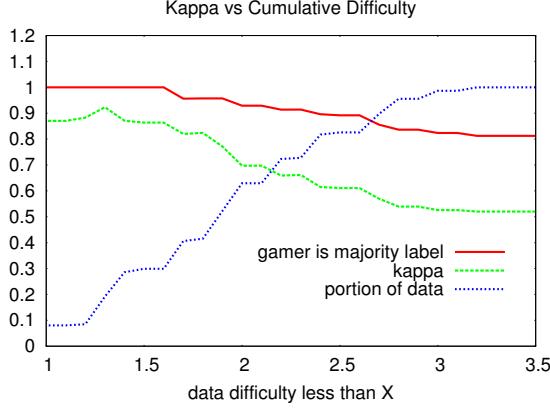

Figure 3: Judged task difficulty versus agreement, gamer avatar preference, and percentage of data covered. The difficulty axis is cumulative.

asked 5 raters to compare the gamer avatars to randomly generated ones (where each asset is selected independently according to a uniform distribution). Figure 3 shows a plot of Kappa and the percent of the time a majority of the raters selected the gamer avatar. The easiest 20% of the data pairs had the strongest agreement, with kappa=.92, and two thirds of the data has kappa = .70. While agreement falls off to .52 for the full data set, the gamer avatar remains the majority judgment 81% of the time.

The fact that random avatars are sometimes preferred indicates that it can be difficult to judge sentimental descriptions. Consider the avatars in Figure 4. Neither conforms to a clear sentimental description based on the questions we asked. The right one is described with conflicting words and the words describing the left one are very general (like “dumb”). This corresponds to our intuition that while many avatars can be succinctly summarized with our questions, some would be more easily described using literal language.

5 Tasks and Evaluation

We formulate three tasks to study the feasibility of learning the relationship between sentimental and literal descriptions. In this section, we first define the space of possible avatars, followed by the tasks.

Avatars Figure 5 summarizes the notation we will develop to describe the data. An avatar is defined by a 19 dimensional vector \vec{a} where each position is an

State of mind: content, humble, satisfied, peaceful, relaxed, calm. Likes: fashion, friends, money, cars, music, education.
 State of mind: playful, happy;
 Likes: sex
 Occupation: hobo
 Overall: dumb
 State of mind: content, humble, satisfied, peaceful, relaxed, calm. Likes: fashion, friends, money, cars, music, education.
 Occupation: teacher, singer, actor, performer, dancer, computer engineer.
 Overall: nerdy, cool, smart, comfy, easygoing, reserved

Figure 4: Avatars rated as difficult.

index into a list of possible items \vec{i} . Each dimension represents a position on the avatar, for example, *hat* or *nose*. Each possible item is called an asset and is associated with a set of positions it can fill. Most assets take up exactly one position, while there are a few cases where assets take multiple positions.⁴ An avatar \vec{a} is valid if all of its mandatory positions are filled, and no two assets conflict on a position. Mandatory positions include hair, eyes, ears, eyebrows, nose, mouth, chin, shirt, pants, and shoes. All other positions are optional. We refer to this set of valid \vec{a} as A . Practically speaking, if an avatar is not valid, it cannot be reliably rendered graphically.

Each item i is associated with the literal descriptions $\vec{d}_i \in D$ where D is the set of literal descriptions. Furthermore, every avatar \vec{a} is associated a list of sentimental query words \vec{q} , describing subjective aspects of an avatar.⁵

Sentimental Word Prediction We first study individual words. The word prediction task is to decide whether a given avatar can be described with a

⁴For example, long sleeve shirts cover up watches, so they take up both shirt and wristwear positions. Costumes tend to span many more positions, for example there a suit that takes up shirt, pants, wristwear and shoes positions.

⁵We do not distinguish which prompt (e.g., “state of mind” or “occupation”) a word in \vec{q} came from, although the vocabularies are relatively disjoint.

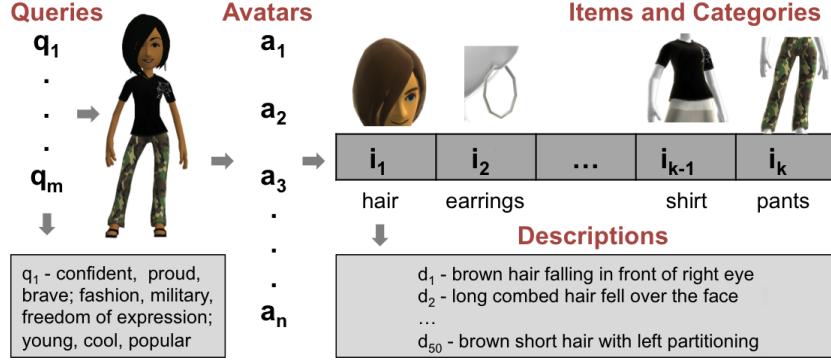

Figure 5: Avatars, queries, items, literal descriptions.

particular sentimental word q^* . We evaluate performance with F-score.

Avatar Ranking We also consider an avatar retrieval task, where the goal is to rank the set of avatars in our data, $\cup_{j=1\dots n} \vec{a_j}$, according to which one best matches a sentimental description, $\vec{q_i}$. As an automated evaluation, we report the average percentile position assigned to the true $\vec{a_i}$ for each example. However, in general, many different avatars can match each $\vec{q_i}$, an interesting phenomena we will further study with human evaluation.

Avatar Generation Finally, we consider the problem of generating novel, previously unseen avatars, by selecting a set of items that best embody some sentimental description. As with ranking, we aim to construct the avatar $\vec{a_i}$ that matches each sentimental description $\vec{q_i}$. We evaluate by considering the item overlap between $\vec{a_i}$ and the output avatar $\vec{a^*}$, discounting for empty positions:⁶

$$f = \frac{\sum_{j=1}^{|\vec{a^*}|} I(\vec{a_j^*} = \vec{a_{ij}})}{\max(\text{numparts}(\vec{a^*}), \text{numparts}(\vec{a_i}))}, \quad (1)$$

where *numparts* returns the number of non-empty avatar positions. The score is a conservative measure because some items are significantly more visually salient than others. For instance, shirts and pants occupy a large portion of the physical realization of the avatar, while rings are small and virtually unnoticeable. We additionally perform a human evaluation in Section 8 to better understand these challenges.

⁶Optional items are infrequently used. Therefore not predicting them at all offers a strong baseline. Yet doing this demonstrates nothing about an algorithm’s ability to predict items which contribute to the sentimental qualities of an avatar.

6 Methods

We present two different models: one that considers words in isolation and another that jointly models the query words. This section defines the models and how we learn them.

6.1 Independent Sentimental Word Model

The independent word model (S-Independent) assumes that each word independently describes the avatar. We construct a separate linear model for each word in the vocabulary.

To train these model, we transform the data to form a binary classification problem for each word, where the positive data includes all avatars the word was seen with, $(q, \vec{a_i}, 1)$ for all i and $q \in \vec{q_i}$, and the rest are negative, $(q, \vec{a_i}, 0)$ for all i and $q \notin \vec{q_i}$.

We use the following features:

- an indicator feature for the cross product of a sentiment query word q , a literal description word $w \in D$, and the avatar position index j (for example, $q = \text{“angry”}$ with $w = \text{“pointy”}$ and $j = \text{eyebrows}$):

$$I(q \in \vec{q_i}, w \in \vec{d_{a_{ij}}}, j)$$

- a bias feature for keeping a position empty:

$$I(q \in \vec{q_i}, a_{ij} = \text{empty}, j)$$

These features will allow the model to capture correlations between our feature norms which provide descriptions of visual attributes, like black, and sentimental words, like gothic.

S-Independent is used for both word prediction and ranking. For prediction, we train a linear model using averaged binary perceptron. For ranking, we try to rank all positive instances above negative instances. We use an averaged structured perceptron to train the ranker (Collins, 2002). To rank with respect to an entire query \vec{q}_i , we sum the scores of each word $q \in \vec{q}_i$.

6.2 Joint Sentimental Model

The second approach (S-Joint) jointly models the query words to learn the relationships between literal and sentimental words with score s :

$$s(\vec{a}|\vec{q}, D) = \sum_{i=1}^{|\vec{a}|} \sum_{j=1}^{|\vec{q}|} \theta^T f(\vec{a}_i, \vec{q}_j, \vec{d}_{a_i})$$

Where every word in the query has a separate factor and every position is treated independently subject to the constraint that \vec{a} is valid. The feature function f uses the same features as the word independent model above.

This model is used for ranking and generation. For ranking, we try to rank the avatar a_i for query q_i above all other avatars in the candidate set. For generation, we try to score a_i above all other valid avatars given the query q_i . In both cases, we train with averaged structured perceptron (Collins, 2002) on the original data, containing query, avatar pairs (\vec{q}_i, \vec{a}_i) .

7 Experimental Setup

Random Baseline For the ranking and avatar generation tasks, we report random baselines. For ranking, we randomly order the avatars. In the generation case, we select an item randomly for every position. This baseline does not generate optional assets because they are rare in the real data.

Sentimental-Literal Overlap (SL-Overlap) We also report a baseline that measures the overlap between words in the sentiment query \vec{q}_i and words in the literal asset descriptions D . In generation, for each position in the avatar, \vec{a}_i , SL-Overlap selects the item whose literal description has the most words in common with \vec{q}_i . If no item had overlap with the query, we backoff to a random choice. In the case of ranking, it orders avatars by the sum over every position of the number of words in common between

Word	F-Score	Precision	Recall	N

the literal description and the query, \vec{q}_i . This baseline tests the degree to which literal and sentimental descriptions overlap lexically.

Feature Generation For all models that use lexical features, we limited the number of words. 6144 unique vocabulary items occur in the query set, and 3524 in the literal description set. There are over 400 million entries in the full set of features that include the cross product of these sets with all possible avatar positions, as described in Section 6. Since this would present a challenge for learning, we prune in two ways. We stem all words with a Porter stemmer. We also filter out all features which do not occur at least 10 times in our training set. The final model has approximately 700k features.

8 Results

We present results for the tasks described in Section 5 with the appropriate models from Section 6.

8.1 Word Prediction Results

The goal of our first experiment is to study when individual sentinel words can be accurately predicted. We computed sentinel word classification accuracy for 1179 word classes with 10 or more

Algorithm	Percentile Rank
S-joint	77.3
S-independant	73.5
SL-overlap	60.4
Random	48.8

Table 3: Automatic evaluation of ranking. The average percentile that a test avatar was ranked given its sentimental description.

mentions. Table 2 shows the top 20 words ordered by F-score.⁷ Many common words can be predicted with relatively high accuracy. Words with strong individual cues like happy (a smiling mouth), and confidence (wide eyes) and nerd (particular glasses) can be predicted well.

The average F-score among all words was .085. 33.2% of words have an F-score of zero. These zeros include words like: unusual, bland, sarcastic, trust, prepared, limber, healthy and poetry. Some of these words indicate broad classes of avatars (e.g., unusual avatars) and others indicate subtle modifications to looks that without other words are not specific (e.g., a prepared surfer vs. a prepared business man). Furthermore, evaluation was done assuming that when a word is not mentioned, it is should be predicted as negative. This fails to account for the fact that people do not mention everything that’s true, but instead make choices about what to mention based on the most relevant qualities. Despite these difficulties, the classification performance shows that we can accurately capture usage patterns for many words.

8.2 Ranking Results

Ranking allows us to test the hypothesis that multiple avatars are valid for a high level description. Furthermore, we consider the differences between S-Joint and S-Independent, showing that jointly modeling all words improves ranking performance.

Automatic Evaluation The results are shown in Table 3. Both S-Independent and S-Joint outperform the SL-overlap baseline. SL-Overlap’s poor performance can be attributed to low direct overlap between sentimental words and literal words. S-Joint also outperforms the S-Independent.

⁷Accuracy numbers are inappropriate in this case because the number of negative instances, in most cases, is far larger than the number of positive ones.

Inspection of the parameters shows that S-Joint does better than S-Independent in modeling words that only relate to a subset of body positions. For example, in one case we found that for the word “puzzled” nearly 50% of the weights were on features that related to eyebrows and eyes. This type of specialization was far more pronounced for S-Joint. The joint nature of the learning allows the features for individual words to specialize for specific positions. In contrast, S-Independent must independently predict all parts for every word.

Human Evaluation We report human relevancy judgments for the top-5 returned results from S-Joint. On average, 56.2% were marked to be relevant. This shows that S-Joint is performing better than automatic numbers would indicate, confirming our intuition that there is a one-to-many relationship between a sentimental description and avatars. Sentimental descriptions, while having significant signal, are not exact. These results also indicate that relying on automatic measures of accuracy that assume a single reference avatar underestimates performance. Figure 6 shows the top ranked results returned by S-Joint for a sentimental description where the model performs well.

8.3 Generation Results

Finally we evaluate three models for avatar generation: Random, SL-Overlap and S-Joint using automatic measures and human evaluation.

Automatic Evaluation Table 4 presents results for automatic evaluation. The Random baseline performs badly, on average assigning items correctly to less than 1 position in the generated avatar. The SL-Overlap baseline improves, but still performs quite poorly. The S-Joint model performs significantly better, correctly guessing 2-3 items for each output avatar. However, as we will see in the manual evaluation, many of the non-matching parts it produces are still a good fit for the query.

Human Evaluation As before, there are many reasonable avatars that could match as well as the reference avatars. Therefore, we also evaluated generation with A/B tests, much like in Section 4. Annotators were asked to judge which of two avatars better matched a sentimental description. They

pensive, confrontational; music, socializing; musician, bar tending, club owner; smart, cool.

Figure 6: A sentimental description paired with the highest ranked avatars found by S-Joint.

Model	Overlap
Random	0.041
SL-Overlap	0.049
S-Joint	0.126

Table 4: Automatic generation evaluation results. The item overlap metric is defined in Section 5.

	Kappa	Majority	Random	Sys.
SL-Overlap	0.20	0.25	0.34	0.32
S-Joint	0.52	0.90	0.07	0.81
Gamer	0.52	0.81	0.08	0.77

Table 5: Human evaluation of automatically generated avatars. Majority represents the percentage of time the system output is preferred by a majority of raters. Random and System (Sys.) indicate the percentage of time each was preferred.

could rate System A or System B as better, or report that they were equal or that neither matched the description. We consider two comparisons: SL-Overlap vs. Random and S-Joint vs Random. Five annotators performed each condition, rating 100 examples with randomly ordered avatars.

We report the results for human evaluation including kappa, majority judgments, and a distribution over judgments in Table 5. The SL-Overlap baseline is indistinguishable from a random avatar. This contrasts with the ranking case, where this simple baseline showed improvement, indicating that generation is a much harder problem. Furthermore, agreement is low; people felt the need to make a choice but

were not consistent.

We also see in Table 5 that people prefer the S-Joint model outputs to random avatars as often as they prefer gamer to random. While this does not necessarily imply that S-Joint creates gamer-quality avatars, it indicates substantial progress by learning a mapping between literal and sentimental words.

Qualitative Results Table 6 presents the highest and lowest weighted features for different sentimental query words. Figure 7 shows four descriptions that were assigned high quality avatars.

In general, many of the weaker avatars had aspects of the descriptions but lacked such distinctive overall looks. This was especially true when the descriptions contained seemingly contradictory information. For example, one avatar was described as being both nerdy and popular. We generated a look that had aspects of both of these descriptions, including a head that contained both conservative elements (like glasses) and less conservative elements (like crazy hair and earrings). However, the combination would not be described as nerdy or popular, because of difficult to predict global interactions between the co-occurring words and items. This is an important area for future work.

9 Conclusions

We explored how visual language, both literal and sentimental, maps to the overall physical appearance and style of virtual characters. While this paper focused on avatar design, our approach has implications for a broad class of natural language-driven

Ambition; business, fashion, success; salesman; smooth, professional. Capable, confident, firm; heavy metal, extreme sports, motorcycles; engineer, mechanic, machinist; aggressive, strong, protective. Stressed, bored, discontent; emo music; works at a record store; goth, dark, drab. Happy, content, confident, home, career, family, secretary, student, classy, clean, casual

Figure 7: Avatars automatically generated with the S-Joint model.

Sentiment	positive features	negative features
happi	mouth:thick, mouth:smilei, mouth:make, mouth:open	mouth:tight, mouth:emotionless, mouth:brownish, mouth:attract
gothic	shoes:brown, shirt:black, pants:hot, shirt:band	shirt:half, shirt:tight, pants:sexi, hair:brownish
retro	eyebrows:men, eyebrows:large, hair:round, pants:light	eyebrows:beauti, pants:side; eyebrows:trim, pants:cut
beach	pants:yello, pants:half, nose:narrow, pants:white	shirt:brown, shirt:side; shoes:long, pants:jean

Table 6: Most positive and negative features for a word stem. A feature is [position]:[literal word].

dialog scenarios. In many situations, a user may be perfectly able to formulate a high-level description of their intent (“Make my resume look cleaner” “Buy me clothes for a summer wedding,” or “Play something more danceable”) while having little or no understanding of the complex parameter space that the underlying software must manipulate in order to achieve this result.

We demonstrated that these high-level sentimental specifications can have a strong relationship to literal aspects of a problem space and showed that sentimental language is a concise, yet noisy, way of specifying high level characteristics. Sentimental language is an unexplored avenue for improving natural language systems that operate in situated settings. It has the potential to bridge the gap between lay and expert understandings of a problem domain.

Abstract

The many differences between Dialectal Arabic and Modern Standard Arabic (MSA) pose a challenge to the majority of Arabic natural language processing tools, which are designed for MSA. In this paper, we retarget an existing state-of-the-art MSA morphological tagger to Egyptian Arabic (ARZ). Our evaluation demonstrates that our ARZ morphology tagger outperforms its MSA variant on ARZ input in terms of accuracy in part-of-speech tagging, diacritization, lemmatization and tokenization; and in terms of utility for ARZ-to-English statistical machine translation.

1 Introduction

Dialectal Arabic (DA) refers to the day-to-day native vernaculars spoken in the Arab World. DA is used side by side with Modern Standard Arabic (MSA), the official language of the media and education (Holes, 2004). Although DAs are historically related to MSA, there are many phonological, morphological and lexical differences between them. Unlike MSA, DAs have no standard orthographies or language academies. Furthermore, different DAs, such as Egyptian Arabic (henceforth, ARZ), Levantine Arabic or Moroccan Arabic have important differences among them, similar to those seen among Romance languages (Holes, 2004; Abdel-Massih et al., 1979). Most tools and resources developed for natural language processing (NLP) of Arabic are designed for MSA. Such resources are quite limited when it comes to processing DA, e.g., a state-of-the-art MSA morphological analyzer only has 60% coverage of Levantine Arabic verb forms (Habash and Rambow, 2006).

In this paper, we describe the process of retargeting an existing state-of-the-art tool for modeling MSA morphology disambiguation to ARZ, the most commonly spoken DA. The MSA tool we extend is MADA – Morphological Analysis and Disambiguation of Arabic (Habash and Rambow, 2005). The approach used in MADA, which was inspired by earlier work by Hajic (2000), disambiguates in context for every aspect of Arabic morphology, thus solving all tasks in “one fell swoop”. The disadvantage of the MADA approach is its dependence on two complex resources: a morphological analyzer for the language and a large collection of manually annotated words for all morphological features in the same representation used by the analyzer. For ARZ, such resources have recently become available, with the development of the CALIMA ARZ morphological analyzer (Habash et al., 2012b) and the release by the Linguistic Data Consortium (LDC) of a large ARZ corpus annotated morphologically in a manner compatible with CALIMA (Maamouri et al., 2012a). In the work presented here, we utilize these new resources within the paradigm of MADA, transforming MADA into MADA-ARZ. The elegance of the MADA solution makes this conceptually a simple extension.

Our evaluation demonstrates that our Egyptian DA version of MADA, henceforth MADA-ARZ, outperforms MADA for MSA on ARZ morphological tagging and improves the quality of ARZ to English statistical machine translation (MT).

The rest of this paper is structured as follows: Section 2 discusses related work. Section 3 presents the challenges of processing Arabic dialects. Section 4 outlines our approach. And Section 5 presents and discusses our evaluation results.

2 Related Work

There has been a considerable amount of work on MSA morphological analysis, disambiguation, part-of-speech (POS) tagging, tokenization, lemmatization and diacritization; for an overview, see (Habash, 2010). Most solutions target specific problems, such as diacritization (Zitouni et al., 2006), tokenization or POS tagging (Diab et al., 2007). In contrast, MADA provides a solution to all of these problems together (Habash and Rambow, 2005).

Previous work on DA morphological tagging focused on creating resources, using noisy or incomplete annotations, and using unsupervised/semi-supervised methods. Duh and Kirchhoff (2005) adopt a minimally supervised approach that only requires raw text data from several DAs, as well as a MSA morphological analyzer. They report a POS accuracy of 70.9% on a rather coarse-grained POS tagset (17 tags).

Al-Sabbagh and Girju (2012) describe a supervised tagger for Egyptian Arabic social networking corpora trained using transformation-based learning (Brill, 1995). They report 94.5% F-measure on tokenization and 87.6% on POS tagging. Their tokenization and POS tagsets are comparable to the set used by the Arabic Treebank (ATB). We do not compare to them since their data sets are not public.

Stallard et al. (2012) show that unsupervised methods for learning DA tokenization can outperform MSA tokenizers on MT from Levantine Arabic to English. We do not compare to them directly since our work is on ARZ. However, we carry a similar MT experiment in Section 5.

Mohamed et al. (2012) annotated a small corpus of Egyptian Arabic for morphological segmentation and learned segmentation models using memory-based learning (Daelemans and van den Bosch, 2005). Their best system achieves a 91.90% accuracy on the task of morpheme-segmentation. We compare to their work and report on their test set in Section 5.

There are some other morphological analyzers for DA. Kilany et al. (2002) worked on ARZ, but the analyzer has very limited coverage. Their lexicon was used as part of the development of CALIMA (Habash et al., 2012b). Other efforts are not about

ARZ (Habash and Rambow, 2006; Salloum and Habash, 2011).

Given the similarity between MSA and DA, there has been some work on mapping DA to MSA to exploit rich MSA resources (Chiang et al., 2006; Abo Bakr et al., 2008; Salloum and Habash, 2011; Salloum and Habash, 2013). Other researchers have studied the value of simply combining DA and MSA data, such as Zbib et al. (2012) for DA to English MT. In our approach, we target DA directly, and we evaluate the use of additional MSA annotated resources to our training in Section 5.

3 Arabic Dialect Challenges

General Arabic Challenges Arabic, as MSA or DA, poses many challenges for NLP. Arabic is a morphologically complex language which includes rich inflectional morphology and a number of clitics. For example, the MSA word *وسيكتوبنھا* *wsyk-tbwnhA* (*wa+sa+ya-ktub-uwna+hA*)¹ ‘and they will write it [lit. and+will+they-write-they+it]’ has two proclitics, one circumfix and one pronominal enclitic. Additionally, Arabic has a high degree of ambiguity resulting from its diacritic-optional writing system and common deviation from spelling standards (e.g., Alif and Ya variants) (Buckwalter, 2007). The Standard Arabic Morphological Analyzer for (SAMA) (Graff et al., 2009) produces 12 analyses per MSA word on average.

Differences between ARZ and MSA As mentioned above, most tools developed for MSA cannot be expected to perform well on ARZ. This is due to the numerous differences between the two variants. Lexically, the number of differences is quite significant. For example, ARZ طَبْرِيَة *Trbyzħ* ‘table’ corresponds to MSA طَاولة *TAwlħ*. Phonologically, there are many important differences which relate to orthography in DA, e.g., the MSA consonant ث /θ/ is pronounced as /t/ in ARZ (or /s/ in more recent borrowings from MSA); for a fuller discussion, see (Habash, 2010; Habash et al., 2012a). Examples of morphological differences include changes in the

¹ Arabic transliteration is presented in the Habash-Soudi-Buckwalter scheme (Habash et al., 2007): (in alphabetical order) *AbtθjHxdðrzssSDTĐSγfqklmnhw* and the additional symbols: ' ئ, ڭ,
morpheme form, e.g., the MSA future proclitic +*سـا*+ appears in ARZ as +*هـا*+. There are some morphemes in ARZ that do not exist in MSA such as the negation circum-clitic *مـشـ*+...+*مـا*+...+*شـ*. And there are MSA features that are absent from ARZ, most notably case and mood.

Since there are no orthographic standards, ARZ words may be written in a variety of ways reflecting different writing rules, e.g., phonologically or etymologically. A conventional orthography for Dialectal Arabic (CODA) has been proposed and used for writing ARZ in the context of NLP applications (Habash et al., 2012a; Al-Sabbagh and Girju, 2012; Eskander et al., 2013). Finally, MSA and ARZ co-exist and are often used interchangeably, especially in more formal settings. The CALIMA morphological analyzer we use addresses several of these issues by modeling both ARZ and MSA together, including a limited set of inter-dialect morphology phenomena, and by mapping ARZ words into CODA orthography internally while accepting a wide range of spelling variants.

4 Approach

4.1 The MADA Approach

MADA is a method for Arabic morphological analysis and disambiguation (Habash and Rambow, 2005; Roth et al., 2008). MADA uses a morphological analyzer to produce, for each input word, a list of analyses specifying every possible morphological interpretation of that word, covering all morphological features of the word (diacritization, POS, lemma, and 13 inflectional and clitic features). MADA then applies a set of models (support vector machines and N-gram language models) to produce a prediction, per word in-context, for different morphological features, such as POS, lemma, gender, number or person. A ranking component scores the analyses produced by the morphological analyzer using a tuned weighted sum of matches with the predicted features. The top-scoring analysis is chosen as the predicted interpretation for that word in context.

4.2 Extending MADA into MADA-ARZ

Adjusting MADA to handle DA requires a number of modifications. The most significant change is re-

placing the MSA analyzer SAMA with the ARZ analyzer CALIMA to address the differences outlined in Section 3. In addition, new feature prediction models are needed; these are trained using ARZ data sets annotated by the LDC (Maamouri et al., 2006; Maamouri et al., 2012b). The data sets were not usable as released due to numerous annotation inconsistencies and differences from CALIMA, as well due to gaps in CALIMA. We synchronized the annotations with the latest version of CALIMA following a technique described by Habash and Rambow (2005). The result of this synchronization step is the data we use in this study (for training, development and testing). Our synchronized annotations fully match the LDC annotations in 90% of the words (in full morphological tag). We performed a manual analysis on randomly chosen 100 words that did not fully match. The choice we made is correct or acceptable in 55% of the cases of mismatch with the LDC annotation, which means that the our choice is accurate in over 95% of all cases.

Some of the original MADA features (which were needed for MSA) are not used in ARZ and so are dropped in MADA-ARZ; these features are case, mood, the question-marking proclitic, state and voice. Additional ARZ feature values have been added, e.g., to handle the progressive particle and future marker, among others. These are provided by CALIMA and are classified and selected by MADA-ARZ. In our current implementation, ARZ features that are not present in MSA, such as the negation and indirect-object enclitics, are not classified by MADA-ARZ classifiers, but since they are provided by CALIMA they can be selected by the whole MADA-ARZ system.

5 Evaluation

We evaluate MADA-ARZ intrinsically — in terms of performance on morphological disambiguation — and extrinsically in the context of MT.

5.1 POS Tagging, Diacritization, Lemmatization and Segmentation

Experimental Settings We use two sets of annotated data from the LDC: ATB-123, which includes parts 1, 2 and 3 of the MSA Penn Arabic Treebank

Train Data	Development			Test		
	MADA MSA	MADA-ARZ ARZ	ALL	MADA MSA	MADA-ARZ ARZ	ALL
Morph Tag	35.8	84.0	77.3	35.7	84.5	75.5
Penn POS	77.5	89.6	90.2	79.0	90.0	90.1
MADA POS	80.7	90.8	91.3	82.1	91.1	91.4
Diacritic	31.3	82.6	72.9	32.2	83.2	72.2
Lemma	64.0	85.2	81.6	67.1	86.3	82.8
Full	26.2	74.3	65.4	27.0	75.4	64.7
ATB Segmentation	90.6	97.4	97.6	90.5	97.4	97.5

Table 1: Evaluation metrics on the ATB-ARZ development and test sets. The best results are **bolded**. We compare MADA and MADA-ARZ with different training data conditions. Definitions of metrics are in Section 5.1. MSA training data is ATB-123. ARZ training data is ATB-ARZ. ALL training data is ATB-123 plus ATB-ARZ.

(Maamouri et al., 2004); and ATB-ARZ, the Egyptian Arabic Treebank (parts 1-5) (Maamouri et al., 2012a). For ATB-123 training, we use all of parts 1 and 2 plus the training portion of ATB-3 (as defined by Zitouni et al. (2006)); for development and test, we split Zitouni et al. (2006)’s devtest set into two. We sub-divide ATB-ARZ into development, training, and test sets (roughly a 10/80/10 split). The ATB-ARZ training data has 134K words, and the ATB-123 training data has 711K words.

We evaluate two systems. We used the latest release of MADA for MSA (v3.2), trained on ATB-123 (MSA), as our baseline. For MADA-ARZ, we compare two training settings: using ATB-ARZ (ARZ) and combining ATB-ARZ with ATB-123 (ALL). We present our results on the ATB-ARZ development and blind test sets (21.1K words and 20.4K words). Tuning for MADA-ARZ was done using a random 10% of the ATB-ARZ training data, which was later integrated back into the training set.

Metrics We use several evaluation metrics to measure the effectiveness of MADA-ARZ. **Morph Tag** refers to the accuracy of correctly predicting the full CALIMA morphological tag (i.e., not the diacritics or the lemma). **Penn POS** and **MADA POS** are also tag accuracy metrics. **Penn POS**, also known as the *Reduced Tag Set*, is a tag set reduction of the full Arabic morphological tag set, which was proposed for MSA (Kulick et al., 2006; Diab, 2007; Habash, 2010); since it retains no MSA-specific morpholog-

ical features, it also makes sense for ARZ. MADA **POS** is the small POS tag set (36 tags) MADA uses internally. **Diacritic** and **Lemma** are the accuracies of the choice of diacritized form and Lemma, respectively. **Full** is the harshest metric, requiring that every morphological feature of the chosen analysis be correct. Finally, **ATB Segmentation** is the percentage of words with correct ATB segmentation (splitting off all clitics except for the determiner + ال + Al+).

Results The results are shown in Table 1. MADA-ARZ performs much better than the MADA baselines in all evaluation metrics. Comparing the two MADA-ARZ systems, it is evident that adding MSA data (ATB123) results in slightly better performance only for the Penn POS, MADA POS, and ATB Segmentation metrics. Including the MSA data results in accuracy reductions for the other metrics, but the resulting system still outperforms the MADA MSA baseline in all cases. The results are consistent for development and blind test.

The CMUQ-ECA Test Set Mohamed et al. (2012) reported on the task of ARZ raw orthography morph segmentation (determining the morphs in the raw word). The CMUQ-ECA test data comprised 36 ARZ political comments and jokes from the Egyptian web site www.masrawy.com. The set contains 2,445 words including punctuation. Their best system gets a 91.9% word-level accuracy. Since MADA-ARZ modifies the spelling

Tokenization	OOV	BLEU	METEOR	TER
Punct	9.2	22.1	27.2	63.2
MADA ATB	5.8	24.4	29.6	60.5
MADA-ARZ ATB	4.9	25.2	29.9	59.4

Table 2: Machine translation results on the test set. ‘‘Punct’’ refers to the baseline which only tokenizes at punctuation.

of the word when it maps into CODA, we needed a manual analysis where no exact match with the gold occurs (11.8% of the time). We determined MADA-ARZ’s accuracy on their test set for morph-segmentation to be 93.2%.

5.2 Egyptian Arabic to English MT

MT Experimental Settings We use the open-source Moses toolkit (Koehn et al., 2007) to build a phrase-based SMT system. We use MGIZA++ for word alignment (Gao and Vogel, 2008). Phrase translations of up to 8 words are extracted in the phrase table. We use SRILM (Stolcke, 2002) with modified Kneser-Ney smoothing to build two 4-gram language models. The first model is trained on the English side of the bitext, while the other is trained on the English Gigaword data. Feature weights are tuned to maximize BLEU (Papineni et al., 2002) on a development set using Minimum Error Rate Training (Och, 2003). We perform case-insensitive evaluation in terms of BLEU, METEOR (Banerjee and Lavie, 2005) and TER (Snover et al., 2006) metrics.

Data We trained on DA-English parallel data (Egyptian and Levantine) obtained from several LDC corpora. The training data amounts to 3.8M untokenized words on the Arabic side. The dev set, used for tuning the parameters of the MT system, has 15,585 untokenized Arabic words. The test set has 12,116 untokenized Arabic words. Both dev and test data contain two sets of reference translations. The English data is lower-cased and tokenized using simple punctuation-based rules.

Systems We build three translation systems which vary in tokenization of the Arabic text. The first system applies only simple punctuation-based rules. The second and third systems use MADA and MADA-ARZ, respectively, to tokenize the Arabic

text in the ATB tokenization scheme (Habash and Sadat, 2006). The Arabic text is also Alif/Ya normalized.

Results The MT results are in Table 2, which also shows the percentage of out-of-vocabulary (OOV) words – test words not in the training data. MADA-ARZ delivers the best translation performance according to all metrics. All MADA-ARZ improvements over MADA are statistically significant at the .01 level (except in the case of METEOR). All improvements over Punct by MADA and MADA-ARZ are also statistically significant. For BLEU scores, we observe 3.1% absolute improvement to Punct (14% relative), and 0.8% absolute improvement to MADA (3.3% relative). In addition to better morphological disambiguation, MADA-ARZ reduces the OOV ratio (16% relative to MADA), which we suspect contributes to the observed improvements in MT quality.

6 Conclusion and Future Work

We have presented MADA-ARZ, a system for morphological tagging of ARZ. We have shown that it outperforms an state-of-the-art MSA tagger (MADA) on ARZ text, and that it helps ARZ-to-English machine translation more than MADA.

In the future, we intend to perform further feature engineering to improve the results of MADA-ARZ, and extend the system to handle other DAs.

Abstract

We present a novel, structured language model - Supertagged Dependency Language Model to model the syntactic dependencies between words. The goal is to identify ungrammatical hypotheses from a set of candidate translations in a MT system combination framework and help select the best translation candidates using a variety of sentence-level features. We use a two-step mechanism based on constituent parsing and elementary tree extraction to obtain supertags and their dependency relations. Our experiments show that the structured language model provides significant improvement in the framework of sentence-level system combination.

1 Introduction

In recent years, there has been a burgeoning interest in incorporating syntactic structure into Statistical machine translation (SMT) models (e.g., Galley et al., 2006; DeNeefe and Knight 2009; Quirk et al., 2005). In addition to modeling syntactic structure in the decoding process, a methodology for candidate translation selection has also emerged. This methodology first generates multiple candidate translations followed by rescoring using global sentence-level syntactic features to select the final translation. The advantage of this methodology is that it allows for easy integration of complex syntactic features that would be too expensive to use during the decoding

process. The methodology is usually applied in two scenarios: one is as part of an n-best reranking (Och et al., 2004; Hasan et al., 2006), where n-best candidate translations are generated through a decoding process. The other is translation selection or reranking (Hildebrand and Vogel 2008; Callison-Burch et al., 2012), where candidate translations are generated by different decoding processes or different decoders.

This paper belongs to the latter; the goal is to identify ungrammatical hypotheses from given candidate translations using grammatical knowledge in the target language that expresses syntactic dependencies between words. To achieve that, we propose a novel Structured Language Model (SLM) - Supertagged Dependency Language Model (SDLM) to model the syntactic dependencies between words. Supertag (Bangalore and Joshi, 1999) is an elementary syntactic structure based on Lexicalized Tree Adjoining Grammar (LTAG). Traditional supertagged n-gram LM predicts the next supertag based on the immediate words to the left with supertags, so it can not explicitly model long-distance dependency relations. In contrast, SDLM predicts the next supertag using the words with supertags on which it syntactically depend, and these words could be anywhere and arbitrarily far apart in a sentence. A candidate translation's grammatical degree or "fluency" can be measured by simply calculating the SDLM likelihood of the supertagged dependency structure that spans the entire sentence.

To obtain the supertagged dependency structure, the most intuitive way is through a LTAG parser (Schabes et al., 1988). However, this could be very

slow as it has time complexity of $O(n^6)$. Instead we propose an alternative mechanism in this paper: first we use a constituent parser¹ of $O(n^3) \sim O(n^5)$ to obtain the parse of a sentence, and then we extract elementary trees with dependencies from the parse in linear time. Aside from the consideration of time complexity, another motivation of this two-step mechanism is that compared with LTAG parsing, the mechanism is more flexible for defining syntactic structures of elementary trees for our needs. Because those structures are defined only within the elementary tree extractor, we can easily adjust the definition of those structures within the extractor and avoid redesigning or retraining our constituent parser.

We experiment with sentence-level translation combination of five different translation systems; the goal is for the system to select the best translation for each input source sentence among the translations provided by the five systems. The results show a significant improvement of 1.45 Bleu score over the best single MT system and 0.72 Bleu score over a baseline sentence-level combination system of using consensus and n-gram LM.

2 Related Work

Och et al., (2004) investigated various syntactic feature functions to rerank the n-best candidate translations. Most features are syntactically motivated and based on alignment information between the source sentence and the target translation. The results are rather disappointing. Only the non-syntactic IBM model 1 yielded significant improvement. All other tree-based feature functions had only a very small effect on the performance.

In contrast to (Och et al., 2004)'s bilingual syntax features, Hasan et al., (2006) focused on monolingual syntax features in n-best reranking. They also investigated the effect of directly using the log-likelihood of the output of a HMM-based supertagger, and found it did not improve performance significantly. It is worth noticing that this log-likelihood is based on supertagged n-gram

LM, which is one type of class-based n-gram LM, so it does not model explicit syntactic dependencies between words in contrast to the work we describe in this paper. Hardmeier et al., (2012) use tree kernels over constituency and dependency parse trees for either the input or output sentences to identify constructions that are difficult to translate in the source language, and doubtful syntactic structures in the output language. The tree fragments extracted by their tree kernels are similar to our elementary trees but they only regard them as the individual inputs of support vector machine regression while binary relations of our elementary trees are considered in a formulation of a structural language model.

Outside the field of candidate translation selection, Hassan et al., (2007) proposed a phrase-based SMT model that integrates supertags into the target side of the translation model and the target n-gram LM. Two kinds of supertags are employed: those from LTAG and Combinatory Categorial Grammar (CCG), and both yield similar improvements. They found that using both or either of the supertag-based translation model and supertagged LM can achieve significant improvement. Again, the supertagged LM is a class-based n-gram LM and does not model explicit syntactic dependencies during decoding.

In the field of MT system combination, word-level confusion network decoding is one of the most successful approaches (Matusov et al., 2006; Rosti et al., 2007; He et al. 2008; Karakos et al. 2008; Sim et al. 2007; Xu et al. 2011). It is capable of generating brand new translations but it is difficult to consider more complex syntax such as dependency LM during decoding since it adds one word at a time while a dependency based LM must parse a complete sentence. Typically, a confusion network approach selects one translation as the best and uses this as the backbone for the confusion network. The work we present here could provide a more sophisticated mechanism for selecting the backbone. Alternatively, one can enhance confusion network models by collaborating with a sentence-level combination model which uses complex syntax to re-rank n-best outputs of a confusion network model. This kind of collaboration is one of our future works.

¹ Stanford parser (<http://nlp.stanford.edu/software/lex-parser.shtml>). We use its PCFG version of $O(n^3)$ for SDLM training of part of Gigaword in addition to Treebank and use its factor version of $O(n^5)$ to calculate the SDLM likelihood of translations.

3 LTAG and Supertag

LTAG (Joshi et al., 1975; Schabes et al., 1988) is a formal tree rewriting formalism, which consists of a set of elementary trees, corresponding to minimal linguistic structures that localize dependencies, including long-distance dependencies, such as predicate-argument structure. Each elementary tree is associated with at least one lexical item on its frontier. The lexical item associated with an elementary tree is called the anchor in that tree; an elementary tree thus serves as a description of syntactic constraints of the anchor. The elementary syntactic structures of elementary trees are called supertags (Bangalore and Joshi, 1999), in order to distinguish them from the standard part-of-speech tags. Some examples are provided in figure 1 (b).

Elementary trees are divided into initial and auxiliary trees. Initial trees are those for which all non-terminal nodes on the frontier are substitutable. Auxiliary trees are defined as initial trees, except that exactly one frontier, non-terminal node must be a foot node, with the same label as the root node. Two operations - substitution and adjunction - are provided in LTAG to combine elementary trees into a derived tree.

4 SDLM

Our goal is to use SDLM to calculate the grammaticality of translated sentences. We do this by calculating the likelihood of the supertagged dependency structure that spans the entire sentence using SDLM. To obtain the supertagged dependency linkage, the most intuitive way is through a LTAG parser (Schabes et al., 1988). However, this could be very slow as it has time complexity of $O(n^6)$. Another possibility is to follow the procedure in (Joshi and Srinivas 1994, Bangalore and Joshi, 1999): use a HMM-based supertagger to assign words with supertags, followed by derivation of a shallow parse in linear time based on only the supertags to obtain the dependencies. But since this approach uses only the local context, in (Joshi and Srinivas 1994), they also proposed another greedy algorithm based on supertagged dependency probabilities to gradually select the path with the maximum path probability to extend to the remaining directions in the dependency list.

In contrast to the LTAG parsing and supertagging-based approaches, we propose an alternative mechanism: first we use a state-of-the-art constituent parser to obtain the parse of a sentence, and then we extract elementary trees with dependencies from the parse to assign each word with an elementary tree. The second step is similar to the approach used in extracting elementary trees from the TreeBank (Xia, 1999; Chen and Vijay-Shanker, 2000).

4.1 Elementary Tree Extraction

We use an elementary tree extractor, a modification of (Chen and Vijay-Shanker, 2000), to serve our purpose. Heuristic rules were used to distinguish arguments from adjuncts, and the extraction process can be regarded as a process that gradually decomposes a constituent parse to multiple elementary trees and records substitutions and adjunctions. From elementary trees, we can obtain supertags by only considering syntactic structure and ignoring anchor words. Take the sentence – “The hungry boys ate dinner” as an example; the constituent parse and extracted supertags are shown in Figure 1.

In Figure 1 (b), dotted lines represent the operations of substitution and adjunction. Note that each word in a translated sentence would be assigned exactly one elementary syntactic structure which is associated with a unique supertag id for the whole corpus. Different anchor words could own the same elementary syntactic structure and would be assigned the same supertag id, such as “ $\alpha 1$ ” for “boys” and “dinner”. For our corpus, around 1700 different elementary syntactic structures (1700 supertag ids) are extracted.

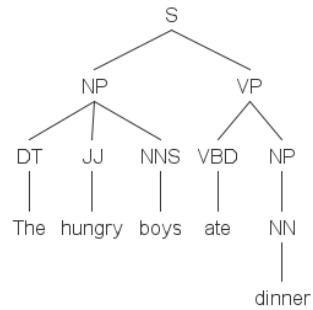

Figure 1. (a) Parse of “The hungry boys ate dinner”

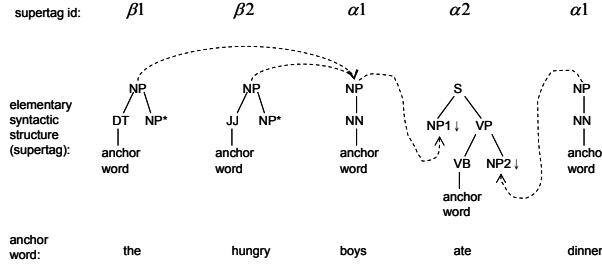

Figure 1. (b) Extracted elementary trees

4.2 Model

Bangalore and Joshi (1999) gave a concise description for dependencies between supertags: “A supertag is dependent on another supertag if the former substitutes or adjoins into the latter”. Following this description, for the example in Figure 1 (b), supertags of “the” and “hungry” are dependent on the supertag of “boys”, and supertags of “boys” and “dinner” are dependent on the supertag of “ate”. These dependencies between supertags also provide the dependencies between anchor words.

Since the syntactic constraints for each word in its context are decided and described through its supertag, the likelihood of SDLM for a sentence could also be regarded as the degree of violations of the syntactic constraints on all words in the sentence. Consider a sentence $S = w_1 w_2 \dots w_n$ with corresponding supertags $T = t_1 t_2 \dots t_n$. We use $d_i=j$ to represent the dependency relations for words or supertags. For example, $d_3 = 5$ means that w_3 depends on w_5 or t_3 depends on t_5 . We propose five different bigram SDLM as follows and evaluate their effects in section 5.

$$\begin{aligned}
 & \prod_i P(w_i | t_{d_i}) && \text{SDLM model(1)} \\
 & \prod_i P(w_i | w_{d_i} t_{d_i}) \approx \prod_i P(t_i | t_{d_i}) P(w_i | t_i) && \text{SDLM model(2)} \\
 & \prod_i P(t_i | t_{d_i}) && \text{SDLM model(3)} \\
 & \prod_i P(w_i | t_i) && \text{SDLM model(4)} \\
 & \prod_i P(w_i | w_{d_i}) && \text{SDLM model(5)}
 \end{aligned}$$

SDLM model (2) is the approximation form of model (1); model (3) and (4) are individual terms of model (2); model (5) models word dependencies based on elementary tree dependencies. The estimation of the probabilities is done using maximum likelihood estimations with Laplace

smoothing. Take Figure 1 (b) as an example; if using model (1), the SDLM likelihood of “The hungry boys ate dinner” is

$$P(\text{the}, \beta_1 | \text{boys}, \alpha_1) * P(\text{hungry}, \beta_2 | \text{boys}, \alpha_1) * P(\text{boys}, \alpha_1 | \text{ate}, \alpha_2) * P(\text{dinner}, \alpha_1 | \text{ate}, \alpha_2) * P(\text{ate}, \alpha_2 | \text{root})$$

In our experiment on sentence-level translation combination, we use a log-linear model to integrate all features including SDLM models. The corresponding weights are trained discriminatively for Bleu score using Minimum Error Rate Training (MERT).

5 Experiment

Our experiments are conducted and reported on the Chinese-English dataset from NIST 2008 (LDC2010T01). It consists of four human reference translations and corresponding machine translations for the NIST Open MT08 test set, which consists of newswire and web data. The test set contains 105 documents with 1312 sentences and output from 23 machine translation systems. Each system provides the top one translation hypothesis for every sentence. We further divide the NIST Open MT08 test set into the tuning set and test set for our experiment of sentence-level translation combination. We divided the 1312 sentences into tuning data of 524 sentences and the test set of 788 sentences. Out of 23 MT systems, we manually select the top five MT systems as our MT systems for our combination experiment.

In terms of SDLM training, since the size of TreeBank-extracted elementary trees is much smaller compared to most practical n-gram LMs trained from the Gigaword corpus, we also extract elementary trees from automatically-generated parses of part of the Gigaword corpus (around one-year newswire of “afp_eng” in Gigaword 4) in addition to TreeBank-extracted elementary trees.

5.1 Feature Functions

For the baseline combination system, we use the following feature functions in the log-linear model to calculate the score of a system translation.

- Sentence consensus based on Translation Edit Ratio (TER)
- Gigaword-trained 3-gram LM and word penalty

For testing SDLM, in addition to all features that the baseline combination system uses, we add single or multiple SDLM models in the log-linear model, and each SDLM model has its own weight.

5.2 Result

From table 1, we can see that the combination of SDLM model 3, 4 and 5 yields the best performance, which is better than the best MT system by Bleu of 1.45, TER of 0.67 and METEOR of 1.25, and also better than the baseline combination system by Bleu of 0.72, TER of 0.25 and METEOR of 0.44. Compared with SDLM model 5, which represents a type of word dependency LM without labels, the results show that adding appropriate syntactic “labels” (here, they are “supertags”) on word dependencies brings benefits.

	Bleu	TER	METEOR
Best MT system	30.16	55.45	54.43
baseline	30.89	55.03	55.24
baseline+ model 1	31.29	54.99	55.63
baseline+ model 2	31.25	55.23	55.37
baseline+ model 3	31.25	55.06	55.40
baseline+ model 4	31.44	54.70	55.54
baseline+ model 5	31.39	55.15	55.68
baseline+ model 3+ model 4+ model 5	31.61	54.78	55.68

Table 1. Result of Sentence-level Translation Combination

6 Conclusion

In this paper we presented Supertagged Dependency Language Model for explicitly modeling syntactic dependencies of the words of translated sentences. Our goal is to select the most grammatical translation from candidate translations. To obtain the supertagged dependency structure of a translation candidate, a two-step mechanism based on constituent parsing and elementary tree extraction is also proposed. SDLM shows its effectiveness in the scenario of translation selection.

There are several avenues for future work: we have focused on bigram dependencies in our models; extension to more than two dependent elementary trees is straightforward. It would also be worth investigating the performance of using our sentence-level model to re-rank n-best outputs of a confusion network model. And in terms of applications, SDLM can be directly applied to

many other NLP tasks, such as speech recognition and natural language generation.

Acknowledgments

We would like to thank Owen Rambow for providing the elementary tree extractor and also thank the anonymous reviewers for their helpful comments. Abstract

We report the results of our work on automating the transliteration decision of named entities for English to Arabic machine translation. We construct a classification-based framework to automate this decision, evaluate our classifier both in the limited news and the diverse Wikipedia domains, and achieve promising accuracy. Moreover, we demonstrate a reduction of translation error and an improvement in the performance of an English-to-Arabic machine translation system.

1 Introduction

Translation of named entities (NEs) is important for NLP applications such as Machine Translation (MT) and Cross-lingual Information Retrieval. For MT, NEs are major subset of the out-of-vocabulary terms (OOVs). Due to their diversity, they cannot always be found in parallel corpora, dictionaries or gazetteers. Thus, state-of-the-art of MT needs to handle NEs in specific ways. For instance, in the English-Arabic automatic translation example given in Figure 1, the noun "North" has been erroneously translated to "الشمالية / Al\$mAlyp" (indicating the north direction in English) instead of being transliterated to "نورث / nwrv".

As shown in Figure 1, direct translation of in-vocabulary terms could degrade translation quality. Also blind transliteration of OOVs does not necessarily contribute to translation adequacy and may actually create noisy contexts for the language model and the decoder.

English Input: Dudley North was an English merchant.

SMT output: كان دودلي الشمالية تاجر الإنجليزية.
kAn dwdly Al\$mAlyp tAjr AlInjlyzyp.

Correct Translation: كان دودلي نورث تاجر إنجليزي.
kAn dwdly nwrv tAjr Injlyzy.

Figure 1: Example of a NE translation error.

An intelligent decision between translation and transliteration should use semantic and contextual information such as the type of the named-entity and the surrounding terms. In this paper, we construct and evaluate a classification-based framework to automate the translation vs. transliteration decision. We evaluate our classifier both in the limited news and diverse Wikipedia domains, and achieve promising accuracy. Moreover, we conduct an extrinsic evaluation of the classifier within an English to Arabic MT system. In an in-domain (news) MT task, the classifier contributes to a modest (yet significant) improvement in MT quality. Moreover, for a Wikipedia translation task, we demonstrate that our classifier can reduce the erroneous translation of 60.5% of the named entities.

In summary our contributions are: (a) We automatically construct a bilingual lexicon of NEs paired with the transliteration/translation decisions in two domains.¹ (b) We build a binary classifier for transliteration and translation decision with a promising accuracy (c) We demonstrate its utility

¹The dataset can be found at <http://www.qatar.cmu.edu/~behrang/NETLexicon>.

within an MT framework.

2 Learning when to transliterate

We model the decision as a binary classification at the token level. A token (within a named-entity) gets translation or transliteration label. In "*Dudley North*" and "*North London*", our classifier is expected to choose transliteration of "North" in the former case, as opposed to translation in the latter. The binary decision needs to use a rich set of local and contextual features. We use the Support Vector Machines as a robust framework for binary classification using a set of interdependent features.² We build two classifiers: (a) **Classifier C_{news}**, trained on a large set of distinct NEs extracted from news-related parallel corpora; and (b) **Classifier C_{diverse}**, trained on a combination of the news related NEs and a smaller set of diverse-topic NEs extracted from Wikipedia titles. We evaluate the two classifiers in both news and the diverse domains to observe the effects of noise and domain change.

2.1 Preparing the labeled data

Our classifier requires a set of NEs with token-level gold labels. We compile such data from two resources: We heuristically extract and label parallel NEs from a large word aligned parallel corpus and we use a lexicon of bilingual NEs collected from Arabic and Wikipedia titles. Starting with a word aligned parallel corpus, we use the UIUC NE tagger (Ratinov and Roth, 2009) to tag the English sentences with four classes of NEs: Person (PER), Location (LOC), Organization (ORG) and Miscellaneous (MISC). Furthermore, we use the word alignments to project and collect the span of the associated Arabic named-entities. To reduce the noisy nature of word alignments, we designed a procedure to clean up the noisy Arabic NE spans by POS verification, and heuristically filtering impossible items (e.g. verbs). This results in a bilingual lexicon of about 57K named-entity pairs. The distribution of NEs categories is reported in Table 1.

To train and evaluate the **C_{diverse}** classifier, we expand our labeled data with Wikipedia NEs using the cross-lingual hyperlinks. Wikipedia article titles often correspond to NEs (Kazama and Tori-

	PER	LOC	ORG	MISC
News _{/57K}	43.0%	10.0%	40.0%	7.0%
Wiki _{/4K}	73.0%	19.0%	2.5%	5.5%

Table 1: Distribution of the four NE categories used in 57K News and 4K Wiki datasets.

sawa, 2007) and have been already used in different works for NEs recognition (Nothman et al., 2013) and disambiguation (Cucerzan, 2007). We improve the Arabic-English Wikipedia title lexicon of Mohit et al. (2012) and build a Wikipedia exclusive lexicon with 4K bilingual entities. In order to test the domain effects, our lexicon includes only NEs which are not present in the parallel corpus. The statistics given in Table 1 demonstrate different nature of the labeled datasets. The two datasets were labeled semi-automatically using the transliteration similarity measure (Fr_{score}) proposed by Freeman et al. (2006), a variant of edit distance measuring the similarity between an English word and its Arabic transliteration. In our experiments, English tokens having an $Fr_{score} > 0.6$ are considered as transliteration, others having $Fr_{score} < 0.5$ as translation. These thresholds were determined after tuning with a held out development set. For tokens having Fr_{score} between 0.5 and 0.6, the decision is not obvious. To label these instances (around 5K unique tokens), we manually transliterate them using Microsoft Maren tool.³ We again compute the Fr_{score} between the obtained transliteration, in its Buckwalter form and the corresponding English token and use the same threshold to distinguish between the two classes. Some examples of NEs and their appropriate classes are presented in Table 2.

Transliteration	Translation
Minnesota ↔ مينيسوتا / mynyswta : 0.77	Agency ↔ ﻋﺎرك/wkAlp : 0.33
Fluke ↔ فلوك / flwk : 0.57	Islamic ↔ ﻷسلامي / AlAslAmyp : 0.55

Table 2: Examples of NEs labeled using Freeman Score.

2.2 Classification Features

We use a total of 32 features selected from the following classes:

Token-based features: These consist of several features based on the token string and indicate

²We use the LIBSVM package (Chang and Lin, 2011).

³<http://afkar.microsoft.com/en/maren>

whether the token is capital initial, composed entirely of capital letters, ends with a period (such as Mr.), contains a digit or a Latin number (e.g. Muhammad II) or contains punctuation marks. The string of the token is also added as a feature. We also add the POS tag, which could be a good indicator for proper nouns that should mainly be transliterated. We also check if the token is a regular noun in the WORDNET (Fellbaum, 1998) which increases its chance of being translated as opposed to transliterated.

Semantic features: These features mainly indicate the NE category obtained using an NE tagger. We also define a number of markers of person (such as Doctor, Engineer, etc.) and organization (such as Corp.) names. We used the list of markers available at: <http://drupal.org/node/1439292>, that we extended manually.

Contextual features: These features are related to the token’s local *context within the NE*. These include information about the current token’s surrounding tokens, its relative position in the NE (beginning, middle or end). Another feature represents the length of the NE in number of tokens.

2.3 Experiments

We train two classifiers and tune their parameters using a held out development set of 500 NEs drawn randomly from the news parallel corpus. We use 55k NEs from the same corpus to train the \mathbf{C}_{news} classifier. Furthermore, we train the $\mathbf{C}_{diverse}$ classifier cumulatively with the 55K news NEs and another 4600 NEs from Wikipedia titles.

The classifiers are evaluated on three different datasets: \mathbf{Test}_{News} which consists of 2K of NEs selected randomly from the news corpus, \mathbf{Test}_{Wiki} consisting of 1K NEs extracted from the Wikipedia and $\mathbf{Test}_{Combination}$, an aggregation of the two previous sets. We manually reviewed the labels of these test sets and fixed any incorrect labels. Table 3 compares the accuracy of the two classifiers under different training and test data settings. Starting with a majority class baseline, our classifiers achieve a promising performance in most settings. The majority class for both classifiers is the *translation* which performs as a baseline approach with an accuracy equal to the distribution of the two classes. We also

	\mathbf{Test}_{News}	\mathbf{Test}_{Wiki}	$\mathbf{Test}_{Combination}$
Baseline	56.70	57.09	56.89
\mathbf{C}_{news}	90.40	84.10	88.64
$\mathbf{C}_{diverse}$	90.42	86.00	89.18

Table 3: Accuracy results for the two classifiers and the baseline on the three test datasets

observe that the addition of a small diverse training set in $\mathbf{C}_{diverse}$ provides a relatively large improvement (about 2%) when tested on Wikipedia. Finally, Figure 2 illustrates the contribution of different classes of features on our diverse classifier (evaluated on \mathbf{Test}_{Wiki}). We observe a fairly linear relationship between the size of the training data and the accuracy. Furthermore, we observe that the features describing the category of the NE are more important than the token’s local context. For example, in the case of ”Dudley North” and ”North London”, the most effective feature for the decision is the category of the named entities.

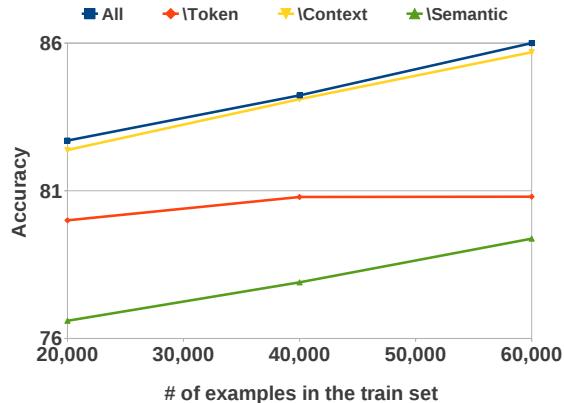

Figure 2: Learning curves obtained on Wiki dataset by removing features individually.

3 Extrinsic MT evaluation

We evaluate the effects of the classifier on an English to Arabic statistical MT system. Our first evaluation focuses on the utility of our classifier in preventing erroneous translation of NEs which need to be transliterated. In the following experiments we use \mathbf{C}_{news} classifier. In order to experiment with a diverse set of NEs, we conducted a study on a small corpus (98,197 terms) of Wikipedia articles from a

diverse set of topics. We use 10 Wikipedia articles describing: Anarchism, Artemis, Buddhism, Isfahan, Shawn Michaels, Turkey, etc. We first use our classifier to locate the subset of NEs which should be transliterated. An annotator validates the decision and examines the phrase table on the default MT decision on those NEs. We observe that out of 1031 NE tokens, 624 tokens (60.5%) which would have been translated incorrectly, are directed to the transliteration module.

Finally, we deploy the transliteration classifier as a pre-translation component to the MT system.⁴ Our MT test set is the MEDAR corpus (Maegaard et al., 2010). The MEDAR corpus consists of about 10,000 words English texts on news related to the climate change with four Arabic reference translations. Due to the lack of non-news English-Arabic corpus, we have to limit this experiment only to the news domain. However, we expect that many of the NEs may already exist in the training corpus and the effects of the classifier is more limited than using a diverse domain like Wikipedia. We automatically locate the NEs in the source language sentences and use the classifier to find those which should be transliterated. For such terms, we offer the transliterated form as an option to the decoder aiming to improve the decoding process. For that a human annotator selected the transliterations from the suggested list that is provided by the automatic transliterator (Maren) without any knowledge of the reference transliterations.

Table 4 shows the impact of adding the classifier to the SMT pipeline with a modest improvement. Moreover, a bilingual annotator examined the automatically tagged NEs in the MT test set and labeled them with the translation vs. transliteration

⁴The baseline MT system is the MOSES phrase-based decoder (Koehn et al., 2007) trained on a standard English-Arabic parallel corpus. The 18 million parallel corpus consists of the non-UN parts of the NIST corpus distributed by the Linguistic Data Consortium. We perform the standard preprocessing and tokenization on the English side. We also use MADA+TOKAN (Habash et al., 2009) to preprocess and tokenize the Arabic side of the corpus. We use the standard setting of GIZA++ and the grow-diagonal-final heuristic of MOSES to get the word alignments. We use a set of 500 sentences to tune the decoder parameters using the MERT (Och, 2003). We use El Kholy and Habash (2010) detokenization framework for the Arabic decoding. We evaluate the MT system with the BLEU metric (Papineni et al., 2002).

	MT Baseline	MT Baseline + Classifier
BLEU	16.63	16.91

Table 4: Results of the extrinsic usage of the classifier in SMT

decisions. Having such gold standard decisions, we evaluated the classifier against the MT test set. The classifier’s accuracy was 89% which is as strong as the earlier intrinsic evaluation. The false positives are 5% which represents around 12.6% of the total errors.

The following example shows how our classifier prevents the MT to choose a wrong decoding for the NE *Python* (being transliterated rather than translated). Moreover, the MT system transliterates the term *Monty* that is unknown to the underlying system. Such entities tend to be unseen in the standard news corpora and consequently unknown (UNK) to the MT systems. Using our classifier in such conditions is expected to reduce the domain gap and improve the translation quality.

English Input: The British comedy troupe **Monty Python**.

bAyvwn.

4 Related work

A number of efforts have been made to undertake the NE translation problem for different language pairs. Among them some use sequence of phonetic-based probabilistic models to convert names written in Arabic into the English script (Glover-Stalls and Knight, 1998) for transliteration of names and technical terms that occurs in Arabic texts and originate in English. Others rely on spelling-based model that directly maps an English letter sequence into an Arabic one (Al-Onaizan and Knight, 2002a). In a related work, Al-Onaizan and Knight (2002b) describe a combination of a phonetic-based model and a spelling-based one to build a transliteration model to generate Arabic to English name translations. In the same direction, Hassan et al. (2007) extracted NE translation pairs from both comparable and parallel corpora and evaluate their quality in a NE translation system. More recently, Ling et al. (2011) propose a Web-based method that translates Chinese NEs into English. Our work is similar in its general objectives and framework to the work pre-

sented by Hermjakob et al. (2008), which describes an approach for identifying NEs that should be transliterated from Arabic into English during translation. Their method seeks to find a corresponding English word for each Arabic word in a parallel corpus, and tag the Arabic words as either NEs or non-NEs based on a matching algorithm. In contrast, we tackle this problem in the reverse direction (translating/transliterating English NEs into Arabic). We also present a novel binary classifier for identifying NEs that should be translated and those that should be transliterated.

5 Conclusion and future work

We reported our recent progress on building a classifier which decides if an MT system should translate or transliterate a given named entity. The classifier shows a promising performance in both intrinsic and extrinsic evaluations. We believe that our framework can be expanded to new languages if the required data resources and tools (mainly parallel corpus, Named Entity tagger and transliteration engine) are available. We plan to expand the features and apply the classifier to new languages and conduct MT experiments in domains other than news.

Better Twitter Summaries?

Joel Judd & Jugal Kalita

Department of Computer Science

University of Colorado

Colorado Springs, Colorado

Email: {jjudd2,jkalita}@uccs.edu

Abstract

This paper describes an approach to improve summaries for a collection of Twitter posts created using the Phrase Reinforcement (PR) Algorithm (Sharifi et al., 2010a). The PR algorithm often generates summaries with excess text and noisy speech. We parse these summaries using a dependency parser and use the dependencies to eliminate some of the excess text and build better-formed summaries. We compare the results to those obtained using the PR Algorithm.

1 Introduction

Millions of people use the Web to express themselves and share ideas. Twitter is a very popular micro blogging site. According to a recent study approximately 340 million Tweets are sent out every day¹. People mostly upload daily routines, fun activities and other words of wisdom for readers. There is also plenty of serious information beyond the personal; according to a study approximately 4% of posts on Twitter have relevant news data². Topics that may be covered by reputable new sources like CNN (Cable News Network) were considered relevant. A topic is simply a keyword or key phrase that one may use to search for Twitter posts containing it. It is possible to gather large amounts of posts from Twitter on many different topics in short amounts of time. Obviously, processing all this information by human hands is impossible. One way to extract information from Twitter posts on a certain topic is to automatically summarize them. (Sharifi et al., 2010a; Sharifi et al., 2010b; Sharifi et al., 2010c) present an algorithm called the Phrase Reinforcement Algorithm to produce summaries of a set of Twitter posts on

a certain topic. The PR algorithm produces good summaries for many topics, but for sets of posts on certain topics, the summaries become syntactically malformed or too wordy. This is because the PR Algorithm does not pay much attention to syntactic well-formedness as it constructs a summary sentence from phrases that occur frequently in the posts it summarizes. In this paper, we attempt to improve Twitter summaries produced by the PR algorithm.

2 The PR Algorithm Revisited

Given a number of Twitter posts on a certain topic, the PR algorithm starts construction of what is called a word graph with a root node containing the topic phrase. It builds a graph showing how words occur before and after the phrase in the root node, considering all the posts on the topic. It builds a subgraph to the left of the topic phrase and another subgraph to its right in a similar manner. To construct the left graph, the algorithm starts with the root node and obtains the set of words that occur immediately before the current node's phrase. For each of these unique words, the algorithm adds them to the graph as nodes with their associated counts to the left of the current node. The algorithm continues this process recursively for each node added to the graph until all the potential words have been added to the left-hand side of the graph. The algorithm repeats these steps symmetrically to construct the right subgraph. Once the full graph is there, the algorithm weights individual nodes. The weights are initialized to the same values as their frequency counts. Then, to account for the fact that some phrases are naturally longer than others, they penalize nodes that occur farther from the root node by an amount that is proportional to their distance. To generate a summary, the algorithm looks for the most overlapping phrases within the graph. Since the nodes' weights are proportional to their overlap, the algorithm searches for the path within the graph

¹<http://blog.twitter.com/2012/03/twitter-turns-six.htm>

²<http://www.pearanalytics.com/blog/wp-content/uploads/2010/05/Twitter-Study-August-2009.pdf>

with the highest cumulative weight. The sequence of words in this path becomes the summary.

3 Problem Description

We start by making some observations on the phrase-reinforcement algorithm. Certain topics do not produce well-formed summaries, while others yield very good summaries. For the posts that have a well-centered topic without a huge amount of variation among the posts, the algorithm works well and creates good summaries. Here is an example summary produced by the PR algorithm.

Phillies defeat Dodgers to take the National League Championship series.

(Sharifi et al., 2010a; Sharifi et al., 2010b; Sharifi et al., 2010c) provide additional examples. The PR algorithm limits the length of the summary to approximately 140 characters, the maximum length of a Twitter post. However, often the summary sentence produced has extraneous parts that appear due to the fact that they appear frequently in the posts being summarized, but these parts make the summary malformed or too wordy. An example with some wordiness is given below.

today is day for vote obama this election day

Some “raw” PR summaries are a lot more wordy than the one above. The goal we address in this paper is to create grammatically better formed summaries by processing the “raw” summaries formed by the PR Algorithm. We drop this excess text and the phrases or extract pieces of text which make sense grammatically to form the final summary. This usually produces a summary with more grammatical accuracy and less noise in between the words. This gets the main point of the summary across better.

4 Approach

The idea behind creating the desired summary is to parse the “raw” summary and build dependencies between the dependent and governor words in each summary. We perform parts of speech tagging and obtain lists of governing and dependent words. This data forms the basis for creating a valid summary. For example given the Twitter post, *today is day for vote obama this election day*, a dependency parser produces the governor-dependent relationships as given in Table 1. Figure 1 also shows the same grammatical dependencies between words in the phrases.

We believe that a word which governs many words is key to the phrase as a whole, and dependent words

Table 1: Governor and Dependent Words for *today is day¹ for vote obama this election day²*

Governor	Dependent
day ¹	today
	is
	for
	day ²
obama	vote
for	obama
day ²	this
	election

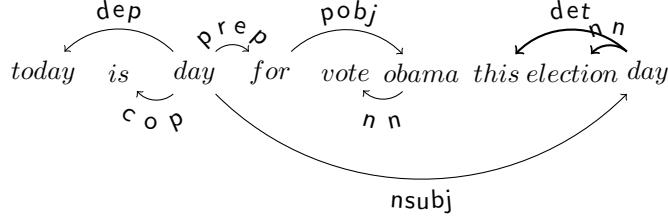

Algorithm 1 Algorithm to Fix “Raw” PRA Summaries

- I. For each word, check grammatical compatibility with words before and after the word being checked.
- II. If a word has no dependencies immediately before or after it, drop the word.
- III. After each word has been checked, check for the words that form a grammatical phrase.
- IV. Write out the summary without the dropped words and without phrases with only two words.
- V. If needed, go back to step III, because there shouldn’t be any more single words with no dependencies to check, and repeat as many times as necessary.

which are closely related, or in other words, lay close to each other in the phrase should be left in the order they appear. Conceptually, our approach works as follows: look at every word and see if it makes sense with the word before and after it. This builds dependencies between the word in question with the words around it. If a word before or after the word being analyzed does not make sense grammatically, it can be removed from that grammatically correct phrase. Dependent words that are not close to each other may not be as important as words that lay close to each other and have more dependencies, and thus may be thrown out of the summaries. Through this process grammatically correct phrases can be formed.

The dependencies are built by tagging each word as a part of speech and seeing if it relates to other words. For example, it checks whether or not the conjunction “and” is serving its purpose of combining a set of words or ideas, in other words, if those dependencies exist. If dependencies exist with the nearby words, that given collection of words can be set aside as a grammatically correct phrase until it reaches words with no dependencies, and the process

Figure 1: Dependency Parse for *today is day¹ for vote obama this election day²*

can continue. The phrases with few words can be dropped, as well as single words. These new phrases can be checked for grammatical accuracy in the same way as the previous phrases, and if they pass, can remain combined forming a longer summary that should be grammatically correct. The main steps are given in Algorithm 1.

Now, take the example summary produced by the PR Algorithm for the election Twitter posts. Looking at this summary, we, as humans, may make changes and make the summary grammatically correct. Two potential ideal summaries would be the following.

today is the day to vote for obama
vote for obama this election day

The actual process used in the making of the grammatical summaries is as follows. Two main lists are created from lists of governor and dependent words, one with the governor words and another with the dependent words. The governor words are checked to see how many dependent words are linked to them. The governing words with the highest number of dependent words are kept for later. For example using the above phrase about the elections, the word “day” was the governing word with the highest amount of dependent words and was thus kept for the final summary. The superscripts on the word “day” differentiate its two occurrences. The dependent words are kept in groups of closely linked dependent words. Using the same example about the election, an intermediate list of closely related dependent words is “today,” “is,” “for,” “vote,” “obama,” “this,” “election,” and “day.” And the final list of closely related dependent words is “for,” “vote,” “obama,” “this,” “election” and “day.” After these two lists are in the final stages the lists are merged placing the words in proper order.

5 Experiments and Results

To begin, the Twitter posts were collected manually and stored in text files. The topics we chose to

Table 2: ROUGE-L without Stopwords, Before

Task	Recall	Precision	F-score
Task 1	0.667	0.343	0.453
Task 2	1.000	0.227	0.370
Task 3	0.353	0.240	0.286
Task 4	0.800	0.154	0.258
Task 5	1.000	0.185	0.313

Task 10	0.455	0.100	0.164
Average	0.696	0.195	0.289

focus on important current events and some pop culture. Approximately 100 posts were collected on ten different topics. These topics are “The Avengers,” “Avril Lavigne,” “Christmas,” “the election,” “Election Day,” “Iron Man 3,” “president 2012,” “Hurricane Sandy,” “Thanksgiving,” and “vote.”

The collections of posts were passed on to three volunteers to produce short accurate summaries that capture the main idea from the posts. The collections of posts were also first run through the PR Algorithm and then through the process described in this paper to try and refine the summaries output by the PR Algorithm. The Stanford CoreNLP parser³ was used to build the lists of governor and dependent words.

We use ROUGE evaluation metrics (Lin 2004) just like (Sharifi et al., 2010a; Sharifi et al., 2010b; Sharifi et al., 2010c), who evaluated summaries obtained with the PR Algorithm. Specifically, we use ROUGE-L, which uses the longest common subsequence (LCS) to compare summaries. As the LCS of the two summaries in comparison increases in length, so does the similarity of the two summaries.

We now discuss results using ROUGE-L on the summaries we produce. Tables 2 through 5 show the results of four different ROUGE-L evaluations, comparing them to the results found using the PR

Algorithm, and Table 6 shows the comparisons of the averaged scores to the scores (Sharifi et al., 2010a) obtained using the PR Algorithm. Table 2 shows the regular ROUGE-L scores, meaning the recall, precision and F-scores for each task and the average overall scores, for the collection of posts before using the dependency parser to refine the summaries. Table 3 displays the results after using the dependency parser on the summaries formed by the PR Algorithm. One of the options in ROUGE is to show the “best” result, for each task. Table 4 has this result for the PR Algorithm results. Table 5 shows the results of the “best” scores, after running it through the dependency parser. Table 6 shows the averages from Tables 3 and 5, using the dependency parser, compared to Sharifi et al.’s results using the PR Algorithm. Stopwords were not removed in our experiments.

Table 4: ROUGE-L Best without Stopwords, Before

	Recall	Precision	F-score
Task 1	1.000	0.429	0.600
Task 2	1.000	0.227	0.370
Task 3	0.500	0.200	0.286
Task 4	1.000	0.154	0.267
Task 5	1.000	0.167	0.286
Task 6	1.000	0.200	0.333
Task 7	1.000	0.125	0.222
Task 8	1.000	0.071	0.133
Task 9	1.000	0.400	0.571
Task 10	1.000	0.100	0.182
Average	0.950	0.207	0.325

As one can see, the use of our algorithm on the summaries produced by the PR Algorithm improves the F-score values, at least in the example cases we tried. In almost every case, there is substantial rise in the F-score. As previously mentioned, some col-

Table 6: ROUGE-L Averages after applying our algorithm vs. Sharifi et al.

	Recall	Precision	F-score
Sharifi (PRA)	0.31	0.34	0.33
Rouge-L after reconstruction	0.46	0.36	0.40
Rouge-L best after reconstruction	0.72	0.43	0.52

lections of Tweets do not produce good summaries. Task 3 had some poor scores in all cases, so one can deduce that the posts on that topic (Christmas) were widely spread, or they did not have a central theme.

6 Conclusion

The PR Algorithm is not a pure extractive algorithm. It creates summaries of Twitter posts by piecing together the most commonly occurring words and phrases in the entire set of tweets, but keeping the order of constituents as close to the order in which they occur in the posts, collectively speaking. As we noted in this paper, the heuristic method using which the PR Algorithm composes a summary sentence out of the phrases sometimes leads to ungrammatical sentences or wordy sentences. This paper shows that the “raw” summaries produced by the PR Algorithm can be improved by taking into account governor-dependency relationships among the constituents. There is nothing in this clean-up algorithm that says that it works only with summaries of tweets. The same approach can potentially be used to improve grammaticality of sentences written by humans in a sloppy manner. In addition, given several sentences with overlapping content (from multiple sources), the same process can potentially be used to construct a grammatical sentence out of all the input sentences. This problem often arises in general multi-document summarization. We believe

that a corrective approach like ours can be used together with a sentence compression approach, such as (Knight and Marcu 2002), to produce even better summaries in conjunction with the PR or other summarization algorithms that work with socially-generated texts which are often malformed and short.

We have shown in this paper that simply focusing on grammatical dependency tends to make the final summaries more grammatical and readable compared to the raw summaries. However, we believe that more complex restructuring of the words and constituents would be necessary to improve the quality of the raw summaries, in general.

Abstract

This paper presents a general, statistical framework for modeling phrase translation via Markov random fields. The model allows for arbitrary features extracted from a phrase pair to be incorporated as evidence. The parameters of the model are estimated using a large-scale discriminative training approach that is based on stochastic gradient ascent and an N-best list based expected BLEU as the objective function. The model is easy to be incorporated into a standard phrase-based statistical machine translation system, requiring no code change in the runtime engine. Evaluation is performed on two Europarl translation tasks, German-English and French-English. Results show that incorporating the Markov random field model significantly improves the performance of a state-of-the-art phrase-based machine translation system, leading to a gain of 0.8-1.3 BLEU points.

1 Introduction

The phrase translation model, also known as the *phrase table*, is one of the core components of a phrase-based statistical machine translation (SMT) system. The most common method of constructing the phrase table takes a two-phase approach. First, the bilingual phrase pairs are extracted heuristically from an automatically word-aligned training data. The second phase is parameter estimation, where each phrase pair is assigned with some scores that are estimated based on counting of words or phrases on the same word-aligned training data.

There has been a lot of research on improving the quality of the phrase table using more principled methods for phrase extraction (e.g., Lamber and Bansch 2005), parameter estimation (e.g., Wuebker et al. 2010; He and Deng 2012), or both (e.g., Marcu and Wong 2002; Denero et al. 2006). The focus of this paper is on the parameter estimation phase. We revisit the problem of scoring a phrase translation pair by developing a new phrase translation model based on Markov random fields (MRFs) and large-scale discriminative training. We strive to address the following three primary concerns.

First of all, instead of parameterizing a phrase translation pair using a set of scoring functions that are learned independently (e.g., phrase translation probabilities and lexical weights) we use a general, statistical framework in which arbitrary features extracted from a phrase pair can be incorporated to model the translation in a unified way. To this end, we propose the use of a MRF model.

Second, because the phrase model has to work with other component models in an SMT system in order to produce good translations and the quality of translation is measured via BLEU score, it is desirable to optimize the parameters of the phrase model jointly with other component models with respect to an objective function that is closely related to the evaluation metric under consideration, i.e., BLEU in this paper. To this end, we resort to a large-scale discriminative training approach, following the pioneering work of Liang et al. (2006). Although there are established methods of tuning a handful of features on small training sets, such as the MERT method (Och 2003), the development of discriminative training methods for millions of features on millions of sentence pairs is still an ongoing area of research. A recent survey is due to Koehn (2010). In this paper we show that by using stochastic gradient ascent and an N-best list based

expected BLEU as the objective function, large-scale discriminative training can lead to significant improvements.

The third primary concern is the ease of adoption of the proposed method. To this end, we use a simple and well-established learning method, ensuring that the results can be easily reproduced. We also develop the features for the MRF model in such a way that the resulting model is of the same format as that of a traditional phrase table. Thus, the model can be easily incorporated into a standard phrase-based SMT system, requiring no code change in the runtime engine.

In the rest of the paper, Section 2 presents the MRF model for phrase translation. Section 3 describes the way the model parameters are estimated. Section 4 presents the experimental results on two Europarl translation tasks. Section 5 reviews previous work that lays the foundation of this study. Section 6 concludes the paper.

2 Model

The traditional translation models are directional models that are based on conditional probabilities. As suggested by the noisy-channel model for SMT (Brown et al. 1993):

$$E^* = \underset{E}{\operatorname{argmax}} P(E|F) = \underset{E}{\operatorname{argmax}} P(E)P(F|E) \quad (1)$$

The Bayes rule leads us to invert the conditioning of translation probability from a foreign (source) sentence F to an English (target) translation E .

However, in practice, the implementation of state-of-the-art phrase-based SMT systems uses a weighted log-linear combination of several models $h(F, E, A)$ including the logarithm of the phrase probability (and the lexical weight) in source-to-target and target-to-source directions (Och and Ney 2004)

$$\begin{aligned} E^* &= \underset{E}{\operatorname{argmax}} \sum_{m=1}^M \lambda_m h_m(F, E, A) \quad (2) \\ &= \underset{E}{\operatorname{argmax}} Score_\lambda(F, E) \end{aligned}$$

where A in $h(F, E, A)$ is a hidden structure that best derives E from F , called the *Viterbi derivation* afterwards. In phrase-based SMT, A consists of (1) the segmentation of the source sentence into phrases, (2) the segmentation of the target sentence

into phrases, and (3) an alignment between the source and target phrases.

In this paper we use Markov random fields (MRFs) to model the joint distribution $P_w(\mathbf{f}, \mathbf{e})$ over a source-target translation phrase pair (\mathbf{f}, \mathbf{e}) , parameterized by \mathbf{w} . Different from the directional translation models, as in Equation (1), the MRF model is undirected, which we believe upholds the spirit of the use of bi-directional translation probabilities under the log-linear framework. That is, the agreement or the *compatibility* of a phrase pair is more effective to score translation quality than a directional translation probability which is modeled based on an imagined generative story does.

2.1 MRF

MRFs, also known as undirected graphical models, are widely used in modeling joint distributions of spatial or contextual dependencies of physical phenomena (Bishop 2006). A Markov random field is constructed from a graph G . The nodes of the graph represent random variables, and edges define the independence semantics between the random variables. An MRF satisfies the Markov property, which states that a node is independent of all of its non-neighbors, defined by the clique configurations of G . In modeling a phrase translation pair, we define two types of nodes, (1) two phrase nodes and (2) a set of word nodes, each for a word in these phrases, such as the graph in Figure 1. Let us denote a clique by c and the set of variables in that clique by $(\mathbf{f}, \mathbf{e})_c$. Then, the joint distribution over the random variables in G is defined as

$$P_w(\mathbf{f}, \mathbf{e}) = \frac{1}{Z} \prod_{c \in C(G)} \varphi_c((\mathbf{f}, \mathbf{e})_c; \mathbf{w}), \quad (3)$$

where $\mathbf{e} = e_1, \dots, e_{|\mathbf{e}|}$, $\mathbf{f} = f_1, \dots, f_{|\mathbf{f}|}$ and $C(G)$ is the set of cliques in G , and each $\varphi_c((\mathbf{f}, \mathbf{e})_c; \mathbf{w})$ is a non-negative potential function defined over a clique c that measures the *compatibility* of the variables in c , \mathbf{w} is a set of parameters that are used within the potential function. Z in Equation (3), sometimes called the *partition function*, is a normalization constant and is given by

$$\begin{aligned} Z &= \sum_{\mathbf{f}} \sum_{\mathbf{e}} \prod_{c \in C(G)} \varphi_c((\mathbf{f}, \mathbf{e})_c; \mathbf{w}) \quad (4) \\ &= \sum_{\mathbf{f}} \sum_{\mathbf{e}} Score(\mathbf{f}, \mathbf{e}), \end{aligned}$$

which ensures that the distribution $P_w(\mathbf{f}, \mathbf{e})$ given by Equation (3) is correctly normalized. The pres-

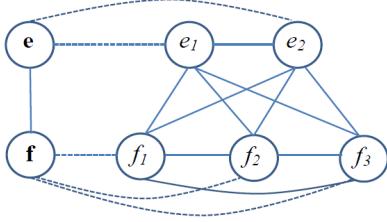

Figure 1: A Markov random field model for phrase translation of $\mathbf{e} = e_1, e_2$ and $\mathbf{f} = f_1, f_2, f_3$.

ence of Z is one of the major limitations of MRFs because it is generally not feasible to compute due to the exponential number of terms in the summation. However, we notice that Z is a global constant which is independent of \mathbf{e} and \mathbf{f} . Therefore, in ranking phrase translation hypotheses, as performed by the decoder in SMT systems, we can drop Z and simply rank each hypothesis by its unnormalized joint probability. In our implementation, we only store in the phrase table for each translation pair (\mathbf{f}, \mathbf{e}) its unnormalized probability, i.e., $Score(\mathbf{f}, \mathbf{e})$ as defined in Equation (4).

It is common to define MRF potential functions of the exponential form as $\varphi_c((\mathbf{f}, \mathbf{e})_c; \mathbf{w}) = \exp(w_c \phi(c))$, where $\phi(c)$ is a real-valued feature function over clique c and w_c is the weight of the feature function. In phrase-based SMT systems, the sentence-level translation probability from F to E is decomposed as the product of a set of phrase translation probabilities. By dropping the phrase segmentation and distortion model components, we have

$$P(E|F) \approx \max_A P(E|A, F) \quad (5)$$

$$P(E|A, F) = \prod_{(\mathbf{f}, \mathbf{e}) \in A} P(\mathbf{e}|\mathbf{f}),$$

where A is the Viterbi derivation. Similarly, the joint probability $P(F, E)$ can be decomposed as

$$P(F, E) \approx \max_A P(F, A, E) \quad (6)$$

$$\begin{aligned} P(F, A, E) &= \prod_{(\mathbf{f}, \mathbf{e}) \in A} P_w(\mathbf{f}, \mathbf{e}) \\ &\propto \sum_{(\mathbf{f}, \mathbf{e}) \in A} \log P_w(\mathbf{f}, \mathbf{e}) \\ &\propto \sum_{(\mathbf{f}, \mathbf{e}) \in A} \sum_{c \in C(G_{(\mathbf{f}, \mathbf{e})})} w_c \phi(c) \\ &= \sum_{(\mathbf{f}, \mathbf{e}) \in A} \mathbf{w} \cdot \Phi(\mathbf{f}, \mathbf{e}) \end{aligned}$$

which is essentially proportional to a weighted linear combination of a set of features.

To instantiate an MRF model, one needs to define a graph structure representing the translation dependencies between source and target phrases, and a set of potential functions over the cliques of this graph.

2.2 Cliques and Potential Functions

The MRF model studied in this paper is constructed from the graph G in Figure 1. It contains two types of nodes, including two phrase nodes for the source and target phrases respectively and word nodes, each for a word in these phrases. The cliques and their corresponding potential functions (or features) attempt to abstract the idea behind those translation models that have been proved effective for machine translation in previous work. In this study we focus on three types of cliques.

First, we consider cliques that contain two phrase nodes. A potential function over such a clique captures phrase-to-phrase translation dependencies similar to the use the bi-directional translation models in phrase-based SMT systems. The potential is defined as $\varphi_p(\mathbf{f}, \mathbf{e}) = w_p \phi_p(\mathbf{f}, \mathbf{e})$, where the feature $\phi_p(\mathbf{f}, \mathbf{e})$, called the *phrase-pair feature*, is an indicator function whose value is 1 if \mathbf{e} is target phrase and \mathbf{f} is source phrase, and 0 otherwise. While the conditional probabilities in a directional translation model are estimated using relative frequencies of phrase pairs extracted from word-aligned parallel sentences, the parameter of the phrase-pair function w_p is learned discriminatively, as we will describe in Section 3.

Second, we consider cliques that contain two word nodes, one in source phrase and the other in target phrase. A potential over such a clique captures word-to-word translation dependencies similar to the use the IBM Model 1 for lexical weighting in phrase-based SMT systems (Koehn et al. 2003). The potential function is defined as $\varphi_t(f, e) = w_t \phi_t(f, e)$, where the feature $\phi_t(f, e)$, called the *word-pair feature*, is an indicator function whose value is 1 if e is a word in target phrase \mathbf{e} and f is a word in source phrase \mathbf{f} , and 0 otherwise.

The third type of cliques contains three word nodes. Two of them are in one language and the third in the other language. A potential over such a clique is intended to capture inter-word dependen-

cies for selecting word translations. The potential function is inspired by the triplet lexicon model (Hasan et al. 2008) which is based on lexicalized triplets (e, f, f') . It can be understood as two source (or target) words triggering one target (or source) word. The potential function is defined as $\varphi_{tp}(f, f', e) = w_{tp}\phi_{tp}(f, f', e)$, where the feature $\phi_{tp}(f, f', e)$, called the *triplet feature*, is an indicator function whose value is 1 if e is a word in target phrase \mathbf{e} and f and f' are two different words in source phrase \mathbf{f} , and 0 otherwise.

For any clique c that contains nodes in only one language we assume that $\varphi(c) = 1$ for all setting of the clique, which has no impact on scoring a phrase pair. One may wish to define a potential over cliques containing a phrase node and word nodes in target language, which could act as a form of target language model. One may also add edges in the graph so as to define potentials that capture more sophisticated translation dependencies. The optimal potential set could vary among different language pairs and depend to a large degree upon the amount and quality of training data. We leave a comprehensive study of features to future work.

3 Training

This section describes the way the parameters of the MRF model are estimated. Although MRFs are by nature generative models, it is not always appropriate to train the parameters using conventional likelihood based approaches mainly for two reasons. The first is due to the difficulty in computing the partition function in Equation (4), especially in a task of our scale. The second is due to the metric divergence problem (Morgan et al. 2004). That is, the maximum likelihood estimation is unlikely to be optimal for the evaluation metric under consideration, as demonstrated on a variety of tasks including machine translation (Och 2003) and information retrieval (Metzler and Croft 2005; Gao et al. 2005). Therefore, we propose a large-scale discriminative training approach that uses stochastic gradient ascent and an N-best list based expected BLEU as the objective function.

We cast machine translation as a structured classification task (Liang et al. 2006). It maps an input source sentence F to an output pair (E, A) where E is the output target sentence and A the Viterbi derivation of E . A is assumed to be constructed during the translation process. In phrase-

based SMT, A consists of a segmentation of the source and target sentences into phrases and an alignment between source and target phrases.

We also assume that translations are modeled using a linear model parameterized by a vector $\boldsymbol{\theta}$. Given a vector $\mathbf{h}(F, E, A)$ of feature functions on (F, E, A) , and assuming $\boldsymbol{\theta}$ contains a component for each feature, the output pair (E, A) for a given input F are selected using the argmax decision rule

$$(E^*, A^*) = \underset{(E, A)}{\operatorname{argmax}} \boldsymbol{\theta}^T \mathbf{h}(F, E, A) \quad (7)$$

In phrase-based SMT, computing the argmax exactly is intractable, so it is performed approximately by beam decoding.

In a phrase-based SMT system equipped by a MRF-based phrase translation model, the parameters we need to learn are $\boldsymbol{\theta} = (\boldsymbol{\lambda}, \mathbf{w})$, where $\boldsymbol{\lambda}$ is a vector of a handful parameters used in the log-linear model of Equation (2), with one weight for each component model; and \mathbf{w} is a vector containing millions of weights, each for one feature function in the MRF model of Equation (3). Our method takes three steps to learn $\boldsymbol{\theta}$:

1. Given a baseline phrase-based SMT system and a pre-set $\boldsymbol{\lambda}$, we generate for each source sentence in training data an N-best list of translation hypotheses.
2. We fix $\boldsymbol{\lambda}$, and optimize \mathbf{w} with respect to an objective function on training data.
3. We fix \mathbf{w} , and optimize $\boldsymbol{\lambda}$ using MERT (Och 2003) to maximize the BLEU score on development data.

Now, we describe Steps 1 and 2 in detail.

3.1 N-Best Generation

Given a set of source-target sentence pairs as training data $(F_n, E_n^r), n = 1 \dots N$, we use the baseline phrase-based SMT system to generate for each source sentence F a list of 100-best candidate translations, each translation E coupled with its Viterbi derivation A , according to Equation (7). We denote the 100-best set by $\text{GEN}(F)$. Then, each output pair (E, A) is labeled by a sentence-level BLEU score, denoted by $s\text{BLEU}$, which is computed according to Equation (8) (He and Deng 2012),

$$s\text{BLEU}(E, E^r) = BP \times \frac{1}{4} \sum_{n=1}^4 \log p_n, \quad (8)$$

where E^r is the reference translation, and $p_n, n = 1 \dots 4$, are precisions of n -grams. While precisions of lower order n -grams, i.e., p_1 and p_2 , are computed directly without any smoothing, matching counts for higher order n -grams could be sparse at the sentence level and need to be smoothed as

$$p_n = \frac{\#(\text{matched ngram}) + \alpha p_n^0}{\#(\text{ngram}) + \alpha}, \text{ for } n = 3, 4$$

where α is a smoothing parameter and is set to 5, and p_n^0 is the prior value of p_n , whose value is computed as $p_n^0 = (p_{n-1})^2 / p_{n-2}$ for $n = 3$ and 4. BP in Equation (8) is the sentence-level *brevity penalty*, computed as $BP = \exp(1 - \beta \frac{r}{c})$, which differs from its corpus-level counterpart (Papineni et al. 2002) in two ways. First, we use a non-clipped BP , which leads to a better approximation to the corpus-level BLEU computation because the per-sentence BP might effectively exceed unity in corpus-level BLEU computation, as discussed in Chiang et al. (2008). Second, the ratio between the length of reference sentence r and the length of translation hypothesis c is scaled by a factor β such that the total length of the references on training data equals that of the 1-best translation hypotheses produced by the baseline SMT system. In our experiments, the value of β is computed, on the N-best training data, as the ratio between the total length of the references and that of the 1-best translation hypotheses.

In our experiments we find that using sBLEU defined above leads to a small but consistent improvement over other variations of sentence-level BLEU proposed previously (e.g., Liang et al. 2006). In particular, the use of the scaling factor β in computing BP makes BP of the baseline's 1-best output close to perfect on training data, and has an effect of forcing the discriminative training to improve BLEU by improving n -gram precisions rather than by improving brevity penalty.

3.2 Parameter Estimation

We use an N-best list based expected BLEU, a variant of that in Rosti et al. (2011), as the objective function for parameter optimization. Given the current model Θ , the expected BLEU, denoted by $x\text{BLEU}(\Theta)$, over one training sample i.e., a labeled N-best list $\text{GEN}(F)$ generated from a pair of source and target sentences (F, E^r) , is defined as

-
- 1 Initialize \mathbf{w} , assuming λ is fixed during training
 - 2 For $t = 1 \dots T$ (T = the total number of iterations)
 - 3 For each training sample (labeled 100-best list)
 - 4 Compute $P_\Theta(E|F)$ for each translation hypothesis E based on the current model $\Theta = (\lambda, \mathbf{w})$
 - 5 Update the model via $\mathbf{w} = \mathbf{w} + \eta \cdot \mathbf{g}(\mathbf{w})$, where η is the learning rate and \mathbf{g} the gradient computed according to Equations (12) and (13)
-

Figure 2: The algorithm of training a MRF-based phrase translation model.

$$\begin{aligned} & x\text{BLEU}(\Theta) \\ &= \sum_{E \in \text{GEN}(F)} P_\Theta(E|F) \text{sBLEU}(E, E^r), \end{aligned} \quad (9)$$

where sBLEU is the sentence-level BLEU, defined in Equation (8), and $P_\Theta(E|F)$ is a normalized translation probability from F to E computed using softmax as

$$P_\Theta(E|F) = \frac{\exp(\text{Score}_\Theta(F, E))}{\sum_{E'} \exp(\text{Score}_\Theta(F, E'))}, \quad (10)$$

where $\text{Score}(\cdot)$ is the translation score according to the current model Θ

$$\begin{aligned} \text{Score}_\Theta(F, E) &= \lambda \cdot \mathbf{h}(F, E, A) \\ &+ \sum_{(\mathbf{f}, \mathbf{e}) \in A} \mathbf{w} \cdot \Phi(\mathbf{f}, \mathbf{e}). \end{aligned} \quad (11)$$

The right hand side of (11) contains two terms. The first term is the score produced by the baseline system, which is fixed during phrase model training. The second term is the translation score produced by the MRF model, which is updated after each training sample during training. Comparing Equations (2) and (11), we can view the MRF model yet another component model under the log linear model framework with its λ being set to 1.

Given the objective function, the parameters of the MRF model are optimized using stochastic gradient ascent. As shown in Figure 2, we go through the training set T times, each time is considered an *epoch*. For each training sample, we update the model parameters as

$$\mathbf{w}^{new} = \mathbf{w}^{old} + \eta \cdot \mathbf{g}(\mathbf{w}^{old}) \quad (12)$$

where η is the learning rate, and the gradient \mathbf{g} is computed as

$$\mathbf{g}(\mathbf{w}) = \frac{\partial x\text{BLEU}(\mathbf{w})}{\partial \mathbf{w}} \quad (13)$$

$$= \sum_{(E,A)} U(\Theta, E) P_\Theta(E|F) \phi(F, E, A),$$

where $U(\Theta, E) = \text{sBLEU}(E, E^r) - \text{xBLEU}(\Theta)$.

Two considerations regarding the development of the training method in Figure 2 are worth mentioning. They significantly simplify the training procedure without sacrificing much the quality of the trained model. First, we do not include a regularization term in the objective function because we find early stopping and cross valuation more effective and simpler to implement. In experiments we produce a MRF model after each epoch, and test its quality on a development set by first combining the MRF model with other baseline component models via MERT and then examining BLEU score on the development set. We performed training for T epochs ($T = 100$ in our experiments) and then pick the model with the best BLEU score on the development set. Second, we do not use the leave-one-out method to generate the N-best lists (Wuebker et al. 2010). Instead, the models used in the baseline SMT system are trained on the same parallel data on which the N-best lists are generated. One may argue that this could lead to overfitting. For example, comparing to the translations on unseen test data, the generated translation hypotheses on the training set are of artificially high quality with the derivations containing artificially long phrase pairs. The discrepancy between the translations on training and test sets could hurt the training performance. However, we found in our experiments that the impact of over-fitting on the quality of the trained MRF models is negligible¹.

4 Experiments

We conducted our experiments on two Europarl translation tasks, German-to-English (DE-EN) and French-to-English (FR-EN). The data sets are published for the shared task in NAACL 2006 Workshop on Statistical Machine Translation (WMT06) (Koehn and Monz 2006).

For DE-EN, the training set contains 751K sentence pairs, with 21 words per sentence on average. The official development set used for the shared

¹ As pointed out by one of the reviewers, the fact that our training works fine without leave-one-out is probably due to the small phrase length limit (i.e., 4) we used. If a longer phrase limit (e.g., 7) is used the result might be different. We leave it to future work.

Systems	DE-EN (TEST2)	FR-EN (TEST2)
Rank-1 system	27.3	30.8
Rank-2 system	26.0	30.7
Rank-3 system	25.6	30.5
Our baseline	26.0	31.4

Table 1: Baseline results in BLEU. The results of top ranked systems are reported in Koehn and Monz (2006)².

task contains 2000 sentences. In our experiments, we used the first 1000 sentences as a development set for MERT training and optimizing parameters for discriminative training, such as learning rate and the number of iterations. We used the rest 1000 sentences as the first test set (TEST1). We used the WMT06 test data as the second test set (TEST2), which contains 2000 sentences.

For FR-EN, the training set contains 688K sentence pairs, with 21 words per sentence on average. The development set contains 2000 sentences. We used 2000 sentences from the WMT05 shared task as TEST1, and the 2000 sentences from the WMT06 shared task as TEST2.

Two baseline phrase-based SMT systems, each for one language pair, are developed as follows. These baseline systems are used in our experiments both for comparison purpose and for generating N-best lists for discriminative training. First, we performed word alignment on the training set using a hidden Markov model with lexicalized distortion (He 2007), then extracted the phrase table from the word aligned bilingual texts (Koehn et al. 2003). The maximum phrase length is set to four. Other models used in a baseline system include a lexicalized reordering model, word count and phrase count, and a trigram language model trained on the English training data provided by the WMT06 shared task. A fast beam-search phrase-based decoder (Moore and Quirk 2007) is used and the distortion limit is set to four. The decoder is modified so as to output the Viterbi derivation for each translation hypothesis.

The metric used for evaluation is case insensitive BLEU score (Papineni et al. 2002). We also performed a significance test using the paired t -test. Differences are considered statistically significant when the p -value is less than 0.05. Table 1

² The official results are accessible at <http://www.statmt.org/wmt06/shared-task/results.html>

#	Systems	DE-EN		FR-EN	
		TEST1	TEST2	TEST1	TEST2
1	Baseline	26.0	26.0	31.3	31.4
2	MRF_{p+t+tp}	27.3^a	27.1^a	32.4^a	32.2^a
3	MRF_{p+t}	27.2 ^a	26.9 ^a	32.3 ^a	32.0 ^a
4	MRF_p	26.8 ^{a^b}	26.7 ^{a^b}	32.2 ^a	31.8 ^{a^b}
5	MRF_t	26.8 ^{a^b}	26.8 ^a	32.1 ^a	31.9 ^{a^b}

Table 2: Main results (BLEU scores) of MRF-based phrase translation models with different feature classes. The superscripts α and β indicate statistically significant difference ($p < 0.05$) from **Baseline** and **MRF_{p+t+tp}**, respectively.

Feature classes	# of features (weights)	
	DE-EN	FR-EN
phrase-pair features (p)	2.5M	2.3M
word-pair features (t)	12.2M	9.7M
triplet features (tp)	13.4M	13.8M

Table 3: Statistics of the features used in building MRF-based phrase translation models.

presents the baseline results. The performance of our phrase-based SMT systems compares favorably to the top-ranked systems, thus providing a fair baseline for our research.

4.1 Results

Table 2 shows the main results measured in BLEU evaluated on TEST1 and TEST2.

Row 1 is the baseline system. Rows 2 to 5 are the systems enhanced by integrating different versions of the MRF-based phrase translation model. These versions, labeled as **MRF_f**, are trained using the method described in Section 3, and differ in the feature classes (which are specified by the subscript f) incorporated in the MRF-based model. In this study we focused on three classes of features, as described in Section 2, phrase-pair features (p), word-pair features (t) and triplet features (tp). The statistics for these features are given in Table 3.

Table 2 shows that all the MRF models lead to a substantial improvement over the baseline system across all test sets, with a statistically significant margin from 0.8 to 1.3 BLEU points. As expected, the best phrase model incorporates all of the three classes of features (**MRF_{p+t+tp}** in Row 2). We also find that both **MRF_p** and **MRF_t**, although using only one class of features, perform quite well. In TEST2 of DE-EN and TEST1 of FR-EN, they are in a near statistical tie with **MRF_{p+t}** and **MRF_{p+t+tp}**.

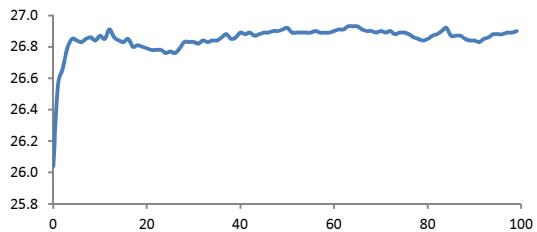

Figure 3: BLEU score on development data (y axis) for DE-EN (top) and FR-EN (bottom) as a function of the number of epochs (x axis).

The result suggests that while the MRF models are very effective in modeling phrase translations, the features we used in this study may not fully realize the potential of the modeling technology.

We also measured the sensitivity of the discriminative training method to different initializations and training parameters. Results show that our method is very robust. All the MRF models in Table 2 are trained by setting the initial feature vector to zero, and the learning rate $\eta=0.01$. Figure 3 plots the BLEU score on development sets as a function of the number of epochs t . The BLEU score improves quickly in the first 5 epochs, and then either remains flat, as on the DE-EN data, or keeps increasing but in a much slower pace, as on the FR-EN data.

4.2 Comparing Objective Functions

This section compares different objective functions for discriminative training. As shown in Table 4, xBLEU is compared to three widely used convex loss functions, i.e., hinge loss, logistic loss, and log loss. The hinge loss and logistic loss take into account only two hypotheses among an N-best list GEN: the one with the best sentence-level BLEU score with respect to its reference translation, denoted by (E^*, A^*) , called the *oracle* candidate henceforth, and the highest scored *incorrect* candidate according to the current model, denoted by (E', A') , defined as

#	Objective functions	DE-EN		FR-EN	
		TEST 1	TEST2	TEST1	TEST2
1	xBLEU	27.2	26.9	32.3	32.0
2	hinge loss	26.4 ^a	26.2 ^a	31.8 ^a	31.5 ^a
3	logistic loss	26.3 ^a	26.2 ^a	31.7 ^a	31.5 ^a
4	log loss	26.5 ^a	26.2 ^a	32.1	31.7 ^a

Table 4: BLEU scores of MRF-based phrase translation models trained using different objective functions. The MRF models use phrase-pair and word-pair features. The superscript α indicates statistically significant difference ($p < 0.05$) from xBLEU.

$$(E', A') = \operatorname{argmax}_{(E, A) \in \text{GEN}(F) \setminus \{(E^*, A^*)\}} \text{Score}_\theta(F, E, A),$$

where $\text{Score}_\theta(\cdot)$ is defined in Equation (11). Let $\mathbf{x} = \mathbf{h}(F, E^*, A^*) - \mathbf{h}(F, E', A')$. The hinge loss under the N-best re-ranking framework is defined as $\max(0, 1 - \boldsymbol{\theta}^T \mathbf{x})$. It is easy to verify that to train a model using this version of hinge loss, the update rule of Equation (12) can be rewritten as

$$\mathbf{w}^{new} = \begin{cases} \mathbf{w}^{old}, & \text{if } \hat{E} = E^* \\ \mathbf{w}^{old} + \eta \mathbf{x}, & \text{otherwise} \end{cases} \quad (14)$$

where \hat{E} is the highest scored candidate in GEN. Following Shalev-Shwartz (2012), by setting $\eta = 1$, we reach the Perceptron-based training algorithm that has been widely used in previous studies of discriminative training for SMT (e.g., Liang et al. 2006; Simianer et al. 2012).

The logistic loss $\log(1 + \exp(-\boldsymbol{\theta}^T \mathbf{x}))$ leads to an update rule similar to that of hinge loss

$$\mathbf{w}^{new} = \begin{cases} \mathbf{w}^{old}, & \text{if } \hat{E} = E^* \\ \mathbf{w}^{old} + \eta P_\theta(\mathbf{x}) \mathbf{x}, & \text{otherwise} \end{cases} \quad (15)$$

where $P_\theta(\mathbf{x}) = 1/(1 + \exp(\boldsymbol{\theta}^T \mathbf{x}))$.

The log loss is widely used when a probabilistic interpretation of the trained model is desired, as in conditional random fields (CRFs) (Lafferty et al. 2001). Given a training sample, log loss is defined as $\log P_\theta(E^*|F)$, where E^* is the oracle translation hypothesis with respect to its reference translation. $P_\theta(E^*|F)$ is computed as Equation (10). So, unlike hinge loss and logistic loss, log loss takes into account the distribution over all hypotheses in an N-best list.

The results in Table 4 suggest that the objective functions that take into account the distribution

over all hypotheses in an N-best list (i.e., xBLEU and log loss) are more effective than the ones that do not. xBLEU, although it is a non-concave function, significantly outperforms the others because it is more closely coupled with the evaluation metric under consideration (i.e., BLEU).

5 Related Work

Among the attempts to learning phrase translation probabilities that go beyond pure counting of phrases on word-aligned corpora, Wuebker et al. (2010) and He and Deng (2012) are most related to our work. The former find phrase alignment directly on training data and update the translation probabilities based on this alignment. The latter learn phrase translation probabilities discriminatively, which is similar to our approach. But He and Deng’s method involves multiple stages, and is not straightforward to implement³. Our method differs from previous work in its use of a MRF model that is simple and easy to understand, and a stochastic gradient ascent based training method that is efficient and easy to implement.

A large portion of previous studies on discriminative training for SMT either use a handful of features or use small training sets of a few thousand sentences (e.g., Och 2003; Shen et al. 2004; Watanabe et al. 2007; Duh and Kirchhoff 2008; Chiang et al. 2008; Chiang et al. 2009). Although there is growing interest in large-scale discriminative training (e.g., Liang et al. 2006; Tillmann and Zhang 2006; Blunsom et al. 2008; Hopkins and May 2011; Zhang et al. 2011), only recently does some improvement start to be observed (e.g., Simianer et al. 2012; He and Deng 2012). It still remains uncertain if the improvement is attributed to new features, new training algorithms, objective functions, or simply large amounts of training data. We show empirically the importance of objective functions. Gimpel and Smith (2012) also analyze objective functions, but more from a theoretical viewpoint.

The proposed MRF-based translation model is inspired by previous work of applying MRFs for information retrieval (Metzler and Croft 2005), query expansion (Metzler et al. 2007; Gao et al. 2012) and POS tagging (Haghghi and Klein 2006).

³ For comparison, the method of He and Deng (2012) also achieved very similar results to ours using the same experimental setting, as described in Section 4.

Another undirected graphical model that has been more widely used for NLP is a CRF (Lafferty et al. 2001). An MRF differs from a CRF in that its partition function is no longer observation dependent. As a result, learning an MRF is harder than learning a CRF using maximum likelihood estimation (Haghghi and Klein 2006). Our work provides an alternative learning method that is based on discriminative training.

6 Conclusions

The contributions of this paper are two-fold. First, we present a general, statistical framework for modeling phrase translations via MRFs, where different features can be incorporated in a unified manner. Second, we demonstrate empirically that the parameters of the MRF model can be learned effectively using a large-scale discriminative training approach which is based on stochastic gradient ascent and an N-best list based expected BLEU as the objective function.

In future work we strive to fully realize the potential of the MRF model by developing features that can capture more sophisticated translation dependencies than those used in this study. We will also explore the use of MRF-based translation models for translation systems that go beyond simple phrases, such as hierarchical phrase based systems (Chiang 2005) and syntax-based systems (Galley et al. 2004).

Automatic Morphological Enrichment of a Morphologically Underspecified Treebank

Sarah Alkuhlani, Nizar Habash and Ryan Roth

Center for Computational Learning Systems

Columbia University

{salkuhlani, habash, ryanr}@ccls.columbia.edu

Abstract

In this paper, we study the problem of automatic enrichment of a morphologically underspecified treebank for Arabic, a morphologically rich language. We show that we can map from a tagset of size six to one with 485 tags at an accuracy rate of 94%-95%. We can also identify the unspecified lemmas in the treebank with an accuracy over 97%. Furthermore, we demonstrate that using our automatic annotations improves the performance of a state-of-the-art Arabic morphological tagger. Our approach combines a variety of techniques from corpus-based statistical models to linguistic rules that target specific phenomena. These results suggest that the cost of treebanking can be reduced by designing underspecified treebanks that can be subsequently enriched automatically.

1 Introduction

Collections of manually-annotated morphological and syntactic analyses of sentences, or treebanks, are an important resource for building statistical parsing models or for syntax-aware approaches to applications such as machine translation. Rich treebank annotations have also been used for a variety of natural language processing (NLP) applications such as tokenization, diacritization, part-of-speech (POS) tagging, morphological disambiguation, base phrase chunking, and semantic role labeling.

The development of a treebank with rich annotations is demanding in time and money, especially for morphologically complex languages. Consequently, the richer the annotation, the slower the annotation process and the smaller the size of the treebank. As such, a tradeoff is usually made between the size of the treebank and the richness of its annotations.

In this paper, we investigate the possibility of automatically enriching the morphologically underspecified Columbia Arabic Treebank (CATiB)

(Habash and Roth, 2009; Habash et al., 2009) with the more complex POS tags and lemmas used in the Penn Arabic Treebank (PATB) (Maamouri et al., 2004). We employ a variety of techniques that range from corpus-based statistical models to handwritten rules based on linguistic observations. Our best method reaches accuracy rates of 94%-95% on full POS tag identification. We can also identify the unspecified lemmas in CATiB with an accuracy over 97%. 37% of our POS tag errors are due to gold tree or gold POS errors. A learning curve experiment to evaluate the dependence of our method on annotated data shows that while the quality of some components may reduce sharply with less data (12% absolute reduction in accuracy when using $\frac{1}{32}$ of the data or some 10K annotated words), the overall effect is a lot smaller (2% absolute drop). These results suggest that the cost of treebanking can be reduced by designing underspecified treebanks that can be subsequently enriched automatically.

The rest of this paper is structured as follows: Section 2 presents related work; Section 3 details various language background facts about Arabic and its treebanking; Section 4 explains our approach; and Section 5 presents and discusses our results.

2 Related Work

Arabic Treebanking There has been a lot work on building treebanks for different languages. In the case of Modern Standard Arabic (MSA), there are three efforts that vary in terms of richness and representation choice. The Penn Arabic Treebank (PATB) (Maamouri et al., 2004; Maamouri et al., 2009b; Maamouri et al., 2009a), the Prague Arabic Dependency Treebank (PADT) (Smrž and Hajíč, 2006; Smrž et al., 2008) and the Columbia Arabic Treebank (CATiB) (Habash and Roth, 2009; Habash et al., 2009). The PATB uses phrase structure representation, while the other two use two

different dependency representations. The PATB and PADT representations are quite detailed. The PATB not only provides tokenization, complex POS tags (485 tags in our data set), and syntactic structure; it also provides empty categories, diacritization, lemma choices, glosses and some semantic tags. In comparison CATiB only provides tokenization, six POS tags and eight dependency relations. The tradeoff is speed: CATiB’s complete POS and syntax annotation rate is 540 tokens/hour (and annotator training takes two months), a much higher speed than reported for complete (POS and syntax) annotation in PATB (around 250-300 tokens/hour and 6-12 months for annotator training) and PADT (around 75 tokens/hour) (Habash and Roth, 2009). An important recent addition to the family of Arabic treebanks is the Quran Treebank, which targets the Classical Arabic language of the Quran, not MSA (Dukes and Buckwalter, 2010).

Treebank Enrichment There has been a number of efforts on developing treebanks with rich representations and on treebank enrichment for many languages, such Danish, English, German, Italian and Spanish (Oepen et al., 2002; Hinrichs et al., 2004; Müller, 2010). Additionally, there has been some work on Arabic treebank enrichment that built on the PATB by manually extending its already rich annotations or automatically converting them to new formalisms. The Arabic Propbank (Propositional Bank) (Palmer et al., 2008) and the OntoNotes project (Hovy et al., 2006) both annotate for Arabic semantic information. Alkuhlani and Habash (2011) add annotations marking functional gender and number, and rationality; and Abdul-Mageed and Diab (2012) annotate the sentence level with sentiment labels. Tounsi et al. (2009) automatically converted the PATB to a lexical functional grammar (LFG) representation. Similarly, Habash and Roth (2009) used a similar technique to build an initial version of CATiB. We use this CATiB version of PATB to evaluate our approach in this paper. Also related to this is the work on automatic enrichment of specific features, e.g., Habash et al. (2007a) demonstrated that nominal case, can be determined for gold syntactic analyses at high accuracy. We replicate their results and improve upon them. And unlike them, we handle all the morphological features in the PATB, not just case.

Morphological Disambiguation There has been a lot of work on Arabic POS tagging and morphological disambiguation (Diab et al., 2004; Habash and Rambow, 2005; Smith et al., 2005; Hajic et al., 2005; Roth et al., 2008; Habash et al., 2013). These approaches are intended to apply to raw text and determine the appropriate in-context morphological reading for each word. In contrast, in this paper, we are starting from a partially disambiguated and relatively rich representation: we have tokenization, general POS tags and syntactic dependency information.

Finally, morphological information (beyond tokenization) has been shown to be useful for many NLP applications. Marton et al. (2011) demonstrated that morphology helps Arabic parsing. Using morphological features such as case has also improved parsing for Russian, Turkish and Hindi (Nivre et al., 2008; Eryigit et al., 2008; Nivre, 2009). Other work has shown value for morphology in the context of Arabic named entity recognition (Benaïjiba et al., 2009). These results support the value of our goal of enriching resources with morphological information, which then can be used to improve different NLP applications.

3 Linguistic Background

In this section, we present some relevant general linguistic facts about Arabic and then discuss the specifics of the tagsets we work with in this paper.

Arabic Linguistic Facts The Arabic language poses many challenges for NLP. Arabic is a morphologically complex language which includes rich inflectional and cliticizational morphology, e.g., the word *وسيكتبونها* *w+s+y-ktb-wn+hA¹* ‘and they will write it’ has two proclitics, one prefix, one suffix and one pronominal enclitic. Additionally, Arabic has a high degree of ambiguity due to the absence of the diacritics and inconsistent spelling of letters such as Alif, ؠ and Ya ي. The Buckwalter Arabic Morphological Analyzer (BAMA) (Buckwalter, 2004), which is used in the PATB, produces an average of 12 analyses per word.

In this paper, we work with gold tokenized Arabic as it appears in the PATB and CATiB treebanks.

As such, the words are partially disambiguated with regards to possible tokenizable clitics and Alif/Ya spelling forms. That said, there is still a lot of ambiguity remaining especially because diacritics are not marked. Words in the treebank may be ambiguous in terms of their POS, lemmas and inflectional features. The inflectional features include gender, number, person, case, state, mood, voice, aspect and the presence of the determiner +ال+ *Al*+ ‘the’, which is not tokenized off in the treebanks.

Arabic has a well known discrepancy in form and function that appears most commonly in the form of irregular plurals, called Broken Plurals, which although functionally are plural, have singular suffixes. We will not discuss form and function discrepancy in this paper except as needed. For more on this see Habash (2010).

The Buckwalter Tagset The Buckwalter POS tagset is perhaps one of the most commonly used tagsets for Arabic NLP research. The tagset’s popularity is in part due to its use in the PATB. Buckwalter tags can be used for tokenized and untokenized text. The untokenized tags are produced by BAMA (Buckwalter, 2004) and consist of 485 tags. The tokenized tags, which are used in the PATB, are derived from the untokenized tags and can reach thousands of tags. Both variants use the same basic 70 or so sub-tag symbols (such as DET ‘determiner’, NSUFF ‘nominal suffix’, ADJ ‘adjective’ and ACC ‘accusative’) (Maamouri et al., 2009a). These sub-tags are combined to form around 170 morpheme tags such as NSUFF_FEM_SG ‘feminine singular nominal suffix’ and CASE_DEF_ACC ‘accusative definite’. The word tags are constructed out of one or more morpheme tags, e.g. DET+NOUN_PROP+CASE_DEF_NOM for the word *الصين Al+Siyn+u* ‘China’.

CATiB Trees and POS Tags CATiB uses the same basic tokenization scheme used by PATB and PADT. However, the CATiB POS tagset is much smaller. Whereas in practice PATB uses 485 Buckwalter tags specifying every aspect of Arabic word morphology such as definiteness, gender, number, person, mood, voice and case, CATiB uses 6 POS tags: **NOM** (non-proper nominals including nouns, pronouns, adjectives and adverbs), **PROP** (proper nouns), **VRB** (verbs), **VRB-PASS** (passive-voice verbs), **PRT** (particles such as prepositions or con-

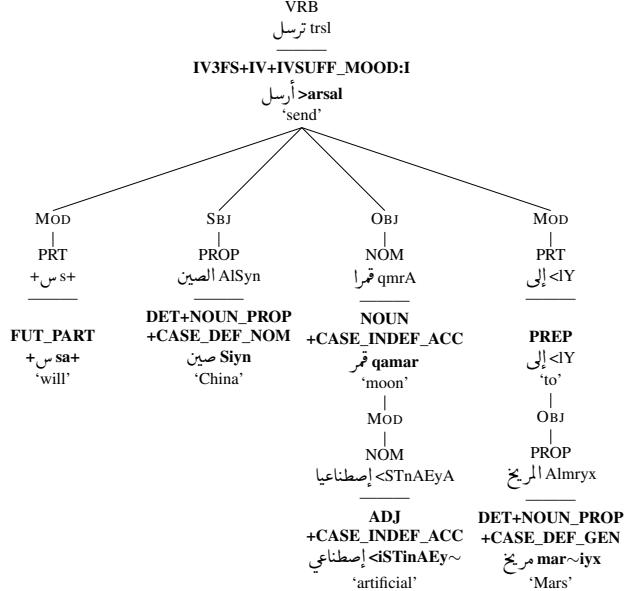

Figure 1: An example dependency tree for the sentence سترسل الصين قمرا إلى المريخ. In every tree node, the terms above the line are part of the CATiB annotations: the word, POS (VRB, PRT, PROP, NOM) and relation (MOD, SBJ, OBJ). The terms under the line are the Buckwalter POS tag, the lemma and the gloss, respectively.

junctions) and **PNX** (punctuation). CATiB uses a dependency representation that models predicate-argument structure (subject, object, etc.) and Arabic nominal structure (idafa, tamyiz, modification). The eight CATiB relation labels are: **SBJ** (subject of verb or topic of simple nominal sentence), **OBJ** (object of verb, preposition, or deverbal noun), **TPC** (topic in complex nominal sentences containing an explicit pronominal referent), **PRD** (predicate marking the complement in some copular constructions), **IDF** (relation between the possessor [dependent] and the possessed [head] in the idafa/possessive nominal construction), **TMZ** (relation of the specifier [dependent] to the specified [head] in the tamyiz/specification nominal constructions), **MOD** (general modifier of verbs or nouns), and — (marking flatness inside constructions such as first-last proper name sequences). This relation label set is much smaller than the twenty or so dash-tags used in PATB to mark syntactic and semantic functions. Furthermore, no empty categories, coreference, or semantic relations (e.g., TMP or LOC) are provided (Habash and Roth, 2009). A detailed dis-

cussion of CATiB guidelines and further comparison with PATB appears in (Habash et al., 2009).

In this paper, we target the enrichment of CATiB with the morphological information used in the PATB: Buckwalter POS tags and lemmas. We do not address other kinds of rich information. Figure 1 presents an example of a CATiB tree with the extensions we predict automatically for each word.

4 Approach

We define our task as assigning a Buckwalter POS tag and lemma to each word in a CATiB syntactic tree, i.e., disambiguating the CATiB POS tag in terms of the finer grained Buckwalter tag in context. Our approach utilizes a variety of corpus-based and rule-based techniques. We use corpus-based techniques that exploit available training data in the form of portions of the PATB that are automatically converted to CATiB style trees. We also use rule-based solutions that allow us to apply linguistic knowledge and insights. An important tool that we use is a morphological analyzer which generates for every word all possible out-of-context analyses. We use these analyses as a constraint on the space from which we will select the appropriate in-context tag. The approach is quite similar to how MADA (Morphological Analysis and Disambiguation for Arabic) (Habash and Rambow, 2005) works except that we are using the CATiB tree as the context in which we disambiguate. Given the degree of richness of the tree, we expect to outperform basic disambiguation on text.

In the rest of this section, we discuss our general strategy, followed by a detailed presentation of our approach: morphological disambiguation and morphological filtering.

4.1 From CATiB to Buckwalter: Devising a Strategy

In CATiB trees, different pieces of information can be relevant to different disambiguation tasks. We analyzed a sample of the data we have and obtained the following observations which we use to devise our strategy for how to address different types of ambiguity:

- Words in the CATiB treebank are tokenized. This resolves many ambiguous cases: analyses involving cliticized prepositions or conjunctions are dismissed. Further more, sepa-

rated clitics are marked, which restricts their reading. The ambiguity in terms of the number of lemmas per word reduces from 2.7 for untokenized words to just 1.1 for tokenized words.

- The CATiB POS tagset, although two orders of magnitude smaller than the Buckwalter tagset, provides a lot of information. It resolves ambiguity amongst verbs (active or passive), nominals, particles, proper nouns and punctuation.
- The CATiB tags NOM and PRT are the most ambiguous. They are challenging because there are both lexical and morphosyntactic features at play. We rely on our training data to learn models of how to disambiguate them. The CATiB treebank annotation does not deterministically allow us to identify the finer grained tag using the POS and relations alone: e.g., the NOM child of an NOM parent (with the relation MOD) can be an ADJ (67% probability) or a NOUN (21%).
- Case, state, mood and to a lesser degree aspect are syntactically dependent features, for which we use the CATiB tree and linguistic rules to disambiguate the correct value in context.
- Gender, number and person are expressed using affixes that highly limit the feature-value possibilities, e.g., the suffix $\ddot{\alpha} + \ddot{h}$ deterministically selects for +NSUFF_FEM_SG suffix tag.

4.2 Morphological Analysis & Disambiguation

We use the morphological analyzer BAMA to get a list of all possible analyses for a word. BAMA returns unranked analyses for untokenized text only. Since we know that the input is already tokenized, we built an extension to BAMA that handles clitics and accepts analyses that are consistent with the tokenization of the input, discarding all other analyses.

We use both the morphological analyzer BAMA and a training set from the PATB to predict the Buckwalter tag for a given word. We use BAMA to get a list of all possible Buckwalter tag and lemma pairs for each word. We then rank these choices using one of the following two methods: a maximum likelihood estimate model (MLE) conditioned on specific features in the CATiB tree or a MADA-like suite of classifiers that select for specific POS tag features such as gender or number.

4.2.1 Maximum Likelihood Model

The MLE model ranks the set of choices from BAMA returning the most probable analysis. We consider two models:

- **MLE Baseline 1** selects the Buckwalter tag with the highest unconditioned probability in the training data, $P(BW)$, among the set of BAMA choices for the word whose tag we want to determine.
- **MLE Baseline 2** selects the Buckwalter tag with the highest probability conditioned on the word and CATiB tag: $P(BW|word, CATiB)$. This model backs off to the Buckwalter tag with the highest probability conditioned on the CATiB tag, i.e., $P(BW|CATiB)$, and then backs off to MLE Baseline 1.

4.2.2 Analysis and Disambiguation of Tokenized Arabic

We retrained the MADA system (Habash and Rambow, 2005) using a tokenized version of the PATB. We call the new version TADA: Tokenized Analysis and Disambiguation of Arabic. TADA takes tokenized text, and returns a ranked list of analyses for each tokenized word and clitic. Just like MADA, TADA uses BAMA to identify possible analyses of the word. It then uses a suite of classifiers to predict inflectional and lexical features that are used to rank the possible analyses.

As expected, TADA outperforms the simple MLE models described earlier; however, its performance is not high enough since it makes no use of tree features. The results are presented in Section 5. However, we will present here a preliminary error analysis of TADA’s output to motivate the morphological filters presented next (Section 4.3).

TADA Preliminary Error Analysis We considered the first 100 errors in the Buckwalter tags in our development set. About half of the errors involved a problem in case (42%), state (13%) or mood (3%). Case and state errors had many overlaps. All of these errors are syntactically determinable using the tree representation in a manner similar to Habash et al. (2007a). In 17% of the cases, a POS error can be resolved using the CATiB tag, (e.g., proper noun vs adjective or verb). In 2% of the cases, the error involved an orthographic normalization (Alif-form) that led to an undesirable solution (e.g.,

السنة $\hat{A}lsn\hbar$ ‘tongues’ vs $Alsn\hbar$ ‘the-year’). These cases should be resolved by enforcing the CATiB tree word form. Ambiguity in CATiB tags was a problem for nominal forms 15% of the time (e.g., NOUN vs ADJ), particles 10% of the time (e.g., $+w$ ‘and’ can be CONJ or SUB_CONJ), and pronouns 5% of the time (e.g., $\text{هم}++hm$ ‘them’ can be IVSUFF_DO:3MP or PVSUFF_DO:3MP [attached to an imperfective or perfective verb]).² In 1% of the cases, there was an error involving ambiguity in number (dual/plural). And finally, in 3% of the cases, we determined that the gold POS tag was actually incorrect. Within the same set of sentences studied, we found 18 lemma choice errors. Almost all, except for three cases, involve a nominal form ambiguity resulting from diacritic absence, e.g., $مهد muhad\sim id$ ‘threatening’ or $muhad\sim ad$ ‘threatened’. Eight of the 18 cases (or 44%) happened without an accompanying POS error. Overall, the accuracy of lemma choice is highly dependent on the correctness of the chosen core Buckwalter tag; lemma accuracy when the tag is correct is 97.9%, but it drops to 71.3% when the tag is wrong.

4.3 Morphological Filters

We implemented a set of filters that take the list of ranked analyses produced by TADA and discard any analyses that are inconsistent with the filters’ decisions in the tree context. TADA ranking is preserved among the remaining analyses.

4.3.1 CATiB Filter

TADA returns all analyses for word, including different forms of the word (i.e., different Alif/Ya forms as part of BAMA’s back-off mode). For example, when given the word $\text{علی} \text{ع}لی$, TADA returns analyses for both the words $\text{ع}لی \text{ع}لی$ ‘on’ and $\text{علی} \text{ع}لی$ ‘Ali’. Since the input to our system is the gold word form from CATiB trees, the CATiB filter will discard analyses that do not match the given word form.

The CATiB filter also resolves some POS ambiguity given information in the CATiB POS tag. For example, the CATiB POS tags NOM or VRB can easily decide whether the ambiguous word $\text{کاتب} kAtb$ is a noun ($kAtib$ ‘writer’) or a verb ($kAtab$ ‘to correspond’).

²This is a peculiarity of the tagset used in PATB. The distinction does not seem to be necessary to our knowledge, but we still consider it the gold goal.

4.3.2 Pronominal Filter

The pronominal filter (PRON) selects the pronouns that are consistent with the verbs they are attached to. A pronoun attached to a verb could either be IVSUFF_DO, PVSUFF_DO or CVSUFF_DO depending on whether the verb is imperfective (IV), perfective (PV), or imperative (CV).

4.3.3 Noun/Adjective Filter

The noun/adjective (NOUN/ADJ) filter is applied to words with the CATiB tag NOM. It uses a nominal classifier, which classifies CATiB NOM words into one of the following Buckwalter noun/adjective classes: NOUN, NOUN.VN, NOUN_QUANT, NOUN_NUM, ADJ, ADJ.VN, ADV_COMP, ADV_NUM. The NA (not-applicable) tag is assigned to all other words. For example, the classifier will decide whether كَبِيرَةٌ *kbyrā* is a noun ‘abomination’ or an adjective ‘great [feminine singular]’ based on the context.

To build the nominal classifier, we use Yamcha (Kudo and Matsumoto, 2003), a support-vector-machine-based sequence tagger trained on our PATB training data. We use the following set of features: the word form, CATiB POS tag, parent features (word form, CATiB POS tag), dependency relation, order of appearance (the word comes before or after its parent), the distance between the word and its parent, and different types of relation-child POS (REL-CTB) features. The REL-CTB features state whether a word has a child with a CATiB POS (CTB) under a dependency relation (REL). A word can have 0 or more children. We have six CATiB POS tags and eight dependency relations and thus up to 48 different REL-CTB binary learning features. An example of this feature is a PRT that has a child NOM under a dependency relation OBJ. In this case, the value of the feature OBJ-NOM is 1. We also add a window of two words before and two words after the word being tagged as static features, and the tag of the previous two words as dynamic features. The nominal classifier predicts the correct nominal class with an accuracy of 97.70%.

4.3.4 Particle Filter

The particle filter (PRT) selects the specific Buckwalter POS for a particle. For example, the particle لَا *lā* can be the negative particle ‘not’, the relative pronoun ‘that’ or the interrogative pronoun ‘what?’. The PRT filter uses a particle classifier that uses the

same learning features and training data as the nominal classifier. The particle classifier predicts the correct particle class with an accuracy of 99.54%.

4.3.5 Verbal Mood and Aspect Filter

The Buckwalter POS tags for verbs have three markers for aspect: imperfective (IV), perfective (PV), and imperative (CV); and three markers for mood: jussive (J), subjunctive (S) and indicative (I). We apply our rule-based mood-and-aspect filter (MOOD/ASPECT) to words that have the CATiB tag VRB or VRB-PASS.

If the verb is preceded by a jussive, subjunctive or future particle then it is imperfective in aspect and its mood is determined by the particle. The mood is indicative if the verb is preceded by a future particle such as سُوفَ *swf* ‘will’; it is jussive if the verb is preceded by a jussive particle such as لَمْ *lm* ‘not+past’, لَوْ *lw* ‘for’; and it is subjunctive if the verb is preceded by a subjunctive particle such as أَنْ *An* ‘that’, لَنْ *ln* ‘not+future’, كَيْ *ky* ‘so as to’, and حَتَّىْ *Ht̄y* ‘until’. This is also valid when a negating لَا *lā* intervenes between the subjunctive particle and the verb. If the verb is proceeded with the particle لَقَدْ *lqd* ‘already’, then the verb is perfective. Otherwise, the verb could be either imperfective (with an indicative mood), perfective or imperative (all allowed through the filter).

4.3.6 Nominal State Filter

The Buckwalter POS tags have three nominal state markers: INDEF, DEF and POSS.³ The nominal state filter (STATE) applies the following rules: If the word is head of an idafa (IDF), then we exclude the INDEF analyses. Otherwise, we exclude the POSS and the non-AI/DET determined DEF analysis (which are only used for IDF heads).

4.3.7 Nominal Case Filter

The nominal case filter (CASE) assigns the values *nom* (nominative), *acc* (accusative) or *gen* (genitive) to each NOM/PROP word primarily based on the CATiB dependency relation label that describes the type of relation between the word and its parent. The nominal case filter extends the case predictor in Habash et al. (2007a). The following four rules are applied in sequence.

³These values do not exactly match the functional values for state in Arabic (Smrž, 2007).

- RULE 1: Assign *acc* to all NOM/PROP words as a default.
- RULE 2: Assign *nom* to NOM/PROP words that (a) head the tree, (b) have the label TPC, (c) have the label SBJ but are not headed by a particle from the closed class of *Inna and its sisters* (Habash et al., 2007a), or (d) have the label PRD but is not headed by a verb or deverbal noun. Exempt words in the closed class of adverb-like nouns such as فوق *fwq* ‘over’, قبل *qbl* ‘before’, حول *Hwl* ‘around’.
- RULE 3: Assign *gen* to NOM/PROP words that have the label OBJ under a preposition, or that have the label IDF.
- RULE 4: All children of NOM/PROP parents whose label is MOD, and NOM/PROP children of conjunctions whose label is OBJ, copy the case of their parent. Conjunctions carry the case temporarily to pass on agreement.

4.3.8 MLE Override

We added an MLE-based component to override answers that are provided by our final system. We used a no-BAMA version of the MLE Baseline 2. The difference between the MLE override component and MLE Baseline 2 is that it takes into account all possible Buckwalter POS tags that appear in the training set for a specific word regardless of whether they are provided by BAMA or not. This MLE override component is trained on the same training set and returns the most common Buckwalter tag and lemma pair for a given word form and CATiB POS tag pair. BAMA is not used here since the reason behind this additional step is to overcome any limitation caused by using BAMA to start with. These limitations include primarily cases of BAMA failure to produce analyses (OOV) or minor version differences between BAMA and the PATB. If a Buckwalter tag and lemma pair appear above a threshold of n times and always with the same word-lemma pair, then we override our answer with the new answer from the MLE. When we override, we only override the core part of the Buckwalter tag. We do not override the state, case, and mood features since they are syntactic features. We tried different values for the threshold and got the best results when $n = 4$.

4.4 Putting it All Together

TADA provides an initial list of ranked analyses. Then, the morphological filters discard analyses that are not consistent with the CATiB tree information. The analysis with the highest TADA rank among the remaining analyses is selected as the answer.

We apply our filters in the following order. We first apply the CATiB filter. After that, we apply the pronominal, noun/adjective and particle filters. These three filters can be applied in any order since they are applied on disjoint sets of words. The next filter is the mood/aspect filter which has to be applied after the particle filter since it depends on the particle choice in predicting the mood of the following verb. At this point, we freeze the lemma choice for the word. The next two filters, state and case, look at syntactic features and should not affect the choice of the lemma.

We use two back-off mechanisms. The first one is with the application of each filter. If the effect of applying a filter results in an empty set (no match found) then we undo the effect of the filter and pass the list of analyses as is to the next filter. The second mechanism is using the MLE override at the end of the pipeline. TADA, the noun/adjective and particle filters, and the MLE override use corpus-based components while all other filters are rule-based.

5 Evaluation

5.1 Experimental Settings

We use a CATiB version of the PATB part 3v3.1 and part 2v3.0 released by the Linguistic Data Consortium (LDC) (Maamouri et al., 2004). We use the train/development/test (80/10/10) splits of Marton et al. (2010) for PATB part 3v3.1 (16.6K sentences; 400K tokens): we use their train as our training data, their development as the tuning data for TADA and their test as our development set. For our blind test, we use the first 1000 sentences in PATB part 2v3.0 (38K tokens).

We report all results in terms of token accuracy on the full Buckwalter tag, reduced Buckwalter tag and the lemma. The reduced Buckwalter tag is the Buckwalter tag without case, state, and mood. The number of tags is reduced to 220 tags (compared to 485 tags for the full Buckwalter tagset).

In cases of gold full Buckwalter tags that are underspecified for case, state or mood, we do not penalize our systems if our more specific predicted

	Full BW	Reduced BW	Diff	Lemma
MLE Baseline 1	57.19	73.44	16.25	90.87

tag otherwise matches the gold tag. Words whose lemmas are unknown (nolemma, TBupdate) or has the lemma DEFAULT (including digits and punctuation) are excluded from the evaluation, but not training: in the development set, 4,498 out of 25,446 words were excluded ($\sim 18\%$).

5.2 Results

Table 1 shows the results of our experiments on the development set. Considering the baseline systems, we see that using both the CATiB POS tag and the word form in MLE Baseline 2 gives us a 20.5% absolute increase above MLE Baseline 1. Using TADA improves the performance significantly (adding 8.46% absolute over MLE Baseline 2). Every additional morphological filter has a positive impact and the improvement of the accuracy for full Buckwalter with each new filter ranged between 0.22% and 1.18% absolute except for the case filter, which adds almost 5%. Adding the MLE override has a positive impact on the accuracy of the full and reduced Buckwalter tags and the lemma.

We apply our baselines, TADA, TADA+filters and TADA+filters+MLE to the blind test set (see Table 2). The test set is a bit harder than the development set, but the results are consistent with those seen for the development set.

5.3 Error Analysis

We conducted an analysis of the errors in the output of the final system TADA+filters+MLE on the development set. We considered 100 randomly selected error cases and examined them in the CATiB trees

	Full BW	Reduced BW	Diff	Lemma

to assess the source of the error. About 37% of all errors are due to gold treebank errors: 21% are gold tree structure/relation errors and 16% are gold POS errors. The rest of the errors result from failures in our system. The most common error is in NOM disambiguation: NOUN/NOUN_NUM, NOUN/ADJ, NOUN/NOUN_QUANT, etc. The NOM errors accounted for 33% of all errors. Case comes second with 12% errors, then PRT and gender-number-person errors with 5% each. State errors contribute to 3% of total errors.

5.4 Learning Curve Study

The non-rule-based components of our approach, namely TADA, NOUN/ADJ and PRT filters, and MLE override depend on the existence of an annotated treebank in rich format. To understand the degree of dependence, we ran a series of experiments on different sizes of the training data: $\frac{1}{2}$, $\frac{1}{4}$, $\frac{1}{8}$, $\frac{1}{16}$, and $\frac{1}{32}$ of the full training set (341.1K words). These data sets were used to train new versions of TADA, the NOUN/ADJ and PRT filters, and the MLE override. The results of running TADA and the final system on the development set using the different data sets are summarized in Tables 3 and 4, respectively. As expected, when the training data size goes down the accuracy goes down. Our final system, which adds filters on top of TADA, had a significant effect on the performance as shown in Table 4. Using only 10.6K of annotated words, the quality of TADA reduces sharply (12.12% absolute reduction in accuracy) while the overall effect on our full system is a lot smaller (2.03% absolute drop). Similarly, the performance of the nominal and particle classifiers degrade when trained on less data. When we use $\frac{1}{32}$ of the training data, the correct nominal class is predicted at an accuracy of 90.49% (7.21% absolute drop), while the correct particle class is predicted at an accuracy of 96.59% (2.95% absolute drop). We used the MLE override threshold determined based

	Size	Full BW	Reduced BW	Diff	Lemma

1/16	21.3K	77.16	90.30	13.14	94.37
1/8	42.6K	79.76	91.63	11.87	95.56
1/4	85.3K	81.91	92.80	10.89	96.22
1/2	170.7K	84.12	93.62	9.50	96.74
1	341.1K	86.15	94.04	7.89	96.97

Table 3: Accuracy of enriching CATiB trees with Buckwalter (BW) tags and lemmas using TADA only for different training sizes on the development set.

	Size	Full BW	Reduced BW	Diff	Lemma
1/32	10.6K	93.24	95.81	2.57	95.68
1/16	21.3K	93.67	96.28	2.61	96.27
1/8	42.6K	94.14	96.79	2.65	96.94
1/4	85.3K	94.56	97.26	2.70	97.22
1/2	170.7K	94.96	97.66	2.70	97.61
1	341.1K	95.27	98.00	2.73	97.81

Table 4: Accuracy of enriching CATiB trees with Buckwalter (BW) tags and lemmas using our best performing system for different training sizes on the development set.

on the full training data, which may not be optimal for smaller data sets.

The contribution of our full system over TADA when using $\frac{1}{32}$ of the full training data is over 19% absolute (on full Buckwalter tag determination) compared to 9% when using the full training data. The morph analysis (out of context) is the same for all experiments and that this provides a lot of stability to the results. The high lemma accuracy overall is a result of disambiguating tokenized words, where the average numbers of lemmas per word is only 1.1 as mentioned above. These results suggest that our approach is usable even in the early stages of developing new richly annotated treebanks.

5.5 Extrinsic Evaluation

We applied our automatic enrichment to the underspecified CATiB treebank (as opposed to the parts of PATB, which we used throughout the paper to simulate CATiB). We evaluate the added value of these annotations by using them to extend the training data for the morphological tagger MADA (Habash and Rambow, 2005), which is used on untokenized text. We train a new set of MADA classifier models using a combination of the original MADA (v 3.2) training data (578K words taken from PATBs 1, 2 and 3) and the enriched CATiB data (218K words). We apply the new MADA system to our development set and evaluate on several metrics. As a baseline, we

process the same development set using MADA (v 3.2). Other than the training data used to construct the classifier models, there are no differences between the two systems. The CATiB-enriched system results in a Buckwalter POS tag accuracy of 85.6% (a 2.2% error reduction over the baseline). When evaluating on the set of 14 MADA morphological features, the new system results in a 85.7% accuracy (2.4% error reduction). The new system also improves PATB segmentation accuracy (99.2%, a 5.4% error reduction). In the future, we will evaluate the contribution of the additional annotations in the context of other applications, such as syntactic parsing.

6 Conclusion and Future Work

We have demonstrated that an underspecified version of an Arabic treebank can be fully specified for Arabic’s rich morphology automatically at an accuracy rate of 94%-95% for POS tags and 97% for lemmas. Our approach combines a variety of techniques from corpus-based statistical models (which require some rich annotations) to linguistic rules that target specific phenomena. Since the underspecified treebank is much faster to manually annotate than its fully specified version, these results suggest that the cost of treebanking can be reduced by designing underspecified treebanks that can be subsequently enriched automatically.

In the future, we plan to extend the automatic enrichment effort to include more complex features such as empty nodes and semantic labels. We also plan to take the insights from this effort and apply them to treebanks of other languages. A small portion of a treebank that is fully annotated in rich format will of course be needed before we can apply these insights to other languages.

Abstract

Social media texts are written in an informal style, which hinders other natural language processing (NLP) applications such as machine translation. Text normalization is thus important for processing of social media text. Previous work mostly focused on normalizing words by replacing an informal word with its formal form. In this paper, to further improve other downstream NLP applications, we argue that other normalization operations should also be performed, e.g., missing word recovery and punctuation correction. A novel beam-search decoder is proposed to effectively integrate various normalization operations. Empirical results show that our system obtains statistically significant improvements over two strong baselines in both normalization and translation tasks, for both Chinese and English.

1 Introduction

Social media texts include SMS (Short Message Service) messages, Twitter messages, Facebook updates, etc. They are different from formal texts due to their significant informal characteristics, so they always pose difficulties for applications such as machine translation (MT) (Aw et al., 2005) and named entity recognition (Liu et al., 2011), because of a lack of training data containing informal texts. Thus, the applications always suffer from a substantial performance drop when evaluated on social media texts. For example, Ritter et al. (2011) reported a drop from 90% to 76% on part-of-speech tagging, and

Foster et al. (2011) found a drop of 20% in dependency parsing.

Creating training data of social media texts specifically for a text processing task is time-consuming. For example, to create parallel Chinese-English training texts for translation of social media texts, it takes three minutes on average to translate an informally written social media text of eleven words from Chinese into English. On the other hand, it takes thirty seconds to normalize the same message, a six-fold increase in speed. After training a text normalization system to normalize social media texts, we can use an existing statistical machine translation (SMT) system trained on normal texts (non-social media texts) to carry out translation. So we argue that normalization followed by regular translation is a more practical approach. Thus, text normalization is important for social media text processing.

Most previous work on normalization of social media text focused on word substitution (Beaufort et al., 2010; Gouws et al., 2011; Han and Baldwin, 2011; Liu et al., 2012). However, we argue that some other normalization operations besides word substitution are also critical for subsequent natural language processing (NLP) applications, such as missing word recovery (e.g., zero pronouns) and punctuation correction.

In this paper, we propose a *novel* beam-search decoder for normalization of social media text for MT. Our decoder can effectively integrate different normalization operations together. In contrast to previous work, some of our normalization operations are specifically designed for MT, e.g., missing word recovery based on conditional random fields

(CRF) (Lafferty et al., 2001) and punctuation correction based on dynamic conditional random fields (DCRF) (Sutton et al., 2004).

To the best of our knowledge, our work is the first to perform missing word recovery and punctuation correction for normalization of social media text, and also the first to perform message-level normalization of Chinese social media text. We investigate the effects on translating social media text after addressing various characteristics of informal social media text through normalization. To show the applicability of our normalization approach for different languages, we experiment with two languages, Chinese and English. We achieved statistically significant improvements over two strong baselines: an improvement of 9.98%/7.35% in BLEU scores for normalization of Chinese/English social media text, and an improvement of 1.38%/1.35% in BLEU scores for translation of Chinese/English social media text. We created two corpora: a Chinese corpus containing 1,000 Weibo¹ messages with their normalizations and English translations; and another similar English corpus containing 2,000 SMS messages from the NUS SMS corpus (How and Kan, 2005). As far as we know, our corpora are the first publicly available Chinese/English corpora for normalization and translation of social media text².

2 Related Work

Zhu et al. (2007) performed text normalization of informally written email messages using CRF (Lafferty et al., 2001). Due to its importance, normalization of social media text has been extensively studied recently. Aw et al. (2005) proposed a noisy channel model consisting of different operations: substitution of non-standard acronyms, deletion of flavor words, and insertion of auxiliary verbs and subject pronouns. Choudhury et al. (2007) used hidden Markov model to perform word-level normalization. Kobus et al. (2008) combined MT and automatic speech recognition (ASR) to better normalize French SMS message. Cook and Stevenson (2009) used an unsupervised noisy channel model considering different word formation processes. Han and Baldwin (2011) normalized informal words using

morphophonemic similarity. Pennell and Liu (2011) only dealt with SMS abbreviations. Xue et al. (2011) normalized social media texts incorporating orthographic, phonetic, contextual, and acronym factors. Liu et al. (2012) designed a system combining different human perspectives to perform word-level normalization. Oliva et al. (2013) normalized Spanish SMS messages using a normalization and a phonetic dictionary. For normalization of Chinese social media text, Xia et al. (2005) investigated informal phrase detection, and Li and Yarowsky (2008) mined informal-formal phrase pairs from Web corpora.

All the above work focused on normalizing words. In contrast, our work also performs other normalization operations such as missing word recovery and punctuation correction, to further improve machine translation. Previously, Aw et al. (2006) adopted phrase-based MT to perform SMS normalization, and required a relatively large number of manually normalized SMS messages. In contrast, our approach performs beam search at the sentence level, and does not require large training data.

We evaluate the success of social media text normalization in the context of machine translation, so research on machine translation of social media text is relevant to our work. However, there is not much comparative evaluation of social media text translation other than the Haitian Creole to English SMS translation task in the 2011 Workshop on Statistical Machine Translation (WMT 2011) (Callison-Burch et al., 2011). However, the setup of the WMT 2011 task is different from ours, in that the task provided parallel training data of SMS texts and their translations. As such, text normalization is not necessary in that task. For example, the best reported system in that task (Costa-jussà and Banchs, 2011) did not perform SMS message normalization.

In speech to speech translation (Paul, 2009; Nakov et al., 2009), the input texts contain wrongly transcribed words due to errors in automatic speech recognition, whereas social media texts contain abbreviations, new words, etc. Although the input texts in both cases deviate from normal texts, the exact deviations are different.

Be	24	i coming; you free?;
Tokenization	19	ok.why ?(ok . why ?);
Time	2	end at 730(end at 7:30); 1130 am(11:30 am);

Table 1: Occurrence frequency of various informal characteristics in 200 Chinese/English social media texts.

3 Challenges in Normalization of Social Media Text

To better understand the informal characteristics of social media texts, we first analyzed a small sample of such texts in Chinese and English. We crawled 200 Chinese messages from Weibo. The informal characteristics of these messages are shown in the first half of Table 1. The manually normalized form is shown in round brackets, and the English gloss is shown in square brackets. Omitted, extraneous, and misused punctuation symbols occur frequently. On average, each Chinese message contains only less than one informal word, and many informal words are either new words or existing words with new meaning. The messages also contain redundant interjections like “哦[oh]”。 Pronouns are often omitted in Chinese messages, especially for “我[I]”。 Chinese informal words can be wrongly segmented due to lack of word segmentation training data containing informal words.

Similarly, 200 English SMS messages were randomly selected from the NUS SMS corpus (How and Kan, 2005). The informal characteristics of these messages are shown in the second half of Table 1. We found that our English messages contain more informal words than Chinese messages. English words are shortened in three ways: (1) using a shorter word form with similar pronunciation; (2) abbreviating a formal word; and (3) using only a prefix of a formal word. Other informal characteristics include: (1) informal punctuation conventions in-

cluding omitted and misused punctuation; (2) redundant interjections; (3) quotation-related problems, e.g., omitted quotation marks; (4) “be” omission; (5) tokenization problems; and (6) informally written time expressions.

4 Methods

As can be seen in Section 3, social media texts of different languages exhibit different informal characteristics. For example, English messages have more informal words than Chinese messages, while punctuation problems are more prevalent for Chinese messages. Also, fixing different types of informal characteristics often depends on each other. For example, to be able to correct punctuation, it helps that the surrounding words are already correctly normalized. On the other hand, with punctuation already corrected, it will be easier to normalize the surrounding words.

In this section, we first present our punctuation correction method based on a DCRF model, and then present missing word recovery based on a CRF model. Next, we present a novel beam-search decoder for normalization of social media text, which can effectively integrate different normalization operations, including statistical and rule-based normalization. Finally, details of text normalization for Chinese and English are presented.

4.1 Punctuation Correction

In normalization of social media text, punctuation correction is also important besides word normalization, as the subsequent NLP applications are typically trained on formal texts with correct punctuation. We define punctuation correction as correcting punctuation in sentences which may have no or unreliable punctuation. The task performs three punctuation operations: insertion, deletion, and substitution.

To our knowledge, no previous work has been done on punctuation correction for normalization of social media text. In ASR, punctuation prediction only inserts punctuation symbols into ASR output that has no punctuation (Kim and Woodland, 2001; Huang and Zweig, 2002), but without punctuation deletion or substitution. Lu and Ng (2010) argued that punctuation prediction should be jointly per-

formed with sentence boundary detection, so they modeled punctuation prediction using a two-layer DCRF model (Sutton et al., 2004).

We also believe that punctuation correction is closely related to sentence boundary detection. Thus, we propose a two-layer DCRF model for punctuation correction. Layer 1 gives the actual punctuation tags *None*, *Comma*, *Period*, *Question-Mark*, and *Exclamatory-Mark*. Layer 2 gives the sentence boundary, including tags *Declarative-Begin*, *Declarative-In*, *Question-Begin*, *Question-In*, *Exclamatory-Begin*, and *Exclamatory-In*, indicating whether the current word is at the beginning of (or inside) a declarative, question, or exclamatory sentence.

We use word n -grams ($n = 1, 2, 3$) and punctuation symbols within 5 words before and after the current word as binary features in the DCRF model. As an example, Table 2 shows the tags and features for the word “*where*” in the message “*where| .|? i| can| not| see| you| !|!*”, where the punctuation symbols after the vertical bars are the corrected symbols.

Tags	Content
Layer 1	<i>Question-Mark</i>
Layer 2	<i>Question-Begin</i>
Features	Content
unigram	<s>@-1 where@0 i@1 can@2 not@3 see@4 you@5
bigram	<s>+where@-1 where+i@0 i+can@1 can+not@2 not+see@3 see+you@4 you+</s>@5
trigram	<s>+where+i@-1 where+i+can@0 i+can+not@1 can+not+see@2 not+see+you@3 see+you+</s>@4
punctuation	.@0 !@5

Table 2: An example of tags and features used in punctuation correction.

Due to the lack of informal training texts with corrected punctuation, we train our punctuation correction model on formal texts with synthetically created punctuation errors. We randomly add, delete, and substitute punctuation symbols in formal texts with equal probabilities. Specifically, for $s \in \{., ?, !\}$, $P(\text{none}|s) = P(,|s) = P(.|s) = P(?|s) = P(!|s) = 0.2$ denotes the probability of replacing a punctuation symbol s (replacing s by *none* denotes deletion); and for a real word (not a punctuation symbol) w , $P(\text{none}|w) = P(,|w) = P(.|w) = P(?|w) = P(!|w) = 0.2$ denotes the probability

of inserting a punctuation symbol after w (inserting *none* after w denotes no insertion).

4.2 Missing Word Recovery

As shown in Section 3, some words are often omitted in social media texts, e.g., the pronoun “我/I” in Chinese and *be* in English. To fix this problem, we propose a CRF model to recover such missing words. We explain the CRF model using *be* in English. The CRF model has five tags: *None*, *BE*, *IS*, *ARE*, and *AM*. In an input sentence, every token (including words, punctuation symbols, and a special start-of-sentence placeholder) will be assigned a tag, denoting the insertion of the form of *be* after the token. We use the same n -gram features as our punctuation correction model, but exclude the punctuation features. The model is trained on synthetically created training texts in which *be* has been randomly deleted with probability 0.5.

4.3 A Decoder for Text Normalization

When designing our text normalization system, we aim for a general framework that can be applied to text normalization across different languages with minimal effort. This is a challenging task, since social media texts in different languages exhibit different informal characteristics, as illustrated in Section 3. Motivated by the beam-search decoders for SMT (Koehn et al., 2007), ASR (Young et al., 2002), and grammatical error correction (Dahlmeier and Ng, 2012), we propose a novel beam-search decoder for normalization of social media text.

Given an input message, the normalization decoder searches for its best normalization, i.e., the best hypothesis, by iteratively performing two sub-tasks: (1) producing new sentence-level hypotheses from hypotheses in the current stack, carried out by *hypothesis producers*; and (2) evaluating the new hypotheses to retain good ones, carried out by *feature functions*. Each hypothesis is the result of applying successive normalization operations on the initial input message, where each normalization operation is carried out by one hypothesis producer that deals with one aspect of the informal characteristics of social media text. The hypotheses are grouped into stacks, where stack i stores all hypotheses obtained by applying i hypothesis producers on the input message. The beam-search algorithm is shown

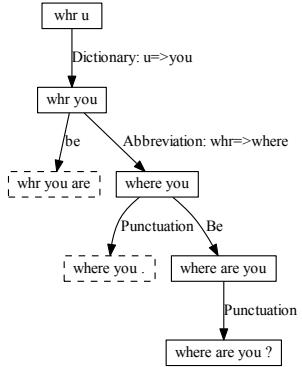

Figure 1: An example search tree when normalizing “*whr u*”. The solid (dashed) boxes represent good (bad) hypotheses. The hypothesis producers are indicated on the edges.

in Algorithm 1, and Figure 1 shows an example search tree for an English message.

Algorithm 1 The beam-search decoder

INPUT: a raw message \mathbf{M} whose length is N
 RETURN: the best normalization for \mathbf{M}

```

1: initialize  $hypothesisStacks[N+1]$  and  $hypothesisProducers$ ;
2: add the initial hypothesis  $\mathbf{M}$  to stack  $hypothesisStacks[0]$ ;
3: for  $i \leftarrow 0$  to  $N-1$  do
4:   for each  $hypo$  in  $hypothesisStacks[i]$  do
5:     for each  $producer$  in  $hypothesisProducers$  do
6:       for each  $newHypo$  produced by  $producer$  from  $hypo$  do
7:         add  $newHypo$  to  $hypothesisStacks[i+1]$ ;
8:         prune  $hypothesisStacks[i+1]$ ;
9: return the best hypothesis in  $hypothesisStacks[0...N]$ ;
```

We give the details of the hypothesis producers for Chinese and English social media texts in the next two subsections. A number of the hypothesis producers detect and deal with informal words w present in a hypothesis by relying on bigram counts of w in a large corpus of formal texts. Specifically, a word w in a hypothesis $\dots w_{-1}ww_1\dots$ is considered an informal word if both bigrams $w_{-1}w$ and ww_1 occur infrequently (≤ 5) in the formal corpus.

Given a hypothesis message h , the feature functions include a language model score (the normalized sentence probability of h), an informal word count penalty (the number of informal words detected in h), and count feature functions. Each count feature function gives the count of the modifications made by a hypothesis producer. The feature func-

tions are used by the decoder to distinguish good hypotheses from bad ones. All feature functions are combined using a linear model to obtain the score for a hypothesis h :

$$score(h) = \sum_i \lambda_i f_i(h), \quad (1)$$

where f_i is the i -th feature function with weight λ_i . The weights of the feature functions are tuned using the pairwise ranking optimization algorithm (Hopkins and May, 2011) on the development set.

4.4 Text Normalization for Chinese

Taking into account the informal characteristics of Chinese social media text in Section 3, we design the following **hypothesis producers** for Chinese text normalization:

Dictionary: We have manually assembled a dictionary of 703 informal-formal word pairs from the Internet. The word pairs are used to produce new hypotheses. For example, given a hypothesis “神马[magical horse] 时候[time]”, if the dictionary contains the word pair “(神马, 什么[what])”, the Dictionary hypothesis producer generates a new hypothesis “什么[what] 时候[time]”.

Punctuation: A punctuation correction model (Section 4.1) is adopted to correct punctuation in the current hypothesis, e.g., it may normalize “什么[what] 时候[time]” into “什么 时候？”.

Pronunciation: We use Chinese Pinyin to model the pronunciation similarity of words. To accomplish this, we pair some Pinyin initials that sound similar into a group. The groups of paired Pinyin initials are (c, ch) , (s, sh) , and (z, zh) . For example, given the hypothesis “北京[Beijing] 筒子[tube] 来了[come]”, the Pinyin of the informal word “筒子” is “t ong z i”. The Pinyin of the formal word “同志[comrade]” is “t ong zh i”. Since the similar sounding Pinyin initials z and zh are paired in a group, a new hypothesis “北京[Beijing] 同志[comrade] 来了[come]” can be produced.

In practice, this hypothesis producer can propose many spurious candidates w' for an informal word w . As such, after we replace w by w' in the hypothesis, we require that some 4-gram containing w' and its surrounding words in the hypothesis appears in a formal corpus. We call this filtering process *contextual filtering*.

Pronoun: With the method of Section 4.2, a CRF model is trained to recover the missing pronoun “我/I”.

Interjection: If a word w in a pre-defined list of frequent redundant interjections appears at the end of a sentence, we produce a new hypothesis by removing w , e.g., from “好的/[ok] 哟/[oh]” to “好/[ok]”.

Resegmentation: This hypothesis producer fixes word segmentation problems. If an informal word is a concatenation of two constituent informal words w_1 and w_2 in our normalization dictionary, the informal word will be segmented into two words w_1 and w_2 . As a result, the Dictionary hypothesis producer can subsequently normalize w_1 and w_2 .

4.5 Text Normalization for English

Similar to Chinese text normalization, we also create the Dictionary, Punctuation, and Interjection hypothesis producers for English text normalization. We also add the following English-specific hypothesis producers:

Pronunciation: This hypothesis producer uses pronunciation similarity to find formal candidates for a given informal word. It considers a word as a sequence of letters and convert it into a sequence of phones using phrase-based SMT trained on the CMU pronouncing dictionary (Weide, 1998). Similar sounding phones are paired together in a group: (ah, ao), (ow, uw), and (s, z). To illustrate, in the hypothesis “wat is it”, the informal word “wat” maps to the phone sequence “ $w\ ao\ t$ ”. Since the formal word “what” maps to the phone sequence “ $w\ ah\ t$ ” and the phones ah and ao are paired in a group, the new hypothesis “what is it” is generated.

Be: We train a CRF model to recover missing words be , as described in Section 4.2.

Retokenization: This hypothesis producer fixes tokenization problems. More precisely, given an informal word which is not a URL or email address and contains a period, it splits the informal word at the period. For example, “how r u.where r u” is normalized to “how r u . where r u”.

Prefix: This hypothesis producer generates a formal word w' for an informal word w if w is a prefix of w' . To avoid spurious candidates, we only generate w' if $|w| \geq 3$ and $|w'| - |w| \leq 4$.

Quotation: If an informal word ends with a letter

in (m, s, t) and if the word produced by inserting a quotation mark before the letter is a formal word, a new hypothesis with the quotation mark inserted is produced. This hypothesis producer thus generates “i’m” from “im”, “she’s” from “shes”, “isn’t” from “isnt”, etc.

Abbreviation: Letters denoting the vowels in a formal word are often deleted to form an informal word. This hypothesis producer generates a formal word w' from an informal word w if w' can be obtained from w by adding missing vowels. To avoid spurious candidates, we only consider w where $|w| \geq 2$.

Time: If a number can be a potential time expression and appears after “at” or before “am” or “pm”, a new hypothesis is produced by changing the number into a time expression, e.g., “1130 am” is normalized to “11 : 30 am”.

Since the Pronunciation, Prefix, and Abbreviation hypothesis producers can propose spurious candidates for an informal word, we also use contextual filtering to further filter the candidates for these hypothesis producers.

5 Experiments

5.1 Evaluation Corpora

As previous work (Choudhury et al., 2007; Han and Baldwin, 2011; Liu et al., 2012) mostly focused on word normalization, no data is available with corrected punctuation and recovered missing words. We thus create the following two corpora (Table 3):

Chinese-English corpus We crawled 1,000 messages from Weibo which were first normalized into formal Chinese and then translated into formal English. The first half of the corpus serves as our development set to tune our text normalization decoder for Chinese, while the second half serves as the test set to evaluate text normalization for Chinese and Chinese-English MT.

English-Chinese corpus From the NUS English SMS corpus (How and Kan, 2005), we randomly selected 2,000 messages. The messages were first normalized into formal English and then translated into formal Chinese. Similar to the Chinese-English corpus, the first half of the corpus serves as our development set while the second half serves as the test set.

Corpus	# messages	# tokens (EN/CN/NCN)
<i>CN2EN-dev</i>	500	6.95K/5.45K/5.70K
<i>CN2EN-test</i>	500	7.14K/5.64K/5.82K
Corpus	# messages	# tokens (EN/CN/NEN)
<i>EN2CN-dev</i>	1,000	16.63K/18.14K/18.21K
<i>EN2CN-test</i>	1,000	16.14K/17.69K/17.76K

Table 3: Statistics of the corpora. *CN2EN-dev/CN2EN-test* is the development/test set in our Chinese-English experiments. *EN2CN-dev/EN2CN-test* is the development/test set in our English-Chinese experiments. *NEN/NCN* denotes manually normalized English/Chinese texts.

The formal corpus used (as described in Section 4) is the concatenation of two Chinese-English spoken parallel corpora: the IWSLT 2009 corpus (Paul, 2009) and another spoken text corpus collected at the Harbin Institute of Technology³. The language model used for Chinese (English) text normalization is the Chinese (English) side of the formal corpus and the LDC Chinese (English) Gigaword corpus.

To evaluate the effect of text normalization on MT, we build phrase-based MT systems using Moses (Koehn et al., 2007), with word alignments generated by GIZA++ (Och and Ney, 2003). The MT training data contains the above formal corpus and some LDC⁴ parallel corpora (LDC2000T46, LDC2002E18, LDC2003E14, LDC2004E12, LDC2005T06, LDC2005T10, LDC2007T23, LDC2008T06, LDC2008T08, LDC2008T18, LDC2009T02, LDC2009T06, LDC2009T15, LDC2010T03). In total, 214M/192M English/Chinese tokens are used to train our MT systems. The language model of the Chinese-English (English-Chinese) MT system is the English (Chinese) side of the FBIS corpus (LDC2003E14) and the English (Chinese) Gigaword corpus. Our MT systems are tuned on the manually normalized messages of our development sets.

Following (Aw et al., 2006; Oliva et al., 2013), we use BLEU scores (Papineni et al., 2002) to evaluate text normalization. We also use BLEU scores to evaluate MT quality. We use the sign test to determine statistical significance, for both text normalization and translation.

⁴<http://www.ldc.upenn.edu/Catalog/>

5.2 Baselines

We compare our text normalization decoder against three baseline methods for performing text normalization. We then send the respective normalized texts to the same MT system to evaluate the effect of text normalization on MT.

The simplest baseline for text normalization is one that does no text normalization. The raw text (un-normalized) is simply passed on to the MT system for translation. We call this baseline ORIGINAL.

The second baseline, LATTICE, is to use a lattice to normalize text. For each input message, a lattice is generated in which each informal word is augmented with its formal candidates taken from the same normalization dictionary (downloaded from Internet) used in our text normalization decoder. The lattice is then decoded by the same language model used in our text normalization decoder to generate the normalized text (Stolcke, 2002). Another possible way of using lattice is to directly feed the lattice to the MT system (Eidelman et al., 2011), but since in this paper, we assume that the MT system can only translate plain text, we leave this as future work.

The third baseline, PBMT, is a competitive baseline that performs text normalization via phrase-based MT, as proposed in Aw et al. (2006). Moses (Koehn et al., 2007) is used to perform text normalization, by “translating” un-normalized text to normalized text. The training data used is the same development set used in our text normalization decoder. The normalized text is then sent to our MT system for translation. This method was also used in the SMS translation task of WMT 2011 by (Stymne, 2011).

In the tables showing experimental results, normalization and translation BLEU scores that are significantly higher than ($p < 0.01$) the LATTICE or PBMT baseline are **in bold** or underlined, respectively.

5.3 Chinese-English Experimental Results

The Chinese-English normalization and translation results are shown in Table 4. The first group of experiments is the three baselines, and the second group is an oracle experiment using manually normalized messages as the output of text normaliza-

System	BLEU scores (%)	
	Normalization	MT
ORIGINAL baseline	61.01	9.06
LATTICE baseline	74.52	11.50
PBMT baseline	76.77	12.65
ORACLE	100.00	15.04
Dictionary	77.80	12.35
Punctuation	65.95	9.63
Pronunciation	61.30	9.13
Pronoun	61.11	9.01
Interjection	61.05	9.14
Resegmentation	60.98	9.03
Dictionary	77.80	12.35
+Punctuation	84.69	<u>13.37</u>
+Pronunciation	84.69	<u>13.40</u>
+Pronoun	84.96	<u>13.50</u>
+Interjection	85.33	<u>13.68</u>
+Resegmentation	86.75	<u>14.03</u>

Table 4: Chinese-English experimental results.

tion which indicates the theoretical upper bounds of perfect normalization. In the normalization experiments, the ORIGINAL baseline gets a BLEU score of 61.01%, and the LATTICE baseline greatly improves the ORIGINAL baseline by 13.51%, which shows that the dictionary collected from the Internet is highly effective in text normalization. The PBMT baseline further improves the BLEU score by 2.25%. In the corresponding MT experiments, as the normalization BLEU scores increase, the MT BLEU scores also increase.

The third group is the isolated experiments, i.e., each experiment only uses one hypothesis producer. As expected, the individual hypothesis producers alone do not work well except the Dictionary hypothesis producer. One interesting discovery is that the Dictionary hypothesis producer outperforms the LATTICE baseline, which shows that our normalization decoder can utilize the dictionary more effectively, probably because of the additional features used in our normalization decoder such as the informal word penalty. The Resegmentation hypothesis producer alone worsens the BLEU scores, since it can only split informal words, and is designed to work together with other hypothesis producers to normalize words.

The last group is the combined experiments. We add each hypothesis producer in the order of its normalization effectiveness in the isolated experiments. Adding the Punctuation hypothesis producer greatly improves the BLEU scores of both normalization

and translation, which confirms the importance of punctuation correction. The Pronoun and Interjection hypothesis producers also contribute some improvements. Finally, Resegmentation significantly improves the normalization/translation BLEU scores by 1.42%/0.35%. Compared with the isolated experiments, the combined experiments show that our normalization decoder can effectively integrate different hypothesis producers to achieve better performance for both text normalization and translation.

Overall, in the Chinese text normalization experiments, our normalization decoder outperforms the best baseline PBMT by 9.98% in BLEU score. In the Chinese-English MT experiments, the normalized texts output by our normalization decoder lead to improved translation quality compared to normalization by the PBMT baseline, by 1.38% in BLEU score.

5.4 English-Chinese Experimental Results

The English-Chinese normalization and translation results are shown in Table 5, with the same experimental setup as in the Chinese-English experiments.

The text normalization BLEU score of the ORIGINAL baseline is much lower in English compared to Chinese, since the English texts contain more informal words. Again, the individual hypothesis producers alone do not work well, except the Dictionary hypothesis producer. The Retokenization hypothesis producer greatly improves the normalization/translation BLEU scores by 2.37%/0.86%. The Punctuation hypothesis producer helps less for English compared to Chinese, suggesting that our Chinese texts contain noisier punctuation.

Overall, we achieved similar improvements in English text normalization and English-Chinese translation, and the improvements in BLEU scores are 7.35% and 1.35% respectively.

5.5 Further Analysis

The effect of contextual filtering. To measure the effect of contextual filtering proposed in Section 4.4, we ran our normalization decoder without contextual filtering. We obtained BLEU scores of 65.05%/22.38% in the English-Chinese experiments, which were lower than 66.54%/22.81% ob-

System	BLEU scores (%)	
	Normalization	MT
ORIGINAL baseline	37.38	13.63
LATTICE baseline	56.98	20.56
PBMT baseline	59.19	21.46
ORACLE	100.00	28.48
Dictionary	59.90	20.84
Retokenization	38.79	14.06
Prefix	38.68	13.90
Interjection	38.37	13.92
Quotation	38.04	13.65
Abbreviation	37.94	13.74
Time	37.65	13.66
Pronunciation	37.62	13.80
Punctuation	37.62	13.79
Be	37.47	13.59
Dictionary	59.90	20.84
+Retokenization	62.27	21.70

+Time	65.59	22.38
+Pronunciation	65.64	22.38
+Punctuation	66.38	22.74
+Be	66.54	22.81

Table 5: English-Chinese experimental results.

tained with contextual filtering. This shows the beneficial effect of contextual filtering.

Decoding speed. The decoding speed of our text normalization decoder was 0.2 seconds per message on our test sets, using a 2.27 GHz Intel Xeon CPU with 32 GB memory.

The effect of text normalization decoder on MT. We manually analyzed the effect of our text normalization decoder on MT. For example, given the un-normalized English test message “*yeah must sign up , im in lt25*”, our English-Chinese MT system translated it into “对[yeah] 必须[must] 签署[sign up] , im 在[in] lt25” On the other hand, our normalization decoder normalized it into “*yeah must sign up , i 'm in lt25*.” which was then translated into “对 必须 签署，我在 lt25。” by our MT system. This example shows that our text normalization decoder uses word normalization and punctuation correction to improve translation.

6 Conclusion

This paper presents a novel beam-search decoder for normalization of social media text. Our decoder for text normalization effectively integrates multiple normalization operations. In our experiments, we achieved statistically significant improve-

ments over two strong baselines: an improvement of 9.98%/7.35% in BLEU scores for normalization of Chinese/English social media text, and an improvement of 1.38%/1.35% in BLEU scores for translation of Chinese/English social media text. Future work can investigate how to more tightly integrate our beam-search decoder for text normalization with a standard MT decoder, e.g., by using a lattice or an n-best list.

Parameter Estimation for LDA-Frames

Jiří Materna

Centre for Natural Language Processing

Botanická 68a, 602 00, Brno, Czech Republic
xmaterna@fi.muni.cz

Abstract

LDA-frames is an unsupervised approach for identifying semantic frames from semantically unlabeled text corpora, and seems to be a useful competitor for manually created databases of selectional preferences. The most limiting property of the algorithm is such that the number of frames and roles must be predefined. In this paper we present a modification of the LDA-frames algorithm allowing the number of frames and roles to be determined automatically, based on the character and size of training data.

1 Introduction

Semantic frames and valency lexicons are useful lexical sources capturing semantic roles valid for a set of lexical units. The structures of linked semantic roles are called semantic frames. Linguists are using them for their ability to describe an interface between syntax and semantics. In practical natural language processing applications, they can be used, for instance, for the word sense disambiguation task or in order to resolve ambiguities in syntactic analysis of natural languages.

The lexicons of semantic frames or verb valencies are mainly created manually or semi-automatically by highly trained linguists. Manually created lexicons involve, for instance, a well-known lexicon of semantic frames FrameNet (Ruppenhofer et al., 2006) or a lexicon of verb valencies VerbNet (Schuler, 2006). These and other similar lexical resources have many promising applications, but suffer from several disadvantages:

- Creation of them requires manual work of trained linguists which is very time-consuming and expensive.
- Coverage of the resources is usually small or limited to some specific domain.
- Most of the resources do not provide any information about relative frequency of usage in corpora. For instance, both patterns [Person] *acquire* [Physical_object] and [Person] *acquire* [Disease] reflect correct usage of verb *acquire*, but the former is much more frequent in English.
- Notion of semantic classes and frames is subjectively biased when the frames are created manually without corpus evidence.

In order to avoid those problems we proposed a method for creating probabilistic semantic frames called LDA-frames (Materna, 2012). The main idea of LDA-frames is to generate the set of semantic frames and roles automatically by maximizing posterior probability of a probabilistic model on a syntactically annotated training corpus. A semantic role is represented as probability distribution over all its realizations in the corpus, a semantic frame as a tuple of semantic roles, each of them connected with some grammatical relation. For every lexical unit (a verb in case of computing verb valencies), a probability distribution over all semantic frames is generated, where the probability of a frame corresponds to the relative frequency of usage in the corpus for a given lexical unit. An example of LDA-frames

computed on the British National Corpus is available at the LDA-frames website¹.

The original LDA-frames algorithm has two parameters that must be predefined – number of frames and number of roles – which is the most limiting property of the algorithm. A simple cross-validation approach can be used in case of very small data. However, real data is much bigger and it is not recommended to use such techniques. For example, the inference on the British National Corpus using a single core 2.4 GHz CPU takes several days to compute one reasonable combination of parameters.

In this paper we present a non-parametric modification of the LDA-frames algorithm allowing to determine the parameters automatically, based on the character and size of training data.

2 LDA-Frames

LDA-frames (Materna, 2012) is an unsupervised approach for identifying semantic frames from semantically unlabeled text corpora. In the LDA-frames, a frame is represented as a tuple of semantic roles, each of them connected with a grammatical relation i.e. subject, object, modifier, etc. These frames are related to a lexical unit via probability distribution. Every semantic role is represented as probability distribution over its realizations.

The method of automatic identification of semantic frames is based on probabilistic generative process. Training data for the algorithm consists of tuples of grammatical relation realizations acquired using a dependency parser from the training corpus for every lexical unit. For example, suppose that the goal is to generate semantic frames of verbs from a corpus for grammatical relations *subject* and *object*. The training data for lexical unit *eat* may look like $\{(peter, \text{cake}), (\text{man}, \text{breakfast}), (\text{dog}, \text{meat}), \dots\}$, where the first component of the tuples corresponds to *subject* and the second to *object*.

In the generative process, each grammatical relation realization is treated as being generated from a given semantic frame according to the realization distribution of the corresponding semantic role. Supposing the number of frames is given by parameter F , the number of semantic roles by R , the num-

ber of slots (grammatical relations) by S and the size of vocabulary is V . The realizations are generated as follows.

For each lexical unit $u \in \{1, 2, \dots, U\}$:

1. Choose a frame distribution φ_u from $\text{Dir}(\alpha)$.
2. For each lexical unit realization $t \in \{1, 2, \dots, T_u\}$ choose a frame $f_{u,t}$ from $\text{Multinomial}(\varphi_u)$, where $f_{u,t} \in \{1, 2, \dots, F\}$.
3. For each slot $s \in \{1, 2, \dots, S\}$ of frame $f_{u,t}$, generate a grammatical relation realization $w_{u,t,s}$ from $\text{Multinomial}(\theta_{r_{f_{u,t},s}})$, where $r_{f,s}$ is a projection $(f, s) \mapsto r$, which assigns a semantic role for each slot s in frame f . The multinomial distribution of realizations, symbolized by θ_r , for semantic role r is generated from $\text{Dir}(\beta)$.

The graphical model for LDA-Frames is shown in figure 1. It is parametrized by hyperparameters of prior distributions α and β , usually set by hand to a value between 0.01 – 0.1.

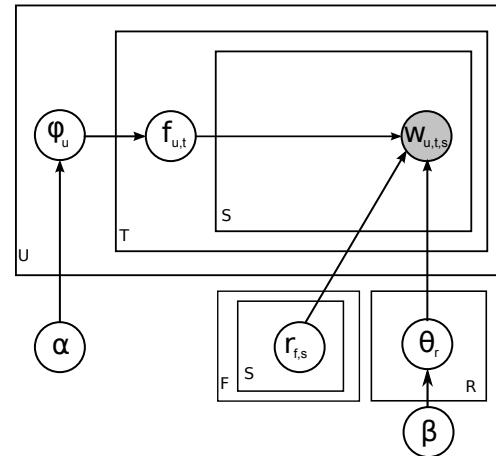

Figure 1: Graphical model for LDA-frames.

The inference is performed using the Collapsed Gibbs sampling (Neal, 2000), where the θ and φ distributions are marginalized out of the equations. In each iteration, latent variables $f_{u,t}$ and $r_{f,s}$ are sampled as follows

$$P(f_{u,t} | \mathbf{f}^{-(u,t)}, \mathbf{r}, \mathbf{w}, \alpha, \beta) \propto \\ (f c_{f_{u,t}, u}^{-1} + \alpha) \prod_{s=1}^S \frac{w c_{w_{u,t,s}, r_{f_{u,t}, s}}^{-1} + \beta}{w c_{*, r_{f_{u,t}, s}}^{-1} + V \beta} \quad (1)$$

¹<http://nlp.fi.muni.cz/projekty/lda-frames/>

$$P(r_{f,s} | \mathbf{f}, \mathbf{r}^{-(f,s)}, \mathbf{w}, \alpha, \beta) \propto \prod_{v=1}^V \left(\frac{wc_{v,r_{f,s}}^{-(f,s)} + \beta}{wc_{*,r_{f,s}}^{-(f,s)} + V\beta} \right)^{wc_{f,s,v}}, \quad (2)$$

where $fc_{f,u}^{-(u,t)}$ is the number of times frame f is assigned to lexical unit u excluding (u, t) , $wc_{v,r}^{-(u,t,s)}$ is the number of times word v is assigned to role r excluding (u, t, s) , and $wc_{f,s,v}$ is the number of times word v is assigned to slot s in frame f . The asterisk sign * stands for any value in its position.

After having all latent variables \mathbf{f} and \mathbf{r} inferred, one can proceed to compute the lexical unit-frame distribution and the semantic role-word distribution using the following formulas:

$$\varphi_u = \frac{fc_{f,u} + \alpha}{\sum_f fc_{f,u} + F\alpha} \quad (3)$$

$$\theta_r = \frac{wc_{v,r} + \beta}{\sum_v wc_{v,r} + V\beta}. \quad (4)$$

3 Parameter Estimation

As one can see from the LDA-frames model, the requirement is to define the number of frames and roles in advance. It is not clear, however, how to select the best values that depend on several factors. First of all, the number of frames and roles usually increase with the growing size of training corpus. If the training data is small and covers just a small proportion of lexical unit usage patterns, the number of semantic frames should be small as well. The parameters are also affected by the granularity of roles and frames. One way to estimate the parameters automatically is to select those that maximize posterior probability of the model given training data.

LDA-frames algorithm generates frames from the Dirichlet distribution (DD) which requires a fixed number of components. Similarly, the latent variables $r_{f,s}$ are chosen from a fixed set of semantic roles. In order to be able to update the number of frames and roles during the inference process, we propose to add the Chinese restaurant process (CRP) (Aldous, 1985) prior for the $r_{f,s}$ variables, and to replace the Dirichlet distribution the semantic frames are generated from with the Dirichlet process (Ferguson, 1973).

3.1 Number of Semantic Roles

In the original version of the LDA-frames model, the latent variables $r_{f,s}$, representing semantic role assignment for slot s in frame f , are chosen from a fixed set of semantic roles without any prior distribution. We propose to generate $r_{f,s}$ from the CRP, which is a single parameter distribution over partitions of integers. The generative process can be described by using an analogy with a Chinese restaurant. Consider a restaurant with an infinite number of tables, each of them associated with some dish, and N customers choosing a table. The first customer sits at the first table. The n^{th} customer sits at table t drawn from the following distribution

$$P(t = \text{occupied table } i) = \frac{n_i}{\gamma + n - 1} \quad (5)$$

$$P(t = \text{next unoccupied table}) = \frac{\gamma}{\gamma + n - 1},$$

where n_i is the number of customers sitting at the table i and $\gamma > 0$ is a concentration parameter which controls how often a customer chooses a new table. The seating plan makes a partition of the customers (Aldous, 1985).

In the proposed modification of the LDA-frames model, the dishes are replaced with the semantic role numbers and customers with slots of frames. In the model we use prior distribution ω corresponding to the CRP with concentration parameter γ . The latent variables $r_{f,s}$ are then sampled as follows

$$P(r_{f,s} | \mathbf{f}, \mathbf{r}^{-(f,s)}, \mathbf{w}, \alpha, \beta, \gamma) \propto (rc_{r_{f,s}}^{-(f,s)} + \gamma) \prod_{v=1}^V \left(\frac{wc_{v,r_{f,s}}^{-(f,s)} + \beta}{wc_{*,r_{f,s}}^{-(f,s)} + V\beta} \right)^{wc_{f,s,v}}, \quad (6)$$

where $rc_r^{-(f,s)}$ is the number of times role r is used in any frame and slot excluding slot s in frame f . Notice that the sampling space has $R+1$ dimensions with the probability of the last unseen component proportional to

$$\gamma \prod_{v=1}^V \frac{1}{V^{wc_{f,s,v}}}. \quad (7)$$

3.2 Number of Semantic Frames

Estimating the number of frames is a little bit more complicated than the case of semantic roles. The idea is to replace DD φ_u with the Dirichlet process.

The Dirichlet process $DP(\alpha_0, G_0)$ is a stochastic process that generates discrete probability distributions. It has two parameters, a base distribution G_0 and a concentration parameter $\alpha_0 > 0$. A sample from the Dirichlet process (DP) is then

$$G = \sum_{k=1}^{\infty} \beta_k \delta_{\phi_k}, \quad (8)$$

where ϕ_k are independent random variables distributed according to G_0 , δ_{ϕ_k} is an atom at ϕ_k , and weights β_k are also random and dependent on the parameter α_0 (Teh et al., 2006). Simply, DP is a distribution over some infinite and discrete distributions. It is the reason why DP is often used instead of DD in order to avoid using a fixed number of components.

The question, however, is how to make the sampled frames shared between different lexical units. We propose to generate base distributions of the DPs from GEM distribution (Pitman, 2002) τ with concentration parameter δ . The idea is inspired by the Hierarchical Dirichlet Process (Teh et al., 2006) used for topic modeling. The graphical model of the non-parametric LDA-frames is shown in figure 2.

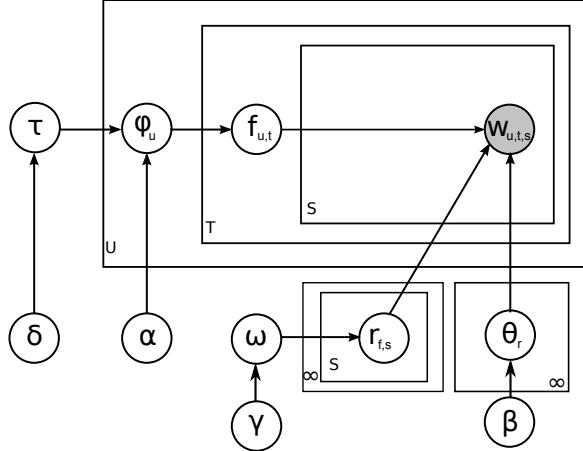

Figure 2: Graphical model for non-parametric LDA-frames.

Since it is hard to integrate out the DP with base distribution generated from GEM in this model, we proceeded to sample τ separately (Porteous, 2010). The base distribution proportions can be sampled by simulating how new components are created for $f_{cf,u}$ draws from DP with the concentration parameter $\alpha\tau_f$, which is a sequence of Bernoulli trials for

each u and f (Heinrich, 2011):

$$\begin{aligned} P(u_{f,u,r} = 1) &= \frac{\alpha\tau_f}{\alpha\tau_f + r - 1} \forall r \in [1, f_{cf,u}] \\ \tau &\sim \text{Dir}(\{u_f\}_f, \delta) \text{ with } u_f = \sum_u \sum_r u_{f,u,r}. \end{aligned} \quad (9)$$

Finally, the latent variables $f_{u,t}$ are sampled as follows

$$\begin{aligned} P(f_{u,t} | \mathbf{f}^{-(u,t)}, \mathbf{r}, \mathbf{w}, \alpha, \beta, \tau) &\propto \\ (fc_{f_{u,t},u}^{-}(u,t) + \alpha\tau_f) \prod_{s=1}^S &\frac{wc_{w_{u,t,s},r_{f_{u,t},s}}^{-(u,t,s)} + \beta}{wc_{*,r_{f_{u,t},s}}^{-(u,t,s)} + V\beta}. \end{aligned} \quad (10)$$

4 Evaluation

The non-parametric algorithm was evaluated by an experiment on a synthetic data set consisting of 155 *subject-object* tuples. The training data was generated randomly from a predefined set of 7 frames and 4 roles for 16 verbs using the following algorithm. For every lexical unit u :

1. Choose a number of corpus realizations $N_u \in \{5, \dots, 15\}$ from the uniform distribution.
2. For each realization $n_u \in \{1, \dots, N_u\}$, among all permitted frames for lexical unit u , choose a semantic frame f_{n_u} from the uniform distribution.
3. For each frame f_{n_u} , generate a realization of all its roles from the uniform distribution.

Each semantic role had 6 possible realizations on average, some of them assigned to more than one semantic role to reflect the character of real languages. Since the data was generated artificially, we knew the number of frames and roles, how the frames were defined, and which frame and which role was responsible for generating each realization in the data.

We ran the non-parametric algorithm with hyperparameters $\alpha = 5, \beta = \gamma = 0.1, \delta = 1.5$. It has been shown that the selection of hyperparameters has little impact on the resulting frames when they are in some reasonable range, thus, the hyperparameters were chosen empirically by hand. The experiment led to correct assignments of $f_{u,t}$ and $r_{f,s}$ after 56 iterations on average (based on 10 independent runs of the algorithm).

In order to compare the non-parametric algorithm with the original, we ran the original algorithm with the same data that had the number of frames and roles set to $R \in \{1 \dots 10\}$, $F \in \{1 \dots 20\}$, and measured the perplexity of the data given to the model after convergence. The perplexities for all settings are shown in figure 3. The lowest perplexity was reached with $F = 7$, $R = 4$ and had the same value as the case of the non-parametric algorithm. The $f_{u,t}$ and $r_{f,s}$ assignments were correct as well.

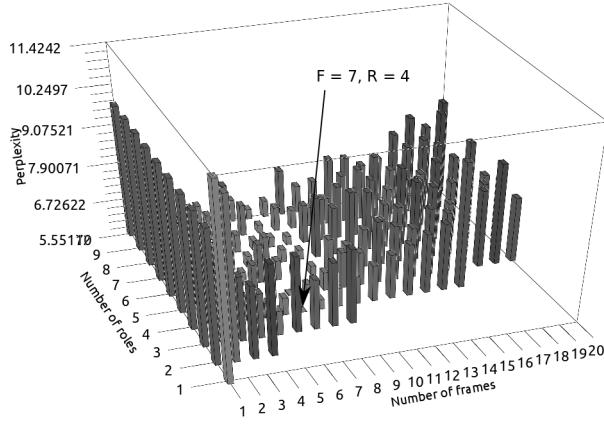

Figure 3: Perplexities for different values of F and R .

We also ran the non-parametric algorithm with the same hyperparameters on real data (1.4 millions of *subject-object* tuples) acquired from the British National Corpus² using the Stanford Parser (de Marneffe et al., 2006). The algorithm reached the optimal perplexity with 427 frames and 144 roles. This experiment has been performed only for illustrating the algorithm on real data. Because of long running time of the algorithm on such huge data set, we did not perform the same experiments as with the case of the small synthetic data.

5 Conclusion

In this paper we presented a method for estimating the number of frames and roles for the LDA-frames model. The idea is based on using the Chinese Restaurant Process and the Dirichlet Process instead of the Dirichlet Distributions and selecting such parameters that maximize the posterior probability of the model for given training data. An experiment showed that the non-parametric algorithm

infers correct values of both the number of frames and roles on a synthetic data set.

Abstract

We provide an approximation algorithm for PCFG parsing, which asymptotically improves time complexity with respect to the input grammar size, and prove upper bounds on the approximation quality. We test our algorithm on two treebanks, and get significant improvements in parsing speed.

1 Introduction

The problem of speeding-up parsing algorithms based on probabilistic context-free grammars (PCFGs) has received considerable attention in recent years. Several strategies have been proposed, including beam-search, best-first and A*. In this paper we focus on the standard approach of approximating the source PCFG in such a way that parsing accuracy is traded for efficiency.

Nederhof (2000) gives a thorough presentation of old and novel ideas for approximating non-probabilistic CFGs by means of finite automata, on the basis of specialized preprocessing of self-embedding structures. In the probabilistic domain, approximation by means of regular grammars is also exploited by Eisner and Smith (2005), who filter long-distance dependencies on-the-fly.

Beyond finite automata approximation, Charniak et al. (2006) propose a coarse-to-fine approach in which an approximated (not necessarily regular) PCFG is used to construct a parse forest for the input sentence. Some statistical parameters are then computed on such a structure, and exploited to filter parsing with the non-approximated grammar. The approach can also be iterated at several levels. In the non-probabilistic setting, a similar filtering ap-

proach was also proposed by Boullier (2003), called “guided parsing.”

In this paper we rely on an algebraic formulation of the inside-outside algorithm for PCFGs, based on a tensor formulation developed for latent-variable PCFGs in Cohen et al. (2012). We combine the method with known techniques for tensor decomposition to approximate the source PCFG, and develop a novel algorithm for approximate PCFG parsing. We obtain improved time upper bounds with respect to the input grammar size for PCFG parsing, and provide error upper bounds on the PCFG approximation, in contrast with existing heuristic methods.

2 Preliminaries

This section introduces the special representation for probabilistic context-free grammars that we adopt in this paper, along with the decoding algorithm that we investigate. For an integer $i \geq 1$, we let $[i] = \{1, 2, \dots, i\}$.

2.1 Probabilistic Context-Free Grammars

We consider context-free grammars (CFGs) in Chomsky normal form, and denote them as $(\mathcal{N}, \mathcal{L}, \mathcal{R})$ where:

- \mathcal{N} is the finite set of nonterminal symbols, with $m = |\mathcal{N}|$, and \mathcal{L} is the finite set of words (lexical tokens), with $\mathcal{L} \cap \mathcal{N} = \emptyset$ and with $n = |\mathcal{L}|$.
- \mathcal{R} is a set of rules having the form $a \rightarrow b c$, $a, b, c \in \mathcal{N}$, or the form $a \rightarrow x$, $a \in \mathcal{N}$ and $x \in \mathcal{L}$.

A probabilistic CFG (PCFG) is a CFG associated with a set of parameters defined as follows:

- For each $(a \rightarrow b c) \in \mathcal{R}$, we have a parameter $p(a \rightarrow b c | a)$.

- For each $(a \rightarrow x) \in \mathcal{R}$, we have a parameter $p(a \rightarrow x | a)$.
- For each $a \in \mathcal{N}$, we have a parameter π_a , which is the probability of a being the root symbol of a derivation.

The parameters above satisfy the following normalization conditions:

$$\sum_{(a \rightarrow b c) \in \mathcal{R}} p(a \rightarrow b c | a) + \sum_{(a \rightarrow x) \in \mathcal{R}} p(a \rightarrow x | a) = 1,$$

for each $a \in \mathcal{N}$, and $\sum_{a \in \mathcal{N}} \pi_a = 1$.

The probability of a tree τ deriving a sentence in the language, written $p(\tau)$, is calculated as the product of the probabilities of all rule occurrences in τ , times the parameter π_a where a is the symbol at the root of τ .

2.2 Tensor Form of PCFGs

A three-dimensional **tensor** $C \in \mathbb{R}^{(m \times m \times m)}$ is a set of m^3 parameters $C_{i,j,k}$ for $i, j, k \in [m]$. In what follows, we associate with each tensor three functions, each mapping a pair of vectors in \mathbb{R}^m into a vector in \mathbb{R}^m .

Definition 1 Let $C \in \mathbb{R}^{(m \times m \times m)}$ be a tensor. Given two vectors $y^1, y^2 \in \mathbb{R}^m$, we let $C(y^1, y^2)$ be the m -dimensional row vector with components:

$$[C(y^1, y^2)]_i = \sum_{j \in [m], k \in [m]} C_{i,j,k} y_j^1 y_k^2.$$

We also let $C_{(1,2)}(y^1, y^2)$ be the m -dimensional column vector with components:

$$[C_{(1,2)}(y^1, y^2)]_k = \sum_{i \in [m], j \in [m]} C_{i,j,k} y_i^1 y_j^2.$$

Finally, we let $C_{(1,3)}(y^1, y^2)$ be the m -dimensional column vector with components:

$$[C_{(1,3)}(y^1, y^2)]_j = \sum_{i \in [m], k \in [m]} C_{i,j,k} y_i^1 y_k^2.$$

For two vectors $x, y \in \mathbb{R}^m$ we denote by $x \odot y \in \mathbb{R}^m$ the Hadamard product of x and y , i.e., $[x \odot y]_i = x_i y_i$. Finally, for vectors $x, y, z \in \mathbb{R}^m$, $xy^\top z^\top$ is the

tensor $D \in \mathbb{R}^{m \times m \times m}$ where $D_{i,j,k} = x_i y_j z_k$ (this is analogous to the outer product: $[xy^\top]_{i,j} = x_i y_j$).

We extend the parameter set of our PCFG such that $p(a \rightarrow b c | a) = 0$ for all $a \rightarrow b c$ not in \mathcal{R} , and $p(a \rightarrow x | a) = 0$ for all $a \rightarrow x$ not in \mathcal{R} . We also represent each $a \in \mathcal{N}$ by a unique index in $[m]$, and we represent each $x \in \mathcal{L}$ by a unique index in $[n]$: it will always be clear from the context whether these indices refer to a nonterminal in \mathcal{N} or else to a word in \mathcal{L} .

In this paper we assume a tensor representation for the parameters $p(a \rightarrow b c | a)$, and we denote by $T \in \mathbb{R}^{m \times m \times m}$ a tensor such that:

$$T_{a,b,c} \triangleq p(a \rightarrow b c | a).$$

Similarly, we denote by $Q \in \mathbb{R}^{m \times n}$ a matrix such that:

$$Q_{a,x} \triangleq p(a \rightarrow x | a).$$

The root probabilities are denoted using a vector $\pi \in \mathbb{R}^{m \times 1}$ such that π_a is defined as before.

2.3 Minimum Bayes-Risk Decoding

Let $z = x_1 \cdots x_N$ be some input sentence; we write $\mathcal{T}(z)$ to denote the set of all possible trees for z . It is often the case that parsing aims to find the highest scoring tree τ^* for z according to the underlying PCFG, also called the “Viterbi parse.”

$$\tau^* = \operatorname{argmax}_{\tau \in \mathcal{T}(z)} p(\tau)$$

Goodman (1996) noted that Viterbi parsers do not optimize the same metric that is usually used for parsing evaluation (Black et al., 1991). He suggested an alternative algorithm, which he called the “Labelled Recall Algorithm,” which aims to fix this issue.

Goodman’s algorithm has two phases. In the first phase it computes, for each $a \in \mathcal{N}$ and for each substring $x_i \cdots x_j$ of z , the marginal $\mu(a, i, j)$ defined as:

$$\mu(a, i, j) = \sum_{\tau \in \mathcal{T}(z): (a, i, j) \in \tau} p(\tau).$$

Here we write $(a, i, j) \in \tau$ if nonterminal a spans words $x_i \cdots x_j$ in the parse tree τ .

Inputs: Sentence $x_1 \cdots x_N$, PCFG $(\mathcal{N}, \mathcal{L}, \mathcal{R})$, parameters $T \in \mathbb{R}^{(m \times m \times m)}$, $Q \in \mathbb{R}^{(m \times n)}$, $\pi \in \mathbb{R}^{(m \times 1)}$.

Data structures:

- Each $\mu(a, i, j) \in \mathbb{R}$ for $a \in \mathcal{N}$, $i, j \in [N]$, $i \leq j$, is a marginal probability.
- Each $\gamma^{i,j} \in \mathbb{R}$ for $i, j \in [N]$, $i \leq j$, is the highest score for a tree spanning substring $x_i \cdots x_j$.

Algorithm:

(Marginals) $\forall a \in \mathcal{N}, \forall i, j \in [N], i \leq j$, compute the marginals $\mu(a, i, j)$ using the inside-outside algorithm.

(Base case) $\forall i \in [N]$,

$$\gamma^{i,i} = \max_{(a \rightarrow x_i) \in \mathcal{R}} \mu(a, i, i)$$

(Maximize Labelled Recall) $\forall i, j \in [N], i < j$,

$$\gamma^{i,j} = \max_{a \in \mathcal{N}} \mu(a, i, j) + \max_{i \leq k < j} (\gamma^{i,k} + \gamma^{k+1,j})$$

Figure 1: The labelled recall algorithm from Goodman (1996). The algorithm in this figure finds the highest score for a tree which maximizes labelled recall. The actual parsing algorithm would use backtrack pointers in the score computation to return a tree. These are omitted for simplicity.

The second phase includes a dynamic programming algorithm which finds the tree τ^* that maximizes the sum over marginals in that tree:

$$\tau^* = \operatorname{argmax}_{\tau \in \mathcal{T}(z)} \sum_{(a, i, j) \in \tau} \mu(a, i, j).$$

Goodman’s algorithm is described in Figure 1.

As Goodman notes, the complexity of the second phase (“Maximize Labelled Recall,” which is also referred to as “minimum Bayes risk decoding”) is $\mathcal{O}(N^3 + mN^2)$. There are two nested outer loops, each of order N , and inside these, there are two separate loops, one of order m and one of order N , yielding this computational complexity. The reason

for the linear dependence on the number of nonterminals is the lack of dependence on the actual grammar rules, once the marginals are computed.

In its original form, Goodman’s algorithm does not enforce that the output parse trees are included in the tree language of the PCFG, that is, certain combinations of children and parent nonterminals may violate the rules in the grammar. In our experiments we departed from this, and changed Goodman’s algorithm by incorporating the grammar into the dynamic programming algorithm in Figure 1. The reason this is important for our experiments is that we *binarize* the grammar prior to parsing, and we need to enforce the links between the split nonterminals (in the binarized grammar) that refer to the same syntactic category. See Matsuzaki et al. (2005) for more details about the binarization scheme we used. This step changes the dynamic programming equation of Goodman to be linear in the size of the grammar (figure 1). However, empirically, it is the inside-outside algorithm which takes most of the time to compute with Goodman’s algorithm. In this paper we aim to asymptotically reduce the time complexity of the calculation of the inside-outside probabilities using an approximation algorithm.

3 Tensor Formulation of the Inside-Outside Algorithm

At the core of our approach lies the observation that there is a (multi)linear algebraic formulation of the inside-outside algorithm. It can be represented as a series of tensor, matrix and vector products. A similar observation has been made for latent-variable PCFGs (Cohen et al., 2012) and hidden Markov models, where only matrix multiplication is required (Jaeger, 2000). Cohen and Collins (2012) use this observation together with tensor decomposition to improve the speed of latent-variable PCFG parsing.

The representation of the inside-outside algorithm in tensor form is given in Figure 2. For example, if we consider the recursive equation for the inside probabilities (where $\alpha^{i,j}$ is a vector varying over the nonterminals in the grammar, describing the inside probability for each nonterminal spanning words i to j):

$$\alpha^{i,j} = \sum_{k=i}^{j-1} T(\alpha^{i,k}, \alpha^{k+1,j})$$

Inputs: Sentence $x_1 \cdots x_N$, PCFG $(\mathcal{N}, \mathcal{L}, \mathcal{R})$, parameters $T \in \mathbb{R}^{(m \times m \times m)}$, $Q \in \mathbb{R}^{(m \times n)}$, $\pi \in \mathbb{R}^{(m \times 1)}$.

Data structures:

- Each $\alpha^{i,j} \in \mathbb{R}^{1 \times m}$, $i, j \in [N]$, $i \leq j$, is a row vector of inside terms ranging over $a \in \mathcal{N}$.
- Each $\beta^{i,j} \in \mathbb{R}^{m \times 1}$, $i, j \in [N]$, $i \leq j$, is a column vector of outside terms ranging over $a \in \mathcal{N}$.
- Each $\mu(a, i, j) \in \mathbb{R}$ for $a \in \mathcal{N}$, $i, j \in [N]$, $i \leq j$, is a marginal probability.

Algorithm:

(Inside base case) $\forall i \in [N], \forall (a \rightarrow x_i) \in \mathcal{R}$,

$$[\alpha^{i,i}]_a = Q_{a,x}$$

(Inside recursion) $\forall i, j \in [N], i < j$,

$$\alpha^{i,j} = \sum_{k=i}^{j-1} T(\alpha^{i,k}, \alpha^{k+1,j})$$

(Outside base case) $\forall a \in \mathcal{N}$,

$$[\beta^{1,N}]_a = \pi_a$$

(Outside recursion) $\forall i, j \in [N], i \leq j$,

$$\begin{aligned} \beta^{i,j} = & \sum_{k=1}^{i-1} T_{(1,2)}(\beta^{k,j}, \alpha^{k,i-1}) + \\ & \sum_{k=j+1}^N T_{(1,3)}(\beta^{i,k}, \alpha^{j+1,k}) \end{aligned}$$

(Marginals) $\forall a \in \mathcal{N}, \forall i, j \in [N], i \leq j$,

$$\mu(a, i, j) = [\alpha^{i,j}]_a \cdot [\beta^{i,j}]_a$$

Figure 2: The tensor form of the inside-outside algorithm, for calculation of marginal terms $\mu(a, i, j)$.

and then apply the tensor product from Definition 1 to this equation, we get that coordinate a in $\alpha^{i,j}$ is

defined recursively as follows:

$$\begin{aligned} [\alpha^{i,j}]_a &= \sum_{k=i}^{j-1} \sum_{b,c} T_{a,b,c} \times \alpha_b^{i,k} \times \alpha_c^{k+1,j} \\ &= \sum_{k=i}^{j-1} \sum_{b,c} p(a \rightarrow b c | a) \times \alpha_b^{i,k} \times \alpha_c^{k+1,j}, \end{aligned}$$

which is exactly the recursive definition of the inside algorithm. The correctness of the outside recursive equations follows very similarly.

The time complexity of the algorithm in this case is $\mathcal{O}(m^3 N^3)$. To see this, observe that each tensor application takes time $\mathcal{O}(m^3)$. Furthermore, the tensor T is applied $\mathcal{O}(N)$ times in the computation of each vector $\alpha^{i,j}$ and $\beta^{i,j}$. Finally, we need to compute a total of $\mathcal{O}(N^2)$ inside and outside vectors, one for each substring of the input sentence.

4 Tensor Decomposition for the Inside-Outside Algorithm

In this section, we detail our approach to approximate parsing using tensor decomposition.

4.1 Tensor Decomposition

In the formulation of the inside-outside algorithm based on tensor T , each vector $\alpha^{i,j}$ and $\beta^{i,j}$ consists of m elements, where computation of each element requires time $\mathcal{O}(m^2)$. Therefore, the algorithm has a $\mathcal{O}(m^3)$ multiplicative factor in its time complexity, which we aim to reduce by means of an approximate algorithm.

Our approximate method relies on a simple observation. Given an integer $r \geq 1$, assume that the tensor T has the following special form, called ‘‘Kruskal form’’:

$$T = \sum_{i=1}^r \lambda_i u_i v_i^\top w_i^\top. \quad (1)$$

In words, T is the sum of r tensors, where each tensor is obtained as the product of three vectors u_i , v_i and w_i , together with a scalar λ_i . Exact Kruskal decomposition of a tensor is not necessarily unique. See Kolda and Bader (2009) for discussion of uniqueness of tensor decomposition.

Consider now two vectors $y^1, y^2 \in \mathbb{R}^m$, associated with the inside probabilities for the left (y^1) and right child (y^2) of a given node in a parse tree. Let us introduce auxiliary arrays $U, V, W \in \mathbb{R}^{r \times m}$, with the i -th row being u_i , v_i and w_i , respectively. Let also $\lambda = (\lambda_1, \dots, \lambda_r)$. Using the decomposition in Eq. (1) within Definition 1 we can express the array $T(y^1, y^2)$ as:

$$\begin{aligned} T(y^1, y^2) &= \left[\sum_{i=1}^r \lambda_i u_i v_i^\top w_i^\top \right] (y^1, y^2) = \\ &= \sum_{i=1}^r \lambda_i u_i (v_i^\top y^1) (w_i^\top y^2) = \\ &= \left(U^\top (\lambda \odot V y^1 \odot W y^2) \right). \end{aligned} \quad (2)$$

The total complexity of the computation in Eq. (2) is now $\mathcal{O}(rm)$. It is well-known that an exact tensor decomposition for T can be achieved with $r = m^2$ (Kruskal, 1989). In this case, there is no computational gain in using Eq. (2) for the inside calculation. The minimal r required for an exact tensor decomposition can be smaller than m^2 . However, identifying that minimal r is NP-hard (Høastad, 1990).

In this section we focused on the computation of the inside probabilities through vectors $T(\alpha^{i,k}, \alpha^{k+1,j})$. Nonetheless, the steps above can be easily adapted for the computation of the outside probabilities through vectors $T_{(1,2)}(\beta^{k,j}, \alpha^{k,i-1})$ and $T_{(1,3)}(\beta^{i,k}, \alpha^{j+1,k})$.

4.2 Approximate Tensor Decomposition

The PCFG tensor T will not necessarily have the exact decomposed form in Eq. (1). We suggest to *approximate* the tensor T by finding the closest tensor according to some norm over $\mathbb{R}^{m \times m \times m}$.

An example of such an approximate decomposition is the canonical polyadic decomposition (CPD), also known as CANDECOMP/PARAFAC decomposition (Carroll and Chang, 1970; Harshman, 1970; Kolda and Bader, 2009). Given an integer r , *least squares* CPD aims to find the nearest tensor in Kruskal form, minimizing squared error.

More formally, for a given tensor $D \in \mathbb{R}^{m \times m \times m}$, let $\|D\|_F = \sqrt{\sum_{i,j,k} D_{i,j,k}^2}$. Let the set of tensors in

Kruskal form \mathcal{C}_r be:

$$\begin{aligned} \mathcal{C}_r = \{C \in \mathbb{R}^{m \times m \times m} \mid C &= \sum_{i=1}^r \lambda_i u_i v_i^\top w_i^\top \\ \text{s.t. } \lambda_i &\in \mathbb{R}, u_i, v_i, w_i \in \mathbb{R}^m, \\ \|u_i\|_2 &= \|v_i\|_2 = \|w_i\|_2 = 1\}. \end{aligned}$$

The least squares CPD of C is a tensor \hat{C} such that $\hat{C} \in \operatorname{argmin}_{\hat{C} \in \mathcal{C}_r} \|C - \hat{C}\|_F$. Here, we treat the argmin as a set because there could be multiple solutions which achieve the same accuracy.

There are various algorithms to perform CPD, such as alternating least squares, direct linear decomposition, alternating trilinear decomposition and pseudo alternating least squares (Faber et al., 2003) and even algorithms designed for sparse tensors (Chi and Kolda, 2011). Most of these algorithms treat the problem of identifying the approximate tensor as an optimization problem. Generally speaking, these optimization problems are hard to solve, but they work quite well in practice.

4.3 Parsing with Decomposed Tensors

Equipped with the notion of tensor decomposition, we can now proceed with approximate tensor parsing in two steps. The first is approximating the tensor using a CPD algorithm, and the second is applying the algorithms in Figure 1 and Figure 2 to do parsing, while substituting all tensor product computations with the approximate $\mathcal{O}(rm)$ operation of tensor product.

This is not sufficient to get a significant speed-up in parsing time. Re-visiting Eq. (2) shows that there are additional ways to speed-up the tensor application T in the context of the inside-outside algorithm.

The first thing to note is that the projections $V y^1$ and $W y^2$ in Eq. (2) can be cached, and do not have to be re-calculated every time the tensor is applied. Here, y^1 and y^2 will always refer to an outside or an inside probability vector over the nonterminals in the grammar. Caching these projections means that after each computation of an inside or outside probability, we can immediately project it to the necessary r -dimensional space, and then re-use this computation in subsequent application of the tensor.

The second thing to note is that the U projection in T can be delayed, because of rule of distributivity. For example, the step in Figure 2 that computes

the inside probability $\alpha^{i,j}$ can be re-formulated as follows (assuming an exact decomposition of T):

$$\begin{aligned}\alpha^{i,j} &= \sum_{k=i}^{j-1} T(\alpha^{i,k}, \alpha^{k+1,j}) \\ &= \sum_{k=1}^{j-1} U^\top (\lambda \odot V\alpha^{i,k} \odot W\alpha^{k+1,j}) \\ &= U^\top \left(\sum_{k=1}^{j-1} (\lambda \odot V\alpha^{i,k} \odot W\alpha^{k+1,j}) \right). \quad (3)\end{aligned}$$

This means that projection through U can be done outside of the loop over splitting points in the sentence. Similar reliance on distributivity can be used to speed-up the outside calculations as well.

The caching speed-up and the delayed projection speed-up make the approximate inside-outside computation asymptotically faster. While naïve application of the tensor yields an inside algorithm which runs in time $\mathcal{O}(rmN^3)$, the improved algorithm runs in time $\mathcal{O}(rN^3 + rmN^2)$.

5 Quality of Approximate Tensor Parsing

In this section, we give the main approximation result, that shows that the probability distribution induced by the approximate tensor is close to the original probability distribution, if the distance between the approximate tensor and the rule probabilities is not too large.

Denote by $\mathcal{T}(N)$ the set of trees in the tree language of the PCFG with N words (any nonterminal can be the root of the tree). Let $\bar{\mathcal{T}}(N)$ be the set of pairs of trees $\bar{\tau} = (\tau_1, \tau_2)$ such that the total number of binary rules combined in τ_1 and τ_2 is $N - 2$ (this means that the total number of words combined is N). Let \hat{T} be the approximate tensor for T . Denote the probability distribution induced by \hat{T} by \hat{p} .¹ Define the vector $\xi(\bar{\tau})$ such that $[\xi(\bar{\tau})]_a = T_{a,b,c} \cdot p(\tau_1 | b) \cdot p(\tau_2 | c)$ where the root τ_1 is nonterminal b and the root of τ_2 is c . Similarly, define $[\hat{\xi}(\bar{\tau})]_a = \hat{T}_{a,b,c} \cdot \hat{p}(\tau_1 | b) \cdot \hat{p}(\tau_2 | c)$.

Define $Z(a, N) = \sum_{\bar{\tau} \in \bar{\mathcal{T}}(N)} [\hat{\xi}(\bar{\tau})]_a$. In addition, define $D(a, N) = \sum_{\bar{\tau} \in \bar{\mathcal{T}}(N)} |[\hat{\xi}(\bar{\tau})]_a - [\xi(\bar{\tau})]_a|$

¹Here, \hat{p} does not have to be a distribution, because \hat{T} could have negative values, in principle, and its slices do not have to normalize to 1. However, we just treat \hat{p} as a function that maps trees to products of values according to \hat{T} .

and define $F(a, N) = D(a, N)/Z(a, N)$. Define $\Delta = \|\hat{T} - T\|_F$. Last, define $\nu = \min_{(a \rightarrow b \mid c) \in \mathcal{R}} p(a \rightarrow b \mid c)$. Then, the following lemma holds:

Lemma 1 *For any a and any N , it holds:*

$$D(a, N) \leq Z(a, N) ((1 + \Delta/\nu)^N - 1)$$

Proof sketch: The proof is by induction on N . Assuming that $1 + F(b, k) \leq (1 + \Delta/\nu)^k$ and $1 + F(c, N - k - 1) \leq (1 + \Delta/\nu)^{N-k-1}$ for F defined as above (this is the induction hypothesis), it can be shown that the lemma holds. ■

Lemma 2 *The following holds for any N :*

$$\sum_{\tau \in \mathcal{T}(N)} |\hat{p}(\tau) - p(\tau)| \leq m ((1 + \Delta/\nu)^N - 1)$$

Proof sketch: Using Hölder's inequality and Lemma 1 and the fact that $Z(a, N) \leq 1$, it follows that:

$$\begin{aligned}\sum_{\tau \in \mathcal{T}(N)} |\hat{p}(\tau) - p(\tau)| &\leq \sum_{\bar{\tau} \in \bar{\mathcal{T}}(N), a} |[\xi(\bar{\tau})]_a - [\hat{\xi}(\bar{\tau})]_a| \\ &\leq \left(\sum_a Z(a, N) \right) ((1 + \Delta/\nu)^N - 1) \\ &\leq m ((1 + \Delta/\nu)^N - 1)\end{aligned}$$

Then, the following is a result that explains how accuracy changes as a function of the quality of the tensor approximation:

Theorem 1 *For any N , and $\epsilon < 1/4$, it holds that if $\Delta \leq \frac{\epsilon\nu}{2Nm}$, then:*

$$\sum_{\tau \in \mathcal{T}(N)} |\hat{p}(\tau) - p(\tau)| \leq \epsilon$$

Proof sketch: This is the result of applying Lemma 2 together with the inequality $(1 + y/t)^t - 1 \leq 2y$ for any $t > 0$ and $y \leq 1/2$. ■

We note that Theorem 1 also implicitly bounds the difference between a marginal $\mu(a, i, j)$ and its approximate version. A marginal corresponds to a sum over a subset of summands in Eq. (1).

A question that remains at this point is to decide whether for a given grammar, the optimal ν that can be achieved is large or small. We define:

$$\Delta_r^* = \min_{\hat{T} \in \mathcal{C}_r} \|T - \hat{T}\|_F \quad (4)$$

The following theorem gives an upper bound on the value of Δ_r^* based on intrinsic property of the grammar, or more specifically T . It relies on the fact that for three-dimensional tensors, where each dimension is of length m , there exists an exact decomposition of T using m^2 components.

Theorem 2 *Let:*

$$T = \sum_{i=1}^{m^2} \lambda_i^* u_i^* (v_i^*)^\top (w_i^*)^\top$$

be an exact Kruskal decomposition of T such that $\|u_i^\|_2 = \|v_i^*\|_2 = \|w_i^*\| = 1$ and $\lambda_i^* \geq \lambda_{i+1}^*$ for $i \in [m^2 - 1]$. Then, for a given r , it holds:*

$$\Delta_r^* \leq \sum_{i=r+1}^{m^2} |\lambda_i^*|$$

Proof: Let \hat{T} be a tensor that achieves the minimum in Eq. (4). Define:

$$T'_r = \sum_{i=1}^r \lambda_i^* u_i^* (v_i^*)^\top (w_i^*)^\top$$

Then, noting that Δ_r^* is a minimizer of the norm difference between T and \hat{T} and then applying the triangle inequality and then Cauchy-Schwartz inequality leads to the following chain of inequalities:

$$\begin{aligned} \Delta_r^* &= \|T - \hat{T}\|_F \leq \|T - T'_r\|_F \\ &= \left\| \sum_{i=r+1}^{m^2} \lambda_i^* u_i^* (v_i^*)^\top (w_i^*)^\top \right\|_F \\ &\leq \sum_{i=r+1}^{m^2} |\lambda_i^*| \cdot \|u_i^* (v_i^*)^\top (w_i^*)^\top\|_F = \sum_{i=r+1}^{m^2} |\lambda_i^*| \end{aligned}$$

as required. ■

6 Experiments

In this section, we describe experiments that demonstrate the trade-off between the accuracy of the tensor approximation (and as a consequence, the accuracy of the approximate parsing algorithm) and parsing time.

Experimental Setting We compare the tensor approximation parsing algorithm versus the vanilla Goodman algorithm. Both algorithms were implemented in Java, and the code for both is almost identical, except for the set of instructions which computes the dynamic programming equation for propagating the beliefs up in the tree. This makes the clocktime comparison reliable for drawing conclusions about the speed of the algorithms. Our implementation of the vanilla parsing algorithm is linear in the size of the grammar (and not cubic in the number of nonterminals, which would give a worse running time).

In our experiments, we use the method described in Chi and Kolda (2011) for tensor decomposition.² This method is fast, even for large tensors, as long as they are sparse. Such is the case with the tensors for our grammars.

We use two treebanks for our comparison: the Penn treebank (Marcus et al., 1993) and the Arabic treebank (Maamouri et al., 2004). With the Penn treebank, we use sections 2–21 for training a maximum likelihood model and section 22 for parsing, while for the Arabic treebank we divide the data into two sets, of size 80% and 20%, one is used for training a maximum likelihood model and the other is used for parsing.

The number of binary rules in the treebank grammar is 7,240. The number of nonterminals is 112 and the number of preterminals is 259³ Unary rules are removed by collapsing non-terminal chains. This increased the number of preterminals. The number of binary rules in the Arabic treebank is significantly smaller and consists of 232 rules. We run all parsing experiments on sentences of length ≤ 40 . The number of nonterminals is 48 and the number of preterminals is 112.

²We use the implementation given in Sandia’s Matlab Tensor Toolbox, which can be downloaded at <http://www.sandia.gov/~tgkolda/TensorToolbox/index-2.5.html>.
