The first thing to note is that the running time of the parsing algorithm is linear in r . This indeed validates the asymptotic complexity of the inside-outside component in Goodman’s algorithm with the approximate tensors. It also shows that most of the time during parsing is spent on the inside-outside algorithm, and not on the dynamic programming algorithm which follows it.

In addition, compared to the baseline which uses a vanilla CKY algorithm (linear in the number of rules), we get a speed up of a factor of 4.75 for Arabic ($r = 140$) and 6.5 for English ($r = 260$) while retaining similar performance. Perhaps more surprising is that using the tensor approximation actually *improves* performance in several cases. We hypothesize that the cause of this is that the tensor decomposition requires less parameters to express the rule probabilities in the grammar, and therefore leads to better generalization than a vanilla maximum likelihood estimate.

We include results for a more complex model for Arabic, which uses horizontal Markovization of order 1 and vertical Markovization of order 2 (Klein and Manning, 2003). This grammar includes 2,188 binary rules. Parsing exhaustively using this grammar takes 1.30 seconds per sentence (on average) with an F_1 measure of 64.43. Parsing with tensor decomposition for $r = 280$ takes 0.62 seconds per sentence (on average) with an F_1 measure of 64.05.

7 Discussion

In this section, we briefly touch on several other topics related to tensor approximation.

7.1 Approximating the Probability of a String

The probability of a sentence z under a PCFG is defined as $p(z) = \sum_{\tau \in T(z)} p(\tau)$, and can be approximated using the algorithm in Section 4.3, running in time $\mathcal{O}(rN^3 + rmN^2)$. Of theoretical interest, we discuss here a time $\mathcal{O}(rN^3 + r^2N^2)$ algorithm, which is more convenient when $r < m$.

Observe that in Eq. (3) vector $\alpha^{i,j}$ always appears within one of the two terms $V\alpha^{i,j}$ and $W\alpha^{i,j}$ in $\mathbb{R}^{r \times 1}$, whose dimensions are independent of m . We can therefore use Eq. (3) to compute $V\alpha^{i,j}$ as $V\alpha^{i,j} = VU^\top \left(\sum_{k=1}^{j-1} (\lambda \odot V\alpha^{i,k} \odot W\alpha^{k+1,j}) \right)$, where VU^\top is a $\mathbb{R}^{r \times r}$ matrix that can be computed off-line, i.e., independently of z . A symmetrical relation can be used to compute $W\alpha^{i,j}$. Finally, we can write $p(z) = \pi^\top U \left(\sum_{k=1}^{N-1} (\lambda \odot V\alpha^{1,k} \odot W\alpha^{k+1,N}) \right)$, where $\pi^\top U$ is a $\mathbb{R}^{1 \times r}$ vector that can again be computed off-line. This algorithm then runs in time $\mathcal{O}(rN^3 + r^2N^2)$.

7.2 Applications to Dynamic Programming

The approximation method presented in this paper is not limited to PCFG parsing. A similar approximation method has been used for latent-variable PCFGs (Cohen and Collins, 2012), and in general, tensor approximation can be used to speed-up inside-outside algorithms for general dynamic programming algorithms or weighted logic programs (Eisner et al., 2004; Cohen et al., 2011). In the general case, the dimension of the tensors will not be necessarily just three (corresponding to binary rules), but can be of a higher dimension, and therefore the speed gain can be even greater. In addition, tensor approximation can be used for computing marginals of latent variables in graphical models.

For example, the complexity of the forward-

backward algorithm for HMMs can be reduced to be linear in the number of states (as opposed to quadratic) and linear in the rank used in an approximate singular-value decomposition (instead of tensor decomposition) of the transition and emission matrices.

7.3 Tighter (but Slower) Approximation Using Singular Value Decomposition

The accuracy of the algorithm depends on the ability of the tensor decomposition algorithm to decompose the tensor with a small reconstruction error. The decomposition algorithm is performed on the tensor T which includes all rules in the grammar.

Instead, one can approach the approximation by doing a decomposition for each *slice* of T separately using singular value decomposition. This will lead to a more accurate approximation, but will also lead to an extra factor of m during parsing. This factor is added because now there is not a single U , V and W , but instead there are such matrices for each non-terminal in the grammar.

8 Conclusion

We described an approximation algorithm for probabilistic context-free parsing. The approximation algorithm is based on tensor decomposition performed on the underlying rule table of the CFG grammar. The approximation algorithm leads to significant speed-up in PCFG parsing, with minimal loss in performance.

Abstract

The rising influence of user-generated online reviews (Cone, 2011) has led to growing incentive for businesses to solicit and manufacture DECEPTIVE OPINION SPAM—fictitious reviews that have been deliberately written to sound authentic and deceive the reader. Recently, Ott et al. (2011) have introduced an opinion spam dataset containing gold standard deceptive *positive* hotel reviews. However, the complementary problem of *negative* deceptive opinion spam, intended to slander competitive offerings, remains largely unstudied. Following an approach similar to Ott et al. (2011), in this work we create and study the first dataset of deceptive opinion spam with *negative* sentiment reviews. Based on this dataset, we find that standard n -gram text categorization techniques can detect negative deceptive opinion spam with performance far surpassing that of human judges. Finally, in conjunction with the aforementioned *positive* review dataset, we consider the possible interactions between sentiment and deception, and present initial results that encourage further exploration of this relationship.

1 Introduction

Consumer’s purchase decisions are increasingly influenced by user-generated online reviews of products and services (Cone, 2011). Accordingly, there is a growing incentive for businesses to solicit and manufacture DECEPTIVE OPINION SPAM—fictitious reviews that have been deliberately written to sound authentic and deceive the reader (Ott et

al., 2011). For example, Ott et al. (2012) has estimated that between 1% and 6% of *positive* hotel reviews appear to be deceptive, suggesting that some hotels may be posting fake positive reviews in order to hype their own offerings.

In this work we distinguish between two kinds of deceptive opinion spam, depending on the sentiment expressed in the review. In particular, reviews intended to promote or hype an offering, and which therefore express a positive sentiment towards the offering, are called *positive* deceptive opinion spam. In contrast, reviews intended to disparage or slander competitive offerings, and which therefore express a negative sentiment towards the offering, are called *negative* deceptive opinion spam. While previous related work (Ott et al., 2011; Ott et al., 2012) has explored characteristics of *positive* deceptive opinion spam, the complementary problem of *negative* deceptive opinion spam remains largely unstudied.

Following the framework of Ott et al. (2011), we use Amazon’s Mechanical Turk service to produce the first publicly available¹ dataset of *negative* deceptive opinion spam, containing 400 gold standard deceptive negative reviews of 20 popular Chicago hotels. To validate the credibility of our deceptive reviews, we show that human deception detection performance on the negative reviews is low, in agreement with decades of traditional deception detection research (Bond and DePaulo, 2006). We then show that standard n -gram text categorization techniques can be used to detect negative deceptive opinion spam with approximately 86% accuracy — far

¹Dataset available at: http://www.cs.cornell.edu/~myleott/op_spam.

surpassing that of the human judges.

In conjunction with Ott et al. (2011)'s *positive* deceptive opinion spam dataset, we then explore the interaction between sentiment and deception with respect to three types of language features: (1) changes in first-person singular use, often attributed to psychological distancing (Newman et al., 2003), (2) decreased spatial awareness and more narrative form, consistent with theories of reality monitoring (Johnson and Raye, 1981) and imaginative writing (Biber et al., 1999; Rayson et al., 2001), and (3) increased negative emotion terms, often attributed to leakage cues (Ekman and Friesen, 1969), but perhaps better explained in our case as an exaggeration of the underlying review sentiment.

2 Dataset

One of the biggest challenges facing studies of deception is obtaining labeled data. Recently, Ott et al. (2011) have proposed an approach for generating *positive* deceptive opinion spam using Amazon's popular Mechanical Turk crowdsourcing service. In this section we discuss our efforts to extend Ott et al. (2011)'s dataset to additionally include *negative* deceptive opinion spam.

2.1 Deceptive Reviews from Mechanical Turk

Deceptive negative reviews are gathered from Mechanical Turk using the same procedure as Ott et al. (2011). In particular, we create and divide 400 HITs evenly across the 20 most popular hotels in Chicago, such that we obtain 20 reviews for each hotel. We allow workers to complete only a single HIT each, so that each review is written by a unique worker.² We further require workers to be located in the United States and to have an average past approval rating of at least 90%. We allow a maximum of 30 minutes to complete the HIT, and reward accepted submissions with one US dollar (\$1).

Each HIT instructs a worker to imagine that they work for the marketing department of a hotel, and that their manager has asked them to write a fake negative review of a competitor's hotel to be posted online. Accompanying each HIT is the name and

²While Mechanical Turk does not provide a convenient mechanism for ensuring the uniqueness of workers, this constraint can be enforced with Javascript. The script is available at: <http://uniqueturker.myleott.com>.

URL of the hotel for which the fake negative review is to be written, and instructions that: (1) workers should not complete more than one similar HIT, (2) submissions must be of sufficient quality, i.e., written for the correct hotel, legible, reasonable in length,³ and not plagiarized,⁴ and, (3) the HIT is for academic research purposes.

Submissions are manually inspected to ensure that they are written for the correct hotel and to ensure that they convey a generally negative sentiment.⁵ The average accepted review length was 178 words, higher than for the positive reviews gathered by Ott et al. (2011), who report an average review length of 116 words.

2.2 Truthful Reviews from the Web

Negative (1- or 2-star) truthful reviews are mined from six popular online review communities: Expedia, Hotels.com, Orbitz, Priceline, TripAdvisor, and Yelp. While reviews mined from these communities cannot be considered *gold standard* truthful, recent work (Mayzlin et al., 2012; Ott et al., 2012) suggests that deception rates among travel review portals is reasonably small.

Following Ott et al. (2011), we sample a subset of the available truthful reviews so that we retain an equal number of truthful and deceptive reviews (20 each) for each hotel. However, because the truthful reviews are on average longer than our deceptive reviews, we sample the truthful reviews according to a log-normal distribution fit to the lengths of our deceptive reviews, similarly to Ott et al. (2011).⁶

3 Deception Detection Performance

In this section we report the deception detection performance of three human judges (Section 3.1) and supervised n -gram Support Vector Machine (SVM) classifiers (Section 3.2).

³We define "reasonable length" to be ≥ 150 characters.

⁴We use <http://plagiarisma.net> to determine whether or not a review is plagiarized.

⁵We discarded and replaced approximately 2% of the submissions, where it was clear that the worker had misread the instructions and instead written a deceptive *positive* review.

⁶We use the R package GAMLS (Rigby and Stasinopoulos, 2005) to fit a log-normal distribution (left truncated at 150 characters) to the lengths of the deceptive reviews.

		Accuracy	TRUTHFUL			DECEPTIVE		
HUMAN	JUDGE 1		P	R	F	P	R	F
	JUDGE 2	61.9%	63.0	57.5	60.1	60.9	66.3	63.5
	JUDGE 3	57.5%	57.3	58.8	58.0	57.7	56.3	57.0
META	MAJORITY	69.4%	70.1	67.5	68.8	68.7	71.3	69.9
	SKEPTIC	58.1%	78.3	22.5	35.0	54.7	93.8	69.1

Table 1: Deception detection performance, incl. (P)recision, (R)ecall, and (F)1-score, for three human judges and two meta-judges on a set of 160 *negative* reviews. The largest value in each column is indicated with boldface.

3.1 Human Performance

Recent large-scale meta-analyses have shown human deception detection performance is low, with accuracies often not much better than chance (Bond and DePaulo, 2006). Indeed, Ott et al. (2011) found that two out of three human judges were unable to perform statistically significantly better than chance (at the $p < 0.05$ level) at detecting *positive* deceptive opinion spam. Nevertheless, it is important to subject our reviews to human judgments to validate their convincingness. In particular, if human detection performance is found to be very high, then it would cast doubt on the usefulness of the Mechanical Turk approach for soliciting gold standard deceptive opinion spam.

Following Ott et al. (2011), we asked three volunteer undergraduate university students to read and make assessments on a subset of the negative review dataset described in Section 2. Specifically, we randomized all 40 deceptive and truthful reviews from each of four hotels (160 reviews total). We then asked the volunteers to read each review and mark whether they believed it to be truthful or deceptive.

Performance for the three human judges appears in Table 1. We additionally show the deception detection performance of two meta-judges that aggregate the assessments of the individual human judges: (1) the MAJORITY meta-judge predicts *deceptive* when at least two out of three human judges predict *deceptive* (and *truthful* otherwise), and (2) the SKEPTIC meta-judge predicts *deceptive* when at least one out of three human judges predicts *deceptive* (and *truthful* otherwise).

A two-tailed binomial test suggests that JUDGE 1 and JUDGE 2 both perform better than chance ($p = 0.0002, 0.003$, respectively), while JUDGE 3 fails to reject the null hypothesis of performing at-chance

($p = 0.07$). However, while the best human judge is accurate 65% of the time, inter-annotator agreement computed using Fleiss' kappa is only *slight* at 0.07 (Landis and Koch, 1977). Furthermore, based on Cohen's kappa, the highest pairwise inter-annotator agreement is only 0.26, between JUDGE 1 and JUDGE 2. These low agreements suggest that while the judges may perform statistically better than chance, they are identifying different reviews as deceptive, i.e., few reviews are consistently identified as deceptive.

3.2 Automated Classifier Performance

Standard n -gram-based text categorization techniques have been shown to be effective at detecting deception in text (Jindal and Liu, 2008; Mihalcea and Strapparava, 2009; Ott et al., 2011; Feng et al., 2012). Following Ott et al. (2011), we evaluate the performance of linear Support Vector Machine (SVM) classifiers trained with unigram and bigram term-frequency features on our novel *negative* deceptive opinion spam dataset. We employ the same 5-fold stratified cross-validation (CV) procedure as Ott et al. (2011), whereby for each cross-validation iteration we train our model on all reviews for 16 hotels, and test our model on all reviews for the remaining 4 hotels. The SVM cost parameter, C , is tuned by nested cross-validation on the training data.

Results appear in Table 2. Each row lists the sentiment of the train and test reviews, where “Cross Val.” corresponds to the cross-validation procedure described above, and “Held Out” corresponds to classifiers trained on reviews of one sentiment and tested on the other. The results suggest that n -gram-based SVM classifiers can detect *negative* deceptive opinion spam in a balanced dataset with performance far surpassing that of untrained human judges (see Section 3.1). Furthermore, our results show that

Train Sentiment	Test Sentiment	Accuracy	TRUTHFUL			DECEPTIVE		
			P	R	F	P	R	F
POSITIVE (800 reviews)	POSITIVE (800 reviews, Cross Val.)	89.3%	89.6	88.8	89.2	88.9	89.8	89.3
	NEGATIVE (800 reviews, Held Out)	75.1%	69.0	91.3	78.6	87.1	59.0	70.3
NEGATIVE (800 reviews)	POSITIVE (800 reviews, Held Out)	81.4%	76.3	91.0	83.0	88.9	71.8	79.4
	NEGATIVE (800 reviews, Cross Val.)	86.0%	86.4	85.5	85.9	85.6	86.5	86.1
COMBINED (1600 reviews)	POSITIVE (800 reviews, Cross Val.)	88.4%	87.7	89.3	88.5	89.1	87.5	88.3
	NEGATIVE (800 reviews, Cross Val.)	86.0%	85.3	87.0	86.1	86.7	85.0	85.9

Table 2: Automated classifier performance for different train and test sets, incl. (P)recision, (R)ecall and (F)1-score.

classifiers trained and tested on reviews of different sentiments perform worse, despite having more training data,⁷ than classifiers trained and tested on reviews of the same sentiment. This suggests that cues to deception differ depending on the sentiment of the text (see Section 4).

Interestingly, we find that training on the combined sentiment dataset results in performance that is comparable to that of the “same sentiment” classifiers (88.4% vs. 89.3% accuracy for positive reviews and 86.0% vs. 86.0% accuracy for negative reviews). This is explainable in part by the increased training set size (1,280 vs. 640 reviews per 4 training folds).

4 Interaction of Sentiment and Deception

An important question is how language features operate in our fake negative reviews compared with the fake positive reviews of Ott et al. (2011). For example, fake positive reviews included less spatial language (e.g., floor, small, location, etc.) because individuals who had not actually experienced the hotel simply had less spatial detail available for their review (Johnson and Raye, 1981). This was also the case for our negative reviews, with less spatial language observed for fake negative reviews relative to truthful. Likewise, our fake negative reviews had more verbs relative to nouns than truthful, suggesting a more narrative style that is indicative of imaginative writing (Biber et al., 1999; Rayson et al., 2001), a pattern also observed by Ott et al. (2011).

There were, however, several important differences in the deceptive language of fake negative relative to fake positive reviews. First, as might be expected, negative emotion terms were more fre-

quent, according to LIWC (Pennebaker et al., 2007), in our fake negative reviews than in the fake positive reviews. But, importantly, the fake negative reviewers over-produced negative emotion terms (e.g., terrible, disappointed) relative to the truthful reviews in the same way that fake positive reviewers over-produced positive emotion terms (e.g., elegant, luxurious). Combined, these data suggest that the more frequent negative emotion terms in the present dataset are not the result of “leakage cues” that reveal the emotional distress of lying (Ekman and Friesen, 1969). Instead, the differences suggest that fake hotel reviewers exaggerate the sentiment they are trying to convey relative to similarly-valenced truthful reviews.

Second, the effect of deception on the pattern of pronoun frequency was not the same across positive and negative reviews. In particular, while first person singular pronouns were produced more frequently in fake reviews than truthful, consistent with the case for positive reviews, the increase was diminished in the negative reviews examined here. In the positive reviews reported by Ott et al. (2011), the rate of first person singular in fake reviews ($M=4.36\%$, $SD=2.96\%$) was twice the rate observed in truthful reviews ($M=2.18\%$, $SD=2.04\%$). In contrast, the rate of first person singular in the deceptive negative reviews ($M=4.47\%$, $SD=2.83\%$) was only 57% greater than for truthful reviews ($M=2.85\%$, $SD=2.23\%$). These results suggest that the emphasis on the self, perhaps as a strategy of convincing the reader that the author had actually been to the hotel, is not as evident in the fake negative reviews, perhaps because the negative tone of the reviews caused the reviewers to psychologically distance themselves from their negative statements, a phenomenon observed in several other deception studies, e.g., Hancock et al. (2008).

⁷“Cross Val.” classifiers are effectively trained on 80% of the data and tested on the remaining 20%, whereas “Held Out” classifiers are trained and tested on 100% of each data.

5 Conclusion

We have created the first publicly-available corpus of gold standard *negative* deceptive opinion spam, containing 400 reviews of 20 Chicago hotels, which we have used to compare the deception detection capabilities of untrained human judges and standard *n*-gram-based Support Vector Machine classifiers. Our results demonstrate that while human deception detection performance is greater for *negative* rather than *positive* deceptive opinion spam, the best detection performance is still achieved through automated classifiers, with approximately 86% accuracy.

We have additionally explored, albeit briefly, the relationship between sentiment and deception by utilizing Ott et al. (2011)'s positive deceptive opinion spam dataset in conjunction with our own. In particular, we have identified several features of language that seem to remain consistent across sentiment, such as decreased awareness of spatial details and exaggerated language. We have also identified other features that vary with the sentiment, such as first person singular use, although further work is required to determine if these differences may be exploited to improve deception detection performance. Indeed, future work may wish to jointly model sentiment and deception in order to better determine the effect each has on language use.

Improving speech synthesis quality by reducing pitch peaks in the source recordings

Luisina Violante, Pablo Rodríguez Zivic and Agustín Gravano

Departamento de Computación, FCEyN

Universidad de Buenos Aires, Argentina

{lviolante, prodriguez, gravano}@dc.uba.ar

Abstract

We present a method for improving the perceived naturalness of corpus-based speech synthesizers. It consists in removing pronounced pitch peaks in the original recordings, which typically lead to noticeable discontinuities in the synthesized speech. We perceptually evaluated this method using two concatenative and two HMM-based synthesis systems, and found that using it on the source recordings managed to improve the naturalness of the synthesizers and had no effect on their intelligibility.

1 Introduction

By definition, corpus-based speech synthesizers, such as concatenative and HMM-based systems, rely heavily on the quality of the speech corpus used for building the systems. Creating speech corpora for this purpose is expensive and time consuming, so when the synthesized speech obtained is not as good as expected, it may be desirable to modify or correct the corpus rather than record a new one. Common corrections are limited to discarding mispronounced words or noisy units. In this work we describe a simple method for attenuating pronounced pitch peaks, a frequent problem in recordings made by professional speakers, and evaluate it using four different corpus-based systems. Sections 2 and 3 describe the speech synthesis systems and corpus employed in this work. In Section 4 we present the method for reducing pitch peaks. In Section 5 we describe how we evaluated the effect of our method on intelligibility and naturalness of the synthesizers.

2 Synthesis systems

Festival¹ is a general framework for building speech synthesis systems, written in C++ and developed by the Center of Speech Technology Research at the University of Edinburgh (Black et al., 2001). It provides an implementation of concatenative speech synthesis as well as synthesis based on Hidden Markov Models (HMM). In this work we used a Festival module called *Clunits unit selection engine* to build concatenative synthesizers. The unit size is the *phone*, although since a percentage of the previous unit is included in the acoustic distance measure, the unit size is rather “*phone plus previous phone*”, thus similar to a *diphone* (Black and Lenzo, 2007). Additionally, we used a second Festival module called *Clustergen parametric synthesis engine* for building HMM-based speech synthesizers.

MARY TTS² is an open-source synthesis platform written in Java, originally jointly developed by the Language Technology Lab at the German Research Center for Artificial Intelligence (DFKI) and the Institute of Phonetics at Saarland University, and currently maintained by DFKI. Like Festival, MARY provides toolkits for building unit selection and HMM-based synthesis voices (Schröder and Trouvain, 2003).

3 Corpus

For building our systems we used the SECYT corpus, created by the Laboratorio de Investigaciones Sensoriales (Universidad de Buenos Aires) for

¹<http://festvox.org/festival>

²<http://mary.dfki.de>

studying the prosody of Argentine Spanish (Torres and Gurlekian, 2004). It consists of 741 declarative sentences recorded by a female professional speaker (pitch range: 130-380Hz). On average, sentences are 7 words and 3.9 seconds long. The entire corpus has manual phonetic transcriptions and time alignments, following a version of the *Speech Assessment Methods Phonetic Alphabet* (SAMPA) adapted for Argentine Spanish (Gurlekian et al., 2001).

A priori, this corpus is a very good candidate for building a synthesis system – its 741 sentences are phonetically balanced, the audio quality is excellent, and it has precise time-aligned phonetic transcriptions. We thus built two concatenation systems using this corpus: Festival’s diphone-like and MARY’s diphone systems. The results were not satisfactory. The new voices presented clearly noticeable discontinuities, both in intensity and pitch, which affected their naturalness – as judged impressionistically by the authors and non-expert colleagues.

In an attempt to attenuate these problems, we leveled the intensity of all recordings to a mean of 72dB using linear interpolation. Specifically, each sound was multiplied by a number such that its new average RMS intensity was 72dB; so that all sentences in the corpus ended up with the same average intensity. After this conversion, we rebuilt the systems. The resulting voices sounded somewhat better, but their most noticeable problem, severe pitch discontinuities, persisted.

Further analysis of the corpus recordings revealed that this issue was likely due to the speaking style employed by the professional speaker. It contains frequent pronounced pitch peaks, a verbal stylistic device acquired by the speaker as part of her professional training. These events produced units with very different pitch levels and slopes, thus leading to the discontinuities mentioned above.

4 Reduction of pitch peaks

We searched for ways to reduce the magnitude of these pitch peaks by manipulating the pitch track of the recordings using the *Time-Domain Pitch-Synchronous OverLap-and-Add* (TD-PSOLA) signal processing technique (Moulines and Charpentier, 1990). We used the implementation of TD-PSOLA included in the Praat toolkit (Boersma and

Weenink, 2012).

We tried several formulas for TD-PSOLA and ended up choosing the one that appeared to yield the best results, evaluated perceptually by the authors:

$$f(x) = \begin{cases} (x - T) * s + T & \text{if } x > T \\ x & \text{otherwise.} \end{cases}$$

This formula linearly scales the pitch track by a scaling factor s above a threshold T , and leaves it intact below T . When $0 < s < 1$, the pitch track gets compressed above the threshold. We experimented with several values for the two constants, and selected $T = 200\text{Hz}$ and $s = 0.4$ as the ones producing the best results. Figure 1 illustrates the pitch peak reduction method. The black solid line corresponds to

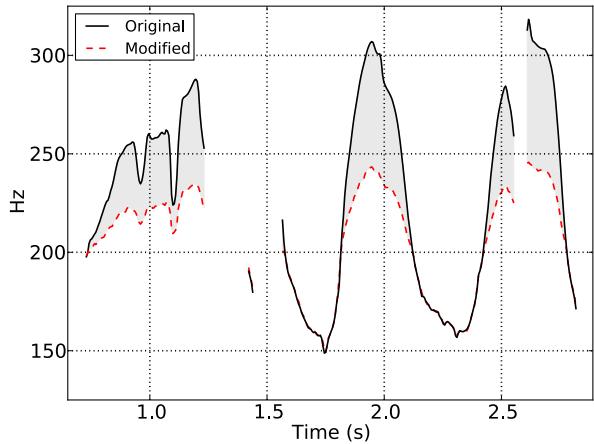

Figure 1: Reduction of pitch peaks. The original pitch track (in black) is scaled down 40% above 200Hz.

the pitch track of the original audio; the red dotted line, to the pitch track of the modified audio. Note that the modified pitch track is scaled down above 200Hz, but identical to the original below it.

5 Evaluation of the method

Next we proceeded to evaluate the effect on synthesizer quality of reducing pitch peaks in the training corpus. For this purpose we prepared two versions of the SECYT corpus – with and without applying our pitch-peak reduction technique. We refer to these two as the *original* and *modified* recordings, respectively. In both cases, the intensity level of all audios was first leveled to a mean of 72dB using linear interpolation, to compensate for differences across recordings.

Subsequently, we built 8 speech synthesizers, consisting in all combinations of: Festival and MARY frameworks, concatenative and HMM-based synthesis, and original and modified recordings. We refer to these systems using the following notation: {fest, mary} - {conc, hmm} - {orig, mod}; e.g., mary_conc_mod is a concatenative system built using the MARY framework with the modified corpus.

We evaluated these systems along two dimensions: intelligibility and naturalness. Our goal was to compare four system pairs: systems built using the original recordings vs. those built using the modified recordings. The null hypothesis was that there was no difference between ‘orig’ and ‘mod’ systems; and the alternative hypothesis was that ‘mod’ systems were better than ‘orig’ ones.

5.1 Intelligibility

To evaluate intelligibility we used the *Semantically Unpredictable Sentences* (SUS) method (Nye and Gaitenby, 1974), which consists in asking participants to listen to and transcribe sentences with correct syntax but no semantic sense, for later measuring and comparing the number of transcription errors. We used a set of 50 such sentences, each 6-10 words long, created by Gurlekian et al. (2012) for evaluating Spanish speech synthesizers. A sample sentence is, *El viento dulce armó un libro de panqueques* (The sweet wind made a book of pancakes).

For each participant, 40 sentences were selected at random and synthesized with the 8 systems (5 sentences per system, with no repetitions). Participants were given the following instructions,

La primera tarea consiste en escuchar varios audios, y transcribir para cada audio la oración que escuches. Prestá atención, porque podés escuchar cada audio una sola vez.

(The first task consists in listening to several audios, and transcribing for each audio the sentence you hear. Pay attention, because you can only listen to each audio once.)

5.2 Naturalness

To evaluate naturalness we used the *Mean Opinion Score* (MOS) method, in which participants are asked to rate the overall quality of synthesized speech on a 10-point scale (Viswanathan and Viswanathan, 2005).

We used a set of 20 sentences, each 5-20 words long, created by Gurlekian et al. (2012), plus 20 additional sentences created for this study. A sample sentence is, *El sector de informática es el nuevo generador de empleo del país* (The information technology sector is the country’s new job creator).

Again, for each participant, 40 sentences were selected at random and synthesized with the 8 systems (5 sentences per system). Participants were given the following instructions,

La segunda (y última) tarea consiste en escuchar otros audios, y puntuar la naturalidad de cada uno. Usar una escala de 1 a 10, donde 1 significa “no suena natural en lo absoluto” y 10 significa “suena completamente natural”. En este caso, podés escuchar cada audio una o más veces.

(The second (and last) task consists in listening to other audios, and score the naturalness of each. Use a scale from 1 to 10, where 1 means “it does not sound natural at all” and 10 means “it sounds completely natural”. In this case, you may listen to each audio one or more times.)

5.3 Results

SUS and MOS tests were administered on a computer interface in a silent laboratory using regular headphones. 14 graduate and undergraduate students (11 male, 3 female; mean age: 27.6) completed both tests – first SUS, followed by MOS.

The transcriptions of the SUS tests were manually corrected for obvious typos and spelling errors that did not form a valid Spanish word. Suspected typos and spelling errors that formed a valid word were not corrected. For example, *peliculas* was corrected to *películas*, and *precion* to *presión*; but *canto* was not corrected to *cantó*, since it is a valid word. Subsequently, we computed the Levenshtein distance between each transcription and the corresponding sentence. Figure 2 shows the distribution of Levenshtein distances for each of our eight systems. We observe that all systems had a low error count, with a median of 0 or 1 errors per sentence. Two-tail Wilcoxon signed-rank tests revealed no significant differences between the systems built with the original and modified recordings ($p=0.70$ for fest_conc, $p = 0.40$ for fest_hmm, $p = 0.69$ for mary_conc, $p=0.40$ for mary_hmm, and $p=0.41$ for all systems together). These results indicate that the intelligibility of all four system types was not affected by the

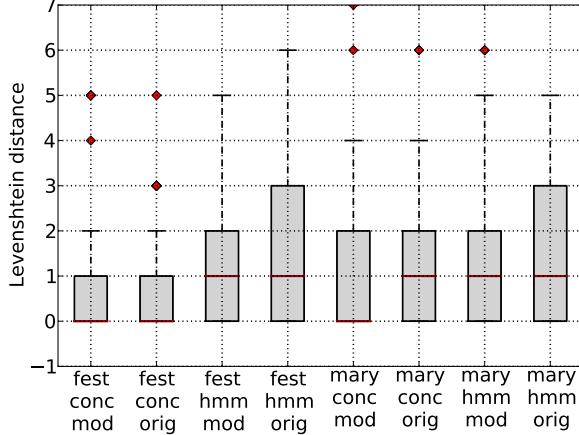

Figure 2: Intelligibility (SUS) results.

modifications performed on the corpus for reducing pitch peaks.

To account for the different interpretations of the 10-point scale, we normalized all MOS test scores by participant using z -scores.³ Figure 3 shows the distribution of values for each system.

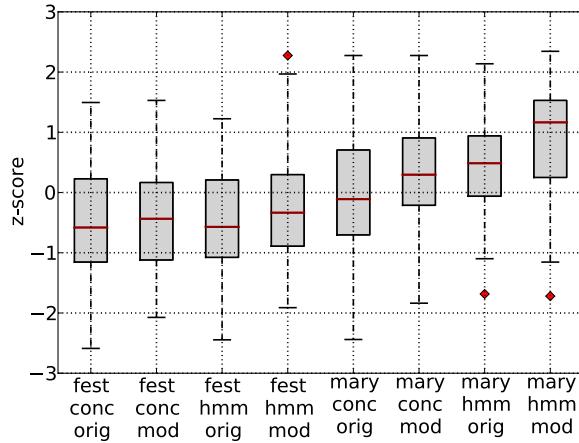

Figure 3: Naturalness (MOS) results.

We performed a series of Wilcoxon signed-rank tests to assess the statistical significance of the observed differences. The null hypothesis was that there was no difference between ‘orig’ and ‘mod’ systems; and the alternative hypothesis was that ‘mod’ systems were perceived as more natural than ‘orig’ ones. Table 5.3 summarizes these results.

For mary_conc and mary_hmm (concatenative and HMM-based systems built using the MARY

³ $z = (x - \bar{x})/s$, where \bar{x} and s are estimates of the participant’s mean and standard deviation, respectively.

	W	p -value
fest_conc	2485	0.559
fest_hmm	2175	0.126
mary_conc	1933	0.016
mary_hmm	1680.5	0.001
All systems	34064.5	0.004

Table 1: Results of Wilcoxon tests comparing systems using the original and modified audios.

framework) the perceived naturalness was significantly higher for systems built using the modified recordings (i.e., after reducing pitch peaks) than for systems built with the original recordings. For fest_conc (concatenative system built with Festival) we found no evidence of such differences. Finally, for fest_hmm (Festival HMM-based) the difference approaches significance at 0.126.

6 Conclusions

In this paper we presented a method for improving the perceived naturalness of corpus-based speech synthesizers. It consists in removing pronounced pitch peaks in the original recordings, which typically produce discontinuities in the synthesized speech. We evaluated this method using two common technologies (concatenative and HMM-based synthesis) and two different implementations (Festival and MARY), aiming at a good coverage of state-of-the-art speech synthesizers, and obtained clear results. First, its utilization on the source recordings had no effect (negative or positive) on the intelligibility of any of the systems. Second, the naturalness of the concatenative and HMM-based systems built with the MARY framework improved significantly; the HMM-based system built with Festival showed an improved naturalness at a level approaching significance; and the Festival concatenative system showed no improvement. In summary, the presented method did not harm the intelligibility of the systems, and in some cases managed to improve their naturalness. Therefore, since the impact of the proposed modifications on all four systems was positive to neutral, developers may find this methodology beneficial.

Acknowledgments

This work was funded in part by CONICET, ANPCYT PICT 2009-0026, and UBACYT 20020090300087. The authors thank Jorge A. Gurlekian, Humberto M. Torres and Christian G. Cossio-Mercado from LIS (INIGEM, CONICET-UBA) for kindly sharing the SECYT corpus and other materials for the present study, as well as for valuable suggestions and comments.

Abstract

We show that existing methods for training preposition error correction systems, whether using well-edited text or error-annotated corpora, do not generalize across very different test sets. We present a new, large error-annotated corpus and use it to train systems that generalize across three different test sets, each from a different domain and with different error characteristics. This new corpus is automatically extracted from Wikipedia revisions and contains over one million instances of preposition corrections.

1 Introduction

One of the main themes that has defined the field of automatic grammatical error correction has been the availability of error-annotated learner data to train and test a system. Some errors, such as determiner-noun number agreement, are easily corrected using rules and regular expressions (Leacock et al., 2010). On the other hand, errors involving the usage of prepositions and articles are influenced by several factors including the local context, the prior discourse and semantics. These errors are better handled by statistical models which potentially require millions of training examples.

Most statistical approaches to grammatical error correction have used one of the following training paradigms: 1) training solely on examples of correct usage (Han et al., 2006); 2) training on examples of correct usage and artificially generated errors (Rozovskaya and Roth, 2010); and 3) training

on examples of correct usage and real learner errors (Dahlmeier and Ng, 2011; Dale et al., 2012). The latter two methods require annotated corpora of errors, and while they have shown great promise, manually annotating grammatical errors in a large enough corpus of learner writing is often a costly and time-consuming endeavor.

In order to efficiently and automatically acquire a very large corpus of annotated learner errors, we investigate the use of error corrections extracted from Wikipedia revision history. While Wikipedia revision history has shown promise for other NLP tasks including paraphrase generation (Max and Wisniewski, 2010; Nelken and Yamangil, 2008) and spelling correction (Zesch, 2012), this resource has not been used for the task of grammatical error correction.

To evaluate the usefulness of Wikipedia revision history for grammatical error correction, we address the task of correcting errors in preposition selection (i.e., where the context licenses the use of a preposition, but the writer selects the wrong one). We first train a model directly on instances of correct and incorrect preposition usage extracted from the Wikipedia revision data. We also generate artificial errors using the confusion distributions derived from this data. We compare both of these approaches to models trained on well-edited text and evaluate each on three test sets with a range of different characteristics. Each training paradigm is applied to multiple data sources for comparison. With these multiple evaluations, we address the following research questions:

1. Across multiple test sets, which data source

is more useful for correcting preposition errors: a large amount of well-edited text, a large amount of potentially noisy error-annotated data (either artificially generated or automatically extracted) or a smaller amount of higher quality error-annotated data?

2. Given error-annotated data, is it better to train on the corrections directly or to use the confusion distributions derived from these corrections for generating artificial errors in well-edited text?
3. What is the impact of having a mismatch in the error distributions of the training and test sets?

2 Related Work

In this section, we only review work in preposition error correction in terms of the three training paradigms and refer the reader to Leacock et al. (2010) for a more comprehensive review of the field.

2.1 Training on Well-Edited Text

Early approaches to error detection and correction did not have access to large amounts of error-annotated data to train statistical models and thus, systems were trained on millions of well-edited examples from news text instead (Gamon et al., 2008; Tetreault and Chodorow, 2008; De Felice and Pulman, 2009). Feature sets usually consisted of n -grams around the preposition, POS sequences, syntactic features and semantic information. Since the model only had knowledge of correct usage, an error was flagged if the system’s prediction for a particular preposition context differed from the preposition the writer used.

2.2 Artificial Errors

The issue with training solely on correct usage was that the systems had no knowledge of typical learner errors. Ideally, a system would be trained on examples of correct and incorrect usage, however, for many years, such error-annotated corpora were not available. Instead, several researchers generated artificial errors based on the error distributions derived from the error-annotated learner corpora available at the time. Izumi et al. (2003) was the first to evaluate a model trained on incorrect usage as well as artificial errors for the task of correcting several different

error types, including prepositions. However, with limited training data, system performance was quite poor. Rozovskaya and Roth (2010) evaluated different ways of generating artificial errors and found that a system trained on artificial errors could outperform the more traditional training paradigm of using only well-edited texts. Most recently, Imamura et al. (2012) showed that performance could be improved by training a model on artificial errors and addressing domain adaptation for the task of Japanese particle correction.

2.3 Error-Annotated Learner Corpora

Recently, error-annotated learner data has become more readily and publicly available allowing models to be trained on both examples of correct usage as well typical learner errors. Han et al. (2010) showed that a preposition error detection and correction system trained on 100,000 annotated preposition errors from the Chungdahm Corpus of Korean Learner English (in addition to 1 million examples of correct usage) outperformed a model trained only on 5 million examples of correct usage. Gamon (2010) and Dahlmeier and Ng (2011) showed that combining models trained separately on examples of correct and incorrect usage could also improve the performance of a preposition error correction system.

3 Mining Wikipedia Revisions for Grammatical Error Corrections

3.1 Related Work

Many NLP researchers have taken advantage of the wealth of information available in Wikipedia revisions. Dutrey et al. (2011) define a typology of modifications found in the French Wikipedia (WiCo-PaCo). They show that the kinds of edits made range from specific lexical changes to more general rewrite edits. Similar types of edits are found in the English Wikipedia. The data extracted from Wikipedia revisions has been used for a wide variety of tasks including spelling correction (Max and Wisniewski, 2010; Zesch, 2012), lexical error detection (Nelken and Yamangil, 2008), sentence compression (Yamangil and Nelken, 2008), paraphrase generation (Max and Wisniewski, 2010; Nelken and Yamangil, 2008), lexical simplification (Yatskar et al., 2010) and entailment (Zanzotto and Pennacchiotti, 2010;

- (1) [Wiki clean] In addition, sometimes it is also left to stand overnight (*at* → *in*) the refrigerator.
- (2) [Wiki clean] Also none of the witnesses present (*of* → *on*) those dates supports Ranneft’s claims.
- (3) [Wiki dirty] . . . cirque has a permanent production (*to* → *at*) the Mirage, love.

Figure 1: Example sentences with preposition errors extracted from Wikipedia revisions. The second preposition is assumed to be the correction.

Cabrio et al., 2012). To our knowledge, no one has previously extracted data for training a grammatical error detection system from Wikipedia revisions.

3.2 Extracting Preposition Correction Data from Wikipedia Revisions

As the source of our Wikipedia revisions, we used an XML snapshot of Wikipedia generated in July 2011 containing 8,735,890 articles and 288,583,063 revisions.¹ We then used the following process to extract preposition errors and their corresponding corrections from this snapshot:

Step 1: Extract the plain text versions of all revisions of all articles using the Java Wikipedia Library (Ferschke et al., 2011).

Step 2: For each Wikipedia article, compare each revision with the revision immediately preceding it using an efficient *diff* algorithm.²

Step 3: Compute all 1-word **edit chains** for the article, i.e., sequences of related edits derived from all revisions of the same article. For example, say revision 10 of an article inserts the preposition *of* into a sentence and revision 12 changes that preposition to *on*. Assuming that no other revisions change this sentence, the corresponding edit chain would contain the following 3 elements: $\epsilon \rightarrow of \rightarrow on$. The extracted chains contain the full context on either side of the 1-word edit, up to the automatically detected sentence boundaries.

Step 4: (a) Ignore any *circular* chains, i.e., where the first element in the edit chain is the same as the last element. (b) Collapse all *non-circular*

chains, i.e., only retain the first and the last elements in a chain. Both these decisions are motivated by the assumption that the intermediate links in the chain are unreliable for training an error correction system since a Wikipedia contributor modified them.

Step 5 : From all remaining 2-element chains, find those where a preposition is replaced with another preposition. If the preposition edit is the only edit in the sentence, we convert the chain into a sentence pair and label it *clean*. If there are other 1-word edits but not within 5 words of the preposition edit on either side, we label the sentence *somewhat clean*. Otherwise, we label it *dirty*. The motivation is that the presence of other nearby edits make the preposition correction less reliable when used in isolation, due to the possible dependencies between corrections.

All extracted sentences were part-of-speech tagged using the Stanford Tagger (Toutanova et al., 2003). Using the above process, we are able to extract approximately 2 million sentences containing prepositions errors and their corrections. Some examples of the sentences we extracted are given in Figure 1. Example (4) shows an example of a bad correction.

4 Corpora

We use several corpora for training and testing our preposition error correction system. The properties of each are outlined in Table 1, organized by paradigm. For each corpus we report the total number of prepositions used for training, as well as the number and percentage of preposition corrections.

4.1 Well-edited Text

We train our system on two well-edited corpora. The first is the same corpus used by Tetreault and

¹<http://dumps.wikimedia.org/enwiki/>

²<http://code.google.com/p/google-diff-match-patch/>

	Corpus	Total # Preps	# Corrected Preps	
Well-edited Text	Wikipedia Snapshot (10m sents)	26,069,860	0	(0%)
	Lexile/SJM	6,719,077	0	(0%)
Artificially Generated Errors	Wikipedia Snapshot	26,127,464	2,844,227	(10.9%)
	Lexile/SJM	6,723,206	792,195	(11.8%)
Naturally Occurring Errors	Wikipedia Revisions All	7,125,317	1,027,643	(20.6%)

Test Corpora	NUCLE Test	9,366	125	(1.3%)
	FCE	33,243	2,900	(8.7%)
	HOO 2011 Test	1,703	81	(4.8%)

Table 1: Corpora characteristics

Chodorow (2008), comprising roughly 1.8 million sentences from the San Jose Mercury News Corpus³ and roughly 1.8 million sentences from grades 11 and 12 of the MetaMetrics Lexile Corpus. Our second corpus is a random sample of 10 million sentences containing at least one preposition from the June 2012 snapshot of English Wikipedia Articles.⁴

4.2 Artificially Generated Errors

Similar to Foster and Andersen (2009) and Rozovskaya and Roth (2010), we artificially introduce preposition errors into well-edited corpora (the two described above). We do this based on a distribution of possible confusions and train a model that is aware of the corrections. The two sets of confusion distributions we used were derived based on the errors extracted from Wikipedia revisions and Lang-8 respectively (discussed in Section 4.3). For each corrected preposition p_i in the revision data, we calculated $P(p_i|p_j)$, where p_j is each of the possible original prepositions that were confused with p_i . Then, for each sentence in the well-edited text, all prepositions are extracted. A preposition is randomly selected (without replacement) and changed based on the distribution of possible confusions (note that the original preposition is also included in the distribution, usually with a high probabili-

ity, meaning that there is a strong preference not to change the preposition). If a preposition is changed to something other than the original preposition, all remaining prepositions in the sentence are left unchanged.

4.3 Naturally Occurring Errors

We have a number of corpora that contain annotated preposition errors. Note that we are only considering incorrectly selected prepositions, we do not consider missing or extraneous.

NUCLE The NUS Corpus of Learner English (NUCLE)⁵ contains one million words of learner essay text, manually annotated with error tags and corrections. We use the same training, dev and test splits as Dahlmeier and Ng (2011).

FCE The CLC FCE Dataset⁶ is a collection of 1,244 exam scripts written by learners of English as part of the Cambridge ESOL First Certificate in English (Yannakoudakis et al., 2011). It includes demographic metadata about the candidate, a grade for each essay and manually-annotated error corrections.

Wikipedia We use three versions of the preposition errors extracted from the Wikipedia revisions as described in Section 3.2. The first includes corrections where the preposition was the only word corrected in the entire sentence

³The San Jose Mercury News is available from the Linguistic Data Consortium (catalog number LDC93T3A).

⁴We used a newer version of the Wikipedia text for the well-edited text, since we assume that more recent versions of the text will be most grammatical, and therefore closer to well-edited.

⁵<http://bit.ly/nuclecorpus>

⁶<http://ilexir.co.uk/applications/clc-fce-dataset/>

(*clean*). The second contains all *clean* corrections, as well as all corrections where there were no other edits within a five-word span on either side of the preposition (\sim *clean*). The third contains all corrections regardless of any other changes in the surrounding context (*all*).

Lang-8 The Lang-8 website contains journals written by language learners, where native speakers highlight and correct errors on a sentence-by-sentence basis. As a result, it contains typical grammatical mistakes made by language learners, which can be easily downloaded. We automatically extract 75,622 sentences with preposition errors and corrections from the first million journal entries.⁷

HOO 2011 We take the test set from the HOO 2011 shared task (Dale and Kilgarriff, 2011) and extract all examples of preposition selection errors. The texts are fragments of ACL papers that have been manually annotated for grammatical errors.⁸

It is important to note that the three test sets we use are from entirely different domains: exam scripts from non-native English speakers (FCE), essays by highly proficient college students in Singapore (NUCLE) and ACL papers (HOO). In addition, they have a different number of total prepositions as well as erroneous prepositions.

5 Preposition Error Correction Experiments

We use the preposition error correction model described in Tetreault and Chodorow (2008)⁹ to evaluate the many ways of using Wikipedia error corrections as described in the Section 4. We use this system since it has been recreated for other work (Dahlmeier and Ng, 2011; Tetreault et al., 2010) and is similar in methodology to Gamon et al. (2008)

⁷Tajiri et al. (2012) extract a corpus of English verb phrases corrected for tense/aspect errors from Lang-8. They kindly provided us with their scripts to carry out the scraping of Lang-8.

⁸The results of the HOO 2011 shared task were not reported at level of preposition selection error, therefore it is not possible to compare the results presented in this paper with those results.

⁹Note that in that work, the model was evaluated in terms of preposition error *detection* rather than correction, however the model itself does not change.

and De Felice and Pulman (2009). In short, the method models the problem of preposition error correction (for replacement errors) as a 36-way classification problem using a multinomial logistic regression model.¹⁰ The system uses 25 lexical, syntactic and *n*-gram features derived from the contexts of each preposition training instance.

We modified the training paradigm of Tetreault and Chodorow (2008) so that a model could be trained on examples of correct usage as well as actual errors. We did this by adding a new feature specifying the writer’s original preposition (as in Han et al. (2010) and Dahlmeier and Ng (2011)).

5.1 Results

We train a preposition correction system using each of the three data paradigms and test on the FCE, NUCLE and HOO 2011 test corpora. For each preposition in the test corpus, we record whether the system predicted that it should be changed, and if so, what it should be changed to. We then compare the prediction to the annotation in the test corpus. We report results in terms of f-score, where precision and recall are calculated as follows:¹¹

$$\text{Precision} = \frac{\text{Number of correct preposition corrections}}{\text{Total number of corrections suggested}}$$

$$\text{Recall} = \frac{\text{Number of correct preposition corrections}}{\text{Total number of corrections in test set}}$$

Note that due to the high volume of unchanged prepositions in the test corpus, we obtain very high accuracies, which are not indicative of true performance, and are not included in our results.

The results of our experiments are presented in Table 2.¹² The first part of the table shows the f-scores of preposition error correction systems that

¹⁰We use liblinear (Fan et al., 2008) with the L1-regularized logistic regression solver and default parameters.

¹¹As Chodorow et al. (2012) note, it is not clear how to handle cases where the system predicts a preposition that is neither the same as the writer preposition nor the correct preposition. We count these cases as false positives.

¹²No thresholds were used in the systems that were trained on well-edited text. Traditionally, thresholds are applied so as to only predict a correction when the system is highly confident. This has the effect of increasing precision at the cost of recall, and sometimes leads to an overall improved f-score. Here we take the prediction of the system, regardless of the confidence, reflecting a lower-bound of this method.

	Data Source	Paradigm	CLC-FCE N=33,243	NUCLE N=9,366	HOO2011 N=1,703
Without Wikipedia Revisions (nonWikiRev)	Wikipedia Snapshot	Well-edited Text	24.43*	5.02*	12.36*
	Lexile/SJM	Well-edited Text	24.73*	4.29*	9.73*
	Wikipedia Snapshot	Artificial Errors (Lang-8)	42.15*	19.91*	28.75
	Lexile/SJM	Artificial Errors (Lang-8)	45.36	18.00*	25.15
	Lang-8	Error-annotated Text	38.22*	8.18*	24.00
	NUCLE train	Error-annotated Text	5.38*	20.14	4.82*

Table 2: Preposition selection error correction results (f-score). The systems with scores in bold are statistically significantly better than all systems marked with an asterisk ($p < 0.01$). Confidence intervals were obtained using bootstrap resampling with 50,000 replicates.

one might be able to train with publicly available data excluding the Wikipedia revisions that we have extracted. We refer to these systems as **nonWikiRev** systems. The second part of the table shows the f-scores of systems trained on the Wikipedia revisions data – either directly on the annotated errors or on the artificial errors produced using the confusion distributions derived from these annotated errors. We refer to this second set of systems as **WikiRev** systems. The **nonWikiRev** systems perform inconsistently, heavily dependent on the characteristics of the test set in question. On the other hand, it is obvious that the **WikiRev** systems — while not always outperforming the best **nonWikiRev** systems — generalize much better across the three test sets. In fact, for the NUCLE test set, the best **WikiRev** system performs as well as the **nonWikiRev** system trained on data from the *same* domain and with *identical* error characteristics as the test set. The distributions of errors in the three test sets are not similar, and therefore, the stability in performance of the **WikiRev** systems cannot be attributed to the hypothesis that the **WikiRev** training data error distributions are more similar to the test data than any of the other training corpora. Therefore, we claim that if a preposition error correction system is to be deployed on data for which the error characteristics are not known in advance, i.e. most real-world scenarios, training the system using Wikipedia revisions is likely to be the most robust option.

6 Discussion

We examine the results of our experiments in light of the research questions we posed in Section 1.

6.1 Which Data Source is More Useful?

We wanted to know whether it was better to have a smaller corpus of carefully annotated corrections, or a much larger (but automatically generated, and therefore noisier) error-annotated corpus. We also wanted to compare this scenario to training on large amounts of well-edited text. From our experiments, it is clear that the composition of the test set plays a major role in answering this question. On a test set with few corrections (NUCLE), training on well-edited text (and without using thresholds) performs particularly poorly. On the other hand, when evaluating on the FCE test set which contains far more errors, training on well-edited text performs reasonably well (though statistically significantly worse than training on all of the Wikipedia errors). Similarly, training on the smaller, high-quality NUCLE corpus and evaluating on the NUCLE test set achieves good results, however training on NUCLE and testing on FCE achieves the lowest f-score of all our systems on that test set.

Figure 2 shows the learning curves obtained by increasing the size of the training data for two of the test sets.¹³ Although one might assume

¹³For space reasons, the graph for HOO2011 is omitted. Also note that the results in Table 2 may not appear in the graph,

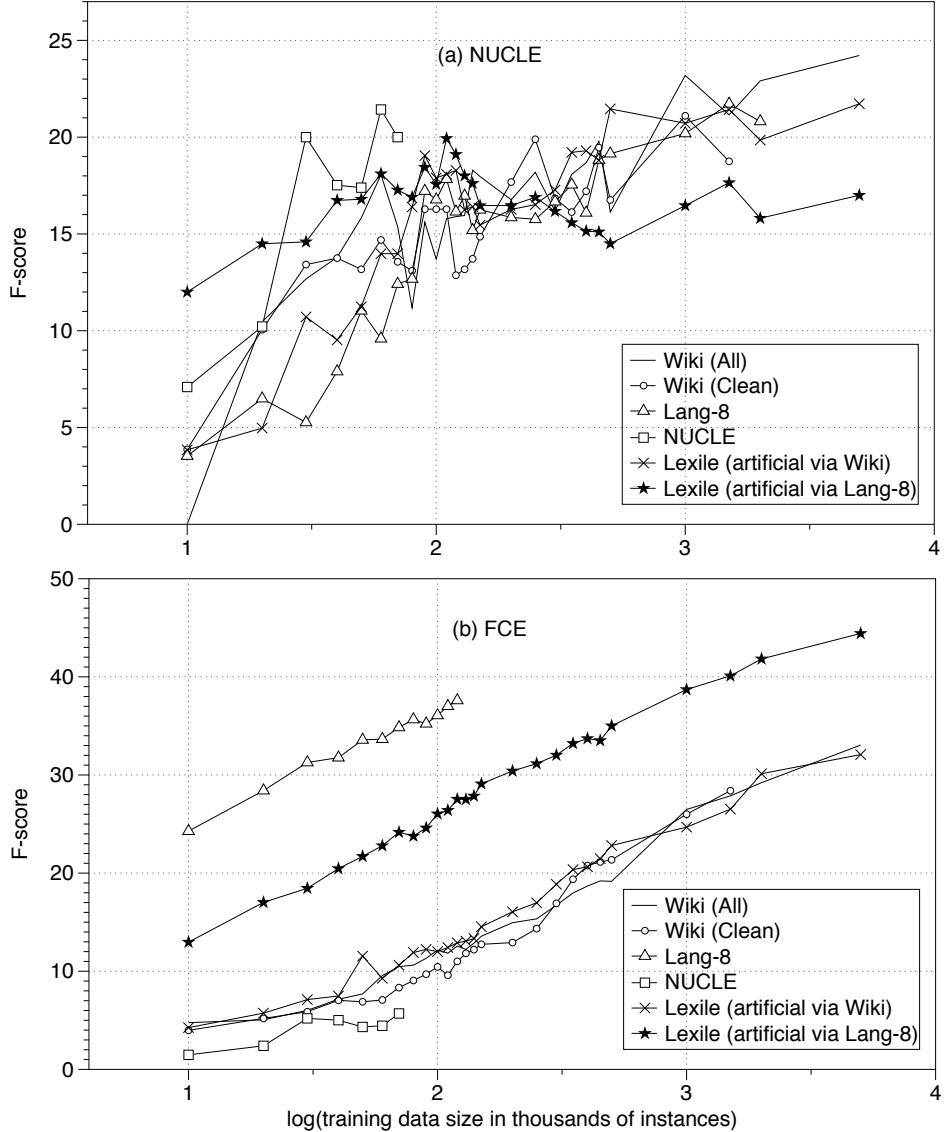

Figure 2: The effect of varying the size of the training corpus

that Wikipedia-*clean* would be more reliable than Wikipedia-*all*, the *cleaness* of the Wikipedia data seems to make very little difference, probably because the data extracted in the *dirty* contexts is not as noisy as we expected. Interestingly, it also seems that additional data would lead to further improvements for models trained on artificial errors in Lexile data and for those trained on all of the automatically extracted Wikipedia errors.

Another interesting aspect of Figure 2 is that

since we were sampling at specific data points which did not correspond exactly to the total sizes of the training corpora.

training on the Lang-8 data shows a very steep rising trend. This suggests that automatically-scraped data that is highly targeted towards language learners is very useful in correcting preposition errors in texts where they are reasonably frequent.

6.2 Natural or Artificially Generated Errors?

Table 2 shows that training on artificially generated errors via Wikipedia revisions performs fairly consistently across test corpora. While using Lang-8 for artificial error generation is also quite promising for FCE, it does not generalize across test sets.

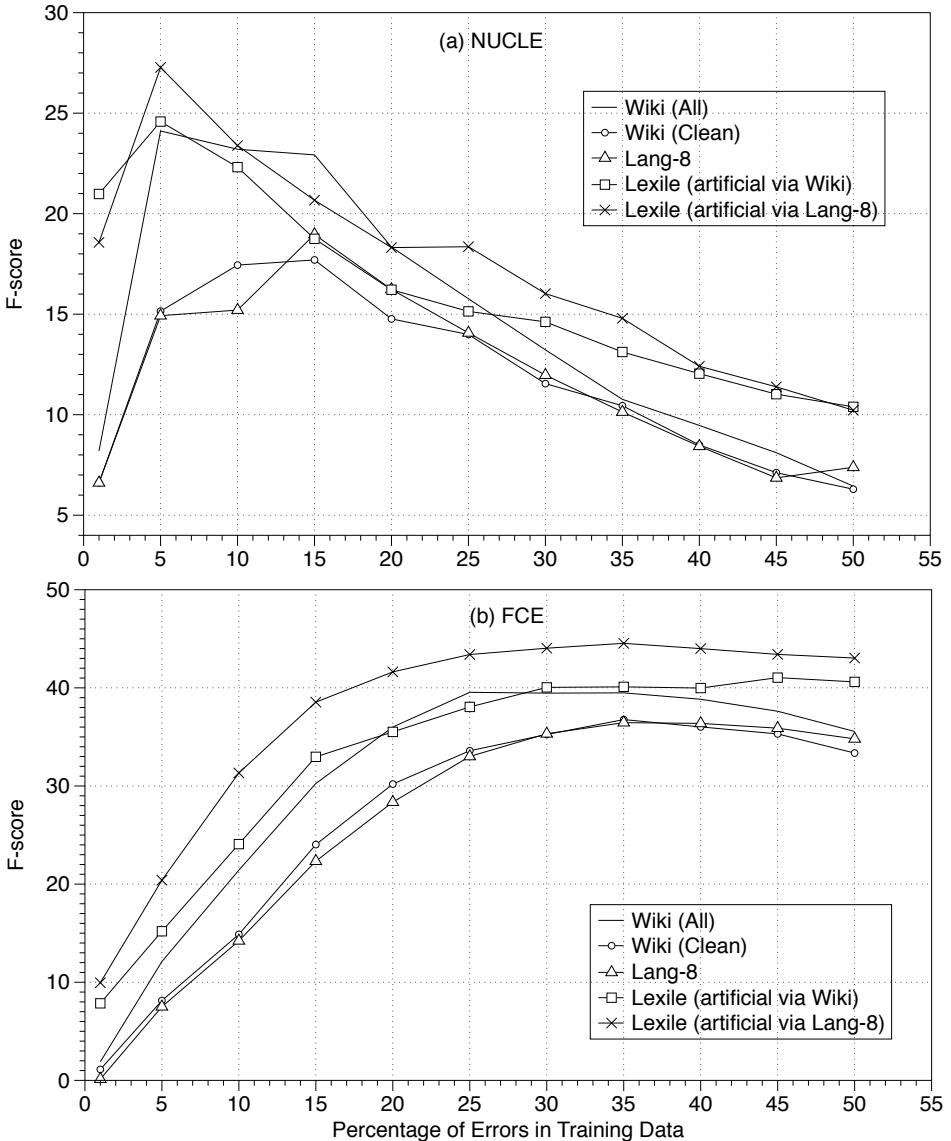

Figure 3: The effect of varying the percentage of errors in the training corpus

On FCE it achieves the highest results, on NUCLE it performs statistically significantly worse than the best system, and on HOO 2011 it achieves a lower (though not statistically significant) result than the best system. This highlights that extracting errors from Wikipedia is useful in two ways: (1) training a system on the errors alone works well and (2) generating artificial errors in well-edited corpora of different domains and training a system on that also works well. It also indicates that if the system were to be applied to a specific domain, applying the confusion distributions to a domain specific corpus – if avail-

able – would likely yield the best results.

6.3 Mismatching Distributions

The proportion of errors in the training and test data plays an important role in the performance of any preposition error correction system. This is clearly evident by comparing system performances across the three test sets which have fairly different compositions. FCE contains a much higher proportion of errors than NUCLE, and HOO falls somewhere in between. Interestingly, the system trained on Lang-8 data (which contains the highest proportion of er-

rors among all training corpora) performs best on the FCE data. On the other hand, the same system performs poorly on NUCLE test which contains far fewer errors. In this instance, the system learns to predict an incorrect preposition too often. We see a similar pattern with the system trained on the NUCLE training data. It performs poorly on FCE which contains many errors, but well on NUCLE test which contains a similar proportion of errors.

In order to better understand the relationship between the percentage of errors in the training data and system performance, we vary the percentage of errors in each training corpus from 1-50% and test on the unchanged FCE and NUCLE test corpora. For each training corpus, we reduce the size to be twice the size of the total number of errors.¹⁴ Keeping this size constant, we then artificially change the percentage of errors. Note that because the total size of the corpus has changed, the results in Table 2 may not appear in the graph. Figure 3 shows the effect on f-score when the data composition is changed. For both test sets, there is a peak after which increasing the proportion of errors in the training corpus is detrimental. For NUCLE test with its low number of preposition errors, this peak is very pronounced. For FCE, it is more of a gentle degradation in performance, but the pattern is clear. Also noteworthy is the fact that the degradation for models trained on artificial errors is less steep suggesting that they may be more stable across test sets.

In general, these results indicate that when building a preposition error detection using error-annotated data, the characteristics of the data to which the system will be applied should play a vital role in how the system is to be trained. Our results show that the **WikiRev** systems are robust across test sets, however if the exact distribution of errors in the data is known in advance, other models may perform better.

7 Conclusion

Although previous approaches to preposition error correction using either well-edited text or small hand-annotated corrections performed well on some specific test set, they did not generalize well across

¹⁴We omit the NUCLE train corpus from this comparison, because it contains too few errors to obtain a meaningful result.

very different test sets. In this paper, we present work that automatically extracts preposition error corrections from Wikipedia Revisions and uses it to build *robust* error correction systems. We show that this data is useful for two purposes. Firstly, a model trained directly on the corrections performs well across test sets. Secondly, models trained on artificial errors generated from the distribution of confusions in the Wikipedia data perform equally well. The distribution of confusions can also be applied to other well-edited corpora in different domains, providing a very powerful method of automatically generating error corpora. The results of our experiments also highlight the importance of the distribution of expected errors in the test set. Models that perform well on one kind of distribution may not necessarily work on a completely different one, as evident in the performances of the systems trained on either Lang-8 or NUCLE. In general, the **WikiRev** models perform well across distributions. We also conducted some preliminary system combination experiments and found that while they yielded promising results, further investigation is necessary. We have also made the Wikipedia preposition correction corpus available for download.¹⁵

In future work, we will examine whether the results we obtain for English generalize to other Wikipedia languages. We also plan to extract multi-word corrections for other types of errors and to examine the usefulness of including error contexts in our confusion distributions (e.g., preposition confusions following verbs versus those following nouns).

Acknowledgments

The authors would like to thank Daniel Dahlmeier, Torsten Zesch, Mamoru Komachi, Tajiri Toshikazu, Tomoya Mizumoto and Yuji Matsumoto for providing scripts and data that enabled us to carry out this research. We would also like to thank Martin Chodorow and the anonymous reviewers for their helpful suggestions and comments.

Supervised Bilingual Lexicon Induction with Multiple Monolingual Signals

Abstract

Prior research into learning translations from source and target language monolingual texts has treated the task as an unsupervised learning problem. Although many techniques take advantage of a seed bilingual lexicon, this work is the first to use that data for supervised learning to combine a diverse set of signals derived from a pair of monolingual corpora into a single discriminative model. Even in a low resource machine translation setting, where induced translations have the potential to improve performance substantially, it is reasonable to assume access to some amount of data to perform this kind of optimization. Our work shows that only a few hundred translation pairs are needed to achieve strong performance on the bilingual lexicon induction task, and our approach yields an average relative gain in accuracy of nearly 50% over an unsupervised baseline. Large gains in accuracy hold for all 22 languages (low and high resource) that we investigate.

1 Introduction

Bilingual lexicon induction is the task of identifying word translation pairs using source and target monolingual corpora, which are often comparable. Most approaches to the task are based on the idea that words that are translations of one another have similar distributional properties across languages. Prior research has shown that contextual similarity (Rapp, 1995), temporal similarity (Schafer and Yarowsky, 2002), and topical information (Mimno et al., 2009)

are all good signals for learning translations from monolingual texts.

Most prior work either makes use of only one or two monolingual signals or uses unsupervised methods (like rank combination) to aggregate orthogonal signals (Schafer and Yarowsky, 2002; Klementiev and Roth, 2006). Surprisingly, no past research has employed *supervised* approaches to combine diverse monolingually-derived signals for bilingual lexicon induction. The field of machine learning has shown decisively that supervised models dramatically outperform unsupervised models, including for closely related problems like statistical machine translation (Och and Ney, 2002).

For the bilingual lexicon induction task, a supervised approach is natural, particularly because computing contextual similarity typically requires a seed bilingual dictionary (Rapp, 1995), and that same dictionary may be used for estimating the parameters of a model to combine monolingual signals. Alternatively, in a low resource machine translation (MT) setting, it is reasonable to assume a small amount of parallel data from which a bilingual dictionary can be extracted for supervision. In this setting, bilingual lexicon induction is critical for translating source words which do not appear in the parallel data or dictionary.

We frame bilingual lexicon induction as a binary classification problem; for a pair of source and target language words, we predict whether the two are translations of one another or not. For a given source language word, we score all target language candidates separately and then rerank them. We use a variety of signals derived from source and target

*Performed while faculty at Johns Hopkins University

monolingual corpora as features and use supervision to estimate the strength of each. In this work we:

- Use the following similarity metrics derived from monolingual corpora to score word pairs: contextual, temporal, topical, orthographic, and frequency.
- For the first time, explore using supervision to combine monolingual signals and learn a discriminative model for predicting translations.
- Present results for 22 low and high resource languages paired with English and show large accuracy gains over an unsupervised baseline.

2 Previous Work

Prior work suggests that a wide variety of monolingual signals, including distributional, temporal, topic, and string similarity, may inform bilingual lexicon induction (Rapp, 1995; Fung and Yee, 1998; Rapp, 1999; Schafer and Yarowsky, 2002; Schafer, 2006; Klementiev and Roth, 2006; Koehn and Knight, 2002; Haghghi et al., 2008; Mimno et al., 2009; Mausam et al., 2010). Klementiev et al. (2012) use many of those signals to score an existing phrase table for end-to-end MT but do not learn any new translations. Schafer and Yarowsky (2002) use an unsupervised rank-combination method for combining orthographic, contextual, temporal, and frequency similarities into a single ranking.

Recently, Ravi and Knight (2011), Dou and Knight (2012), and Nuhn et al. (2012) have worked toward learning a phrase-based translation model from monolingual corpora, relying on decipherment techniques. In contrast to that work, we use a seed bilingual lexicon for supervision and multiple monolingual signals proposed in prior work.

Haghghi et al. (2008) and Daumé and Jagarlamudi (2011) use some supervision to learn how to project contextual and orthographic features into a low-dimensional space, with the goal of representing words which are translations of one another as vectors which are close together in that space. However, both of those approaches focus on only two signals, high resource languages, and frequent words (frequent nouns, in the case of Haghghi et al. (2008)). In our classification framework, we can incorporate any number of monolingual signals, in-

Language	#Words	Language	#Words
Nepali	0.4	Somali	0.5
Uzbek	1.4	Azeri	2.6
Tamil	3.7	Albanian	6.5
Bengali	6.6	Welsh	7.5
Bosnian	12.9	Latvian	40.2
Indonesian	21.8	Romanian	24.1
Serbian	25.8	Turkish	31.2
Ukrainian	37.6	Hindi	47.4
Bulgarian	49.5	Polish	104.5
Slovak	124.3	Urdu	287.2
Farsi	710.3	Spanish	972

Table 1: Millions of monolingual web crawl and Wikipedia word tokens
cluding contextual and string similarity, and directly learn how to combine them.

3 Monolingual Data and Signals

3.1 Data

Throughout our experiments, we seek to learn how to translate words in a given source language into English. Table 1 lists our languages of interest, along with the total amount of monolingual data that we use for each. We use web crawled timestamped news articles to estimate temporal similarity, Wikipedia pages which are inter-lingually linked to English pages to estimate topic similarity, and both datasets to estimate frequency and contextual similarity. Following Irvine et al. (2010), we use pairs of Wikipedia page titles to train a simple transliterator for languages written in a non-Roman script, which allows us to compute orthographic similarity for pairs of words in different scripts.

3.2 Signals

Our definitions of orthographic, topic, temporal, and contextual similarity are taken from Klementiev et al. (2012), and the details of each may be found there. Here, we give briefly describe them and give our definition of a novel, frequency-based signal.

Orthographic We measure orthographic similarity between a pair of words as the normalized¹ edit distance between the two words. For non-Roman script languages, we transliterate words into the Roman script before measuring orthographic similarity.

Topic We use monolingual Wikipedia pages to estimate topical signatures for each source and target

¹Normalized by the average of the lengths of the two words

language word. Signature vectors are the length of the number of inter-lingually linked source and English Wikipedia pages and contain counts of how many times the word appears on each page. We use cosine similarity to compare pairs of signatures.

Temporal We use time-stamped web crawl data to estimate temporal signatures, which, for a given word, are the length of the number of time-stamps (dates) and contain counts of how many times the word appears in news articles with the given date. We use a sliding window of three days and use cosine similarity to compare signatures. We expect that source and target language words which are translations of one another will appear with similar frequencies over time in monolingual data.

Contextual We score monolingual contextual similarity by first collecting context vectors for each source and target language word. The context vector for a given word contains counts of how many times words appear in its context. We use bag of words contexts in a window of size two. We gather both source and target language contextual vectors from our web crawl data and Wikipedia data (separately).

Frequency Words that are translations of one another are likely to have similar relative frequencies in monolingual corpora. We measure the frequency similarity of two words as the absolute value of the difference between the logs of their relative monolingual corpus frequencies.

4 Supervised Bilingual Lexicon Induction

4.1 Baseline

Our unsupervised baseline method is based on ranked lists derived from each of the signals listed above. For each source word, we generate ranked lists of English candidates using the following six signals: Crawls Context, Crawls Time, Wikipedia Context, Wikipedia Topic, Edit distance, and Log Frequency Difference. Then, for each English candidate we compute its mean reciprocal rank² (MRR) based on the six ranked lists. The baseline ranks English candidates according to the MRR scores. For evaluation, we use the same test sets, accuracy metric, and correct translations described below.

²The MRR of the j th English word, e_j , is $\frac{1}{N} \sum_{i=1}^N \frac{1}{rank_{ij}}$, where N is the number of signals and $rank_{ij}$ is e_j 's rank according to signal i .

4.2 Supervised Approach

In addition to the monolingual resources described in Section 3.1, we have a bilingual dictionary for each language, which we use to project context vectors and for supervision and evaluation. For each language, we choose up to 8,000 source language words among those that occur in the monolingual data at least three times and that have at least one translation in our dictionary. We randomly divide the source language words into three equally sized sets for training, development, and testing. We use the training data to train a classifier, the development data to choose the best classification settings and feature set, and the test set for evaluation.

For all experiments, we use a linear classifier trained by stochastic gradient descent to minimize squared error³ and perform 100 passes over the training data.⁴ The binary classifiers predict whether a pair of words are translations of one another or not. The translations in our training data serve as positive supervision, and the source language words in the training data paired with random English words⁵ serve as negative supervision. We used our development data to tune the number of negative examples to three for each positive example. At test time, after scoring all source language words in the test set paired with all English words in our candidate set,⁶ we rank the English candidates by their classification scores and evaluate accuracy in the top- k translations.

4.3 Features

Our monolingual features are listed below and are based on raw similarity scores as well as ranks:

- Crawls Context: Web crawl context similarity score
- Crawls Context RR: reciprocal rank of crawls context

³We tried using logistic rather than linear regression, but performance differences on our development set were very small and not statistically significant.

⁴We use <http://hunch.net/~vw/> version 6.1.4, and run it with the following arguments that affect how updates are made in learning: –exact adaptive norm –power t 0.5

⁵Among those that appear at least five times in our monolingual data, consistent with our candidate set.

⁶All English words appearing at least five times in our monolingual data. In practice, we further limit the set to those that occur in the top-1000 ranked list according to at least one of our signals.

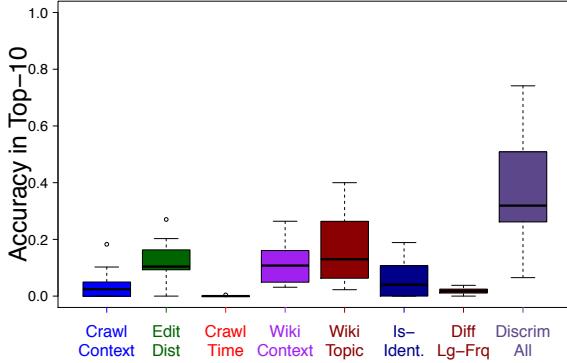

Figure 1: Each box-and-whisker plot summarizes performance on the development set using the given feature(s) across all 22 languages. For each source word in our development sets, we rank all English target words according to the monolingual similarity metric(s) listed. All but the last plot show the performance of individual features. *Discrim-All* uses supervised data to train classifiers for each language based on all of the features.

- Crawls Time: Web crawl temporal similarity score
- Crawls Time RR: reciprocal rank of crawls time
- Edit distance: normalized (by average length of source and target word) edit distance
- Edit distance RR: reciprocal rank of edit distance
- Wiki Context: Wikipedia context similarity score
- Wiki Context RR: recip. rank of wiki context
- Wiki Topic: Wikipedia topic similarity score
- Wiki Topic RR: recip. rank of wiki topic
- Is-Identical: source and target words are the same
- Difference in log frequencies: Difference between the logs of the source and target word monolingual frequencies
- Log Freqs Diff RR: reciprocal rank of difference in log frequencies

We train classifiers separately for each source language, and the learned weights vary based on, for example, corpora size and the relatedness of the source language and English (e.g. edit distance is informative if there are many cognates). In order to use the trained classifiers to make top-k translation predictions for a given source word, we rank candidates by their classification scores.

4.4 Feature Evaluation and Selection

After training initial classifiers, we use our development data to choose the most informative subset of features. Figure 1 shows the top-10 accuracy on the development data when we use individual features

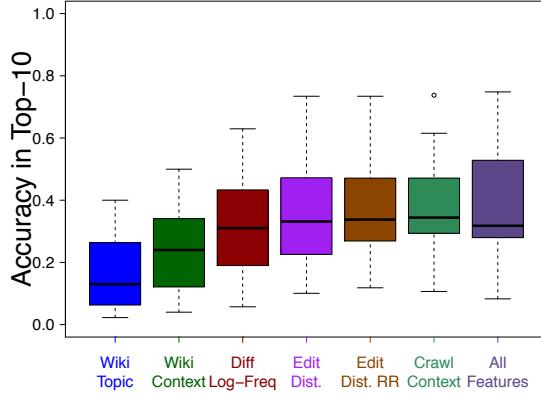

Figure 2: Performance on the development set goes up as features are greedily added to the feature space. Mean performance is slightly higher using this subset of six features (second to last bar) than using all features (last bar).

to predict translations. Top-10 accuracy refers to the percent of source language words for which a correct English translation appears in the top-10 ranked English candidates. Each box-and-whisker plot summarizes performance over the 22 languages. We don't display reciprocal rank features, as their performance is very similar to that of the corresponding raw similarity score. It's easy to see that features based on the Wikipedia topic signal are the most informative. It is also clear that training a supervised model to combine all of the features (the last plot) yields performance that is dramatically higher than using any individual feature alone.

Figure 2, from left to right, shows a greedy search for the best subset of features among those listed above. Again, the Wikipedia topic score is the most informative stand-alone feature, and the Wikipedia context score is the most informative second feature. Adding features to the model beyond the six shown in the figure does not yield additional performance gains over our set of languages.

4.5 Learning Curve Analysis

Figure 3 shows learning curves over the number of positive training instances. In all cases, the number of randomly generated negative training instances is three times the number of positive. For all languages, performance is stable after about 300 correct translations are used for training. This shows that our supervised method for combining signals requires only a small training dictionary.

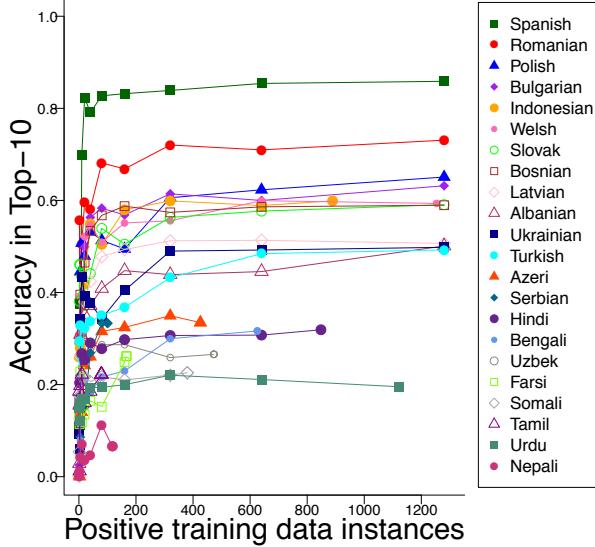

Figure 3: Learning curves over number of positive training instances, up to 1250. For some languages, 1250 positive training instances are not available. In all cases, evaluation is on the development data and the number of negative training instances is three times the number of positive. For all languages, performance is fairly stable after about 300 positive training instances.

5 Results

We use a model based on the six features shown in Figure 2 to score and rank English translation candidates for the test set words in each language. Table 2 gives the result for each language for the MRR baseline and our supervised technique. Across languages, the average top-10 accuracy using the MRR baseline is 30.4, and the average using our technique is 43.9, a relative improvement of about 44%. We did not attempt a comparison with more sophisticated unsupervised rank aggregation methods. However, we believe the improvements we observe drastically outweigh the expected performance differences between different rank aggregation methods. Figure 4 plots the accuracies yielded by our supervised technique versus the total amount of monolingual data for each language. An increase in monolingual data tends to improve accuracy. The correlation isn't perfect, however. For example, performance on Urdu and Farsi is relatively poor, despite the large amounts of monolingual data available for each. This may be due to the fact that we have large web crawls for those languages, but their Wikipedia datasets, which tend to provide a strong topic signal, are relatively small.

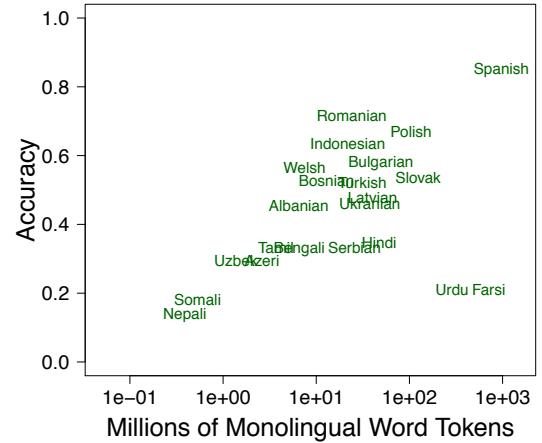

Figure 4: Millions of monolingual word tokens vs. Lexicon Induction Top-10 Accuracy

Lang	MRR	Supv.	Lang	MRR	Supv.
Nepali	11.2	13.6	Somali	16.7	18.1
Uzbek	23.2	29.6	Azeri	16.1	29.4
Tamil	28.4	33.3	Albanian	32.0	45.3
Bengali	19.3	32.8	Welsh	36.1	56.4
Bosnian	32.6	52.8	Latvian	29.6	47.7
Indonesian	41.5	63.5	Romanian	53.3	71.6
Serbian	29.0	33.3	Turkish	31.4	52.1
Ukrainian	29.7	46.0	Hindi	18.2	34.6
Bulgarian	40.2	57.9	Polish	47.4	67.1
Slovak	34.6	53.5	Urdu	13.2	21.2
Farsi	10.5	21.1	Spanish	74.8	85.0

Table 2: Top-10 Accuracy on test set. Performance increases for all languages moving from the baseline (*MRR*) to discriminative training (*Supv.*).

6 Conclusions

On average, we observe relative gains of more than 44% over an unsupervised rank-combination baseline by using a seed bilingual dictionary and a diverse set of monolingual signals to train a supervised classifier. Using supervision for bilingual lexicon induction makes sense. In some cases a dictionary is already assumed for computing contextual similarity, and, in the remaining cases, one could be compiled easily, either automatically, e.g. Haghghi et al. (2008), or through crowdsourcing, e.g. Irvine and Klementiev (2010) and Callison-Burch and Dredze (2010). We have shown that only a few hundred translation pairs are needed to achieve good performance. Our framework has the additional advantage that any new monolingually-derived similarity metrics can easily be added as new features.

Abstract

Bilingual dictionaries are expensive resources and not many are available when one of the languages is resource-poor. In this paper, we propose algorithms for creation of new reverse bilingual dictionaries from existing bilingual dictionaries in which English is one of the two languages. Our algorithms exploit the similarity between word-concept pairs using the English Wordnet to produce reverse dictionary entries. Since our algorithms rely on available bilingual dictionaries, they are applicable to any bilingual dictionary as long as one of the two languages has Wordnet type lexical ontology.

1 Introduction

The Ethnologue organization¹ lists 6,809 distinct languages in the world, most of which are resource-poor. Most existing online bilingual dictionaries are between two resource-rich languages (e.g., English, Spanish, French or German) or between a resource-rich language and a resource-poor language. There are languages for which we are lucky to find a single bilingual dictionary online. For example, the University of Chicago hosts bilingual dictionaries from 29 Southeast Asian languages², but many of these languages have only one bilingual dictionary online.

Existing algorithms for creating new bilingual dictionaries use intermediate languages or intermediate dictionaries to find chains of words with the same meaning. For example, (Gollins and Sanderson, 2001) use lexical triangulation to translate in parallel across multiple intermediate languages and

fuse the results. They query several existing dictionaries and then merge results to maximize accuracy. They use four pivot languages, German, Spanish, Dutch and Italian, as intermediate languages. Another existing approach for creating bilingual dictionaries is using probabilistic inference (Mausam et al., 2010). They organize dictionaries in a graph topology and use random walks and probabilistic graph sampling. (Shaw et al., 2011) propose a set of algorithms to create a reverse dictionary in the context of single language by using converse mapping. In particular, given an English-English dictionary, they attempt to find the original words or terms given a synonymous word or phrase describing the meaning of a word.

The goal of this research is to study the feasibility of creating a reverse dictionary by using only one existing dictionary and Wordnet lexical ontology. For example, given a Karbi³-English dictionary, we will construct an ENG-AJZ dictionary. The remainder of this paper is organized as follows. In Section 2, we discuss the nature of bilingual dictionaries. Section 3 describes the algorithms we propose to create new bilingual dictionaries from existing dictionaries. Results of our experiments are presented in Section 4. Section 5 concludes the paper.

2 Existing Online Bilingual Dictionaries

Powerful online translators developed by Google and Bing provide pairwise translations (including for individual words) for 65 and 40 languages, respectively. Wiktionary, a dictionary created by volunteers, supports over 170 languages. We find a

¹<http://www.ethnologue.com/>

²<http://dsal.uchicago.edu/dictionaries/list.html>

³Karbi is an endangered language spoken by 492,000 people (2007 Ethnologue data) in Northeast India, ISO 639-3 code AJZ. ISO 693-3 code for English is ENG.

large number of bilingual dictionaries at PanLex⁴ including an ENG-Hindi⁵ and a Vietnamese⁶-ENG dictionary. The University of Chicago has a number of bilingual dictionaries for South Asian languages. Xobdo⁷ has a number of dictionaries, focused on Northeast India.

We classify the many freely available dictionaries into three main kinds.

- Word to word dictionaries: These are dictionaries that translate one word in one language to one word or a phrase in another language. An example is an ENG-HIN dictionary at Panlex.
- Definition dictionaries: One word in one language has one or more meanings in the second language. It also may have pronunciation, parts of speech, synonyms and examples. An example is the VIE-ENG dictionary, also at Panlex.
- One language dictionaries: A dictionary of this kind is found at dictionary.com.

We have examined several hundred online dictionaries and found that they occur in many different formats. Extracting information from these dictionaries is arduous. We have experimented with five existing bilingual dictionaries: VIE-ENG, ENG-HIN, and a dictionary supported by Xobdo with 4 languages: Assamese⁸, ENG, AJZ, and Dimasa⁹. We consider the last one to be a collection of 3 bilingual dictionaries: ASM-ENG, AJZ-ENG, and DIS-ENG. We choose these languages since one of our goals is to work with resource-poor languages to enhance the quantity and quality of resources available.

3 Proposed Solution Approach

A dictionary entry, called *LexicalEntry*, is a 2-tuple $\langle \text{LexicalUnit}, \text{Definition} \rangle$. A *LexicalUnit* is a word or a phrase being defined, also called *definendum* (Landau, 1984). A list of entries sorted by the *LexicalUnit* is called a *lexicon* or a *dictionary*. Given a *LexicalUnit*, the *Definition* associated with it usually contains its class and pronunciation, its

⁸Assamese is an Indo-European language spoken by about 30 million people, but it is resource-poor, ISO 693-3 code ASM.

⁹Dimasa is another endangered language from Northeast India, spoken by about 115,000 people, ISO 693-3 code DIS.

meaning, and possibly additional information. The meaning associated with it can have several *Senses*. A *Sense* is a discrete representation of a single aspect of the meaning of a word. Thus, a dictionary entry is of the form $\langle \text{LexicalUnit}, \text{Sense}_1, \text{Sense}_2, \dots \rangle$.

In this section, we propose a series of algorithms, each one of which automatically creates a reverse dictionary, or *ReverseDictionary*, from a dictionary that translates a word in language L_1 to a word or phrase in language L_2 . We require that at least one of two these languages has a Wordnet type lexical ontology (Miller, 1995). Our algorithms are used to create reverse dictionaries from them at various levels of accuracy and sophistication.

3.1 Direct Reversal (DR)

The existing dictionary has alphabetically sorted *LexicalUnits* in L_1 and each of them has one or more *Senses* in L_2 . To create *ReverseDictionary*, we simply take every pair $\langle \text{LexicalUnit}, \text{Sense} \rangle$ in *SourceDictionary* and swap the positions of the two.

Algorithm 1 DR Algorithm

```

ReverseDictionary :=  $\phi$ 
for all LexicalEntryi in SourceDictionary do
    for all Sensej in LexicalEntryi do
        Add tuple <Sensej, LexicalEntryi.LexicalUnit> to
        ReverseDictionary
    end for
end for

```

This is a baseline algorithm so that we can compare improvements as we create new algorithms. If in our input dictionary, the sense definitions are mostly single words, and occasionally a simple phrase, even such a simple algorithm gives fairly good results. In case there are long or complex phrases in senses, we skip them. The approach is easy to implement, and produces a high-accuracy *ReverseDictionary*. However, the number of entries in the created dictionaries are limited because this algorithm just swaps the positions of *LexicalUnit* and *Sense* of each entry in the *SourceDictionary* and does not have any method to find the additional words having the same meanings.

3.2 Direct Reversal with Distance (DRwD)

To increase the number of entries in the output dictionary, we compute the distance between words in the Wordnet hierarchy. For example, the words "hasta-lipi" and "likhavat" in HIN have the meanings "handwriting" and "script", respectively. The distance between "handwriting" and "script" in Wordnet hierarchy is 0.0, so that "handwriting" and "script" likely have the same meaning. Thus, each of "hasta-lipi" and "likhavat" should have both meanings "handwriting" and "script". This approach helps us find additional words having the same meanings and possibly increase the number of lexical entries in the reverse dictionaries.

To create a *ReverseDictionary*, for every LexicalEntry_i in the existing dictionary, we find all $\text{LexicalEntry}_j, i \neq j$ with distance to LexicalEntry_i equal to or smaller than a threshold α . As results, we have new pairs of entries $\langle \text{LexicalEntry}_i.\text{LexicalUnit}, \text{LexicalEntry}_j.\text{Sense} \rangle$; then we swap positions in the two-tuples, and add them into the *ReverseDictionary*. The value of α affects the number of entries and the quality of created dictionaries. The greater the value of α , the larger the number of lexical entries, but the smaller the accuracy of the *ReverseDictionary*.

The distance between the two *LexicalEntries* is the distance between the two *LexicalUnits* if the *LexicalUnits* occur in Wordnet ontology; otherwise, it is the distance between the two *Senses*. The distance between each phrase pair is the average of the total distances between every word pair in the phrases (Wu and Palmer, 1994). If the distance between two words or phrases is 1.00, there is no similarity between these words or phrases, but if they have the same meaning, the distance is 0.00.

We find that a *ReverseDictionary* created using the value 0.0 for α has the highest accuracy. This approach significantly increases the number of entries in the *ReverseDictionary*. However, there is an issue in this approach. For instance, the word "tuhbi" in DIS means "crowded", "compact", "dense", or "packed". Because the distance between the English words "slow" and "dense" in Wordnet is 0.0, this algorithm concludes that "slow" has the meaning "tuhbi" also, which is wrong.

Algorithm 2 DRwD Algorithm

```

ReverseDictionary :=  $\phi$ 
for all  $\text{LexicalEntry}_i \in \text{SourceDictionary}$  do
    for all  $\text{Sense}_j \in \text{LexicalEntry}_i$  do
        for all  $\text{all } \text{LexicalEntry}_u \in \text{SourceDictionary}$  do
            for all  $\text{Sense}_v \in \text{LexicalEntry}_u$  do
                if  $\text{distance}(\langle \text{LexicalEntry}_i.\text{LexicalUnit}, \text{Sense}_j \rangle, \langle \text{LexicalEntry}_u.\text{LexicalUnit}, \text{Sense}_v \rangle) \leq \alpha$  then
                    Add tuple  $\langle \text{Sense}_j, \text{LexicalEntry}_u.\text{LexicalUnit} \rangle$  to ReverseDictionary
                end if
            end for
        end for
    end for
end for

```

3.3 Direct Reversal with Similarly (DRwS)

The DRwD approach computes simply the distance between two senses, but does not look at the meanings of the senses in any depth. The DRwS approach represents a concept in terms of its Wordnet synset¹⁰, synonyms, hyponyms and hypernyms. This approach is like the DRwD approach, but instead of computing the distance between lexical entries in each pair, we calculate the similarity, called *simValue*. If the *simValue* of a $\langle \text{LexicalEntry}_i, \text{LexicalEntry}_j \rangle, i \neq j$ pair is equal or larger than β , we conclude that the LexicalEntry_i has the same meaning as LexicalEntry_j .

To calculate *simValue* between two phrases, we obtain the *ExpansionSet* for every word in each phrase from the WordNet database. An *ExpansionSet* of a phrase is a union of synset, and/or synonym, and/or hyponym, and/or hypernym of every word in it. We compare the similarity between the *ExpansionSets*. The value of β and the kinds of *ExpansionSets* are changed to create different *ReverseDictionarys*. Based on experiments, we find that the best value of β is 0.9, and the best *ExpansionSet* is the union of synset, synonyms, hyponyms, and hypernyms. The algorithm for computing the *simValue* of entries is shown in Algorithm 3.

¹⁰Synset is a set of cognitive synonyms.

Algorithm 3 simValue(*LexicalEntry_i*, *LexicalEntry_j*)

```

simWords :=  $\emptyset$ 
if LexicalEntryi.LexicalUnit &
LexicalEntryj.LexicalUnit have a Word-
net lexical ontology then
    for all (LexicalUnitu  $\in$  LexicalEntryi) &
    (LexicalUnitv  $\in$  LexicalEntryj) do
        Find ExpansionSet of every
        LexicalEntry based on LexicalUnit
    end for
else
    for all (Senseu  $\in$  LexicalEntryi) &
    (Sensev  $\in$  LexicalEntryj) do
        Find ExpansionSet of every
        LexicalEntry based on Sense
    end for
end if
simWords  $\leftarrow$  ExpansionSet(LexicalEntryi)  $\cap$ 
ExpansionSet(LexicalEntryj)
n  $\leftarrow$  ExpansionSet(LexicalEntryi).length
m  $\leftarrow$  ExpansionSet(LexicalEntryj).length
simValue  $\leftarrow$  min{  $\frac{\text{simWords.length}}{n}$ ,  $\frac{\text{simWords.length}}{m}$  }

```

4 Experimental results

The goals of our study are to create the high-precision reverse dictionaries, and to increase the numbers of lexical entries in the created dictionaries. Evaluations were performed by volunteers who are fluent in both source and destination languages. To achieve reliable judgment, we use the same set of 100 non-stop word ENG words, randomly chosen from a list of the most common words¹¹. We pick randomly 50 words from each created *ReverseDictionary* for evaluation. Each volunteer was requested to evaluate using a 5-point scale, 5: excellent, 4: good, 3: average, 2: fair, and 1: bad. The average scores of entries in the *ReverseDictionary*s is presented in Figure 1. The DRwS dictionaries are the best in each case. The percentage of agreements between raters is in all cases is around 70%.

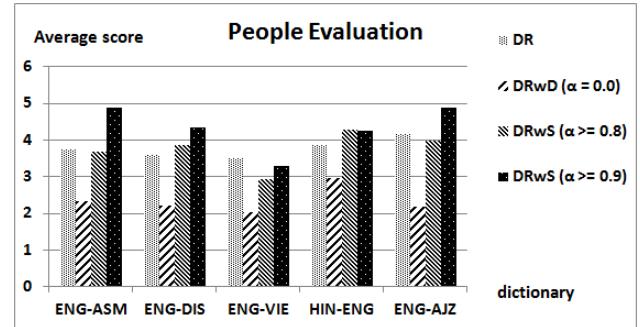

The dictionaries we work with frequently have several meanings for a word. Some of these meanings are unusual, rare or very infrequently used. The

¹¹<http://www.world-english.org/english500.htm>

DR algorithm creates entries for the rare or unusual meanings by direct reversal. We noticed that our evaluators do not like such entries in the reversed dictionaries and mark them low. This results in lower average scores in the DR algorithm comparing to averages cores in the DRwS algorithm. The DRwS algorithm seems to have removed a number of such unusual or rare meanings (and entries similar to the rare meanings, recursively) improving the average score

Our proposed approaches do not work well for dictionaries containing an abundance of complex phrases. The original dictionaries, except the VIE-ENG dictionary, do not contain many long phrases or complex words. In Vietnamese, most words we find in the dictionary can be considered compound words composed of simpler words put together. However, the component words are separated by space. For example, "bái thần giáo" means "idolatry". The component words are "bái" meaning "bow low"; "thần" meaning "deity"; and "giáo" meaning "lance", "spear", "to teach", or "to educate". The presence of a large number of compound words written in this manner causes problems with the ENG-VIE dictionary. If we look closely at Figure 1, all language pairs, except ENG-VIE show substantial improvement in score when we compare the DR algorithm with DRwS algorithm.

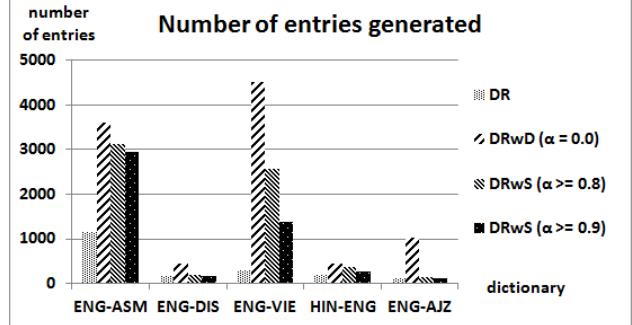

Figure 1: Average entry score in *ReverseDictionary*

The DRwD approach significantly increases the number of entries, but the accuracy of the created dictionaries is much lower. The DRwS approach using a union of synset, synonyms, hyponyms, and hypernyms of words, and $\beta \geq 0.9$ produces the best reverse dictionaries for each language pair. The DRwS approach increases the number of entries in the created dictionaries compared to the DR algorithm as

shown in Figure 2.

Figure 2: Number of lexical entries in *ReverseDictionarys* generated from 100 common words

We also create the entire reverse dictionary for the AJZ-ENG dictionary. The total number of entries in the ENG-AJZ dictionaries created by using the DR algorithm and DRwS algorithm are 4677 and 5941, respectively. Then, we pick 100 random words from the ENG-AJZ created by using the DRwS algorithm for evaluation. The average score of every entry in this created dictionary is 4.07. Some of the reversal bilingual dictionaries can be downloaded at <http://cs.uccs.edu/lin-clab/creatingBilingualLexicalResource.html>.

5 Conclusion

We proposed approaches to create a reverse dictionary from an existing bilingual dictionary using Wordnet. We show that a high precision reverse dictionary can be created without using any other intermediate dictionaries or languages. Using the Wordnet hierarchy increases the number of entries in the created dictionaries. We perform experiments with several resource-poor languages including two that are in the UNESCO's list of endangered languages.

Abstract

This paper examines the efficacy of the application of a pre-existing technique in the area of event-event temporal relationship identification. We attempt to both reproduce the results of said technique, as well as extend the previous work with application to a newly-created domain of biographical data. We find that initially the simpler feature sets perform as expected, but that the final improvement to the feature set underperforms. In response, we provide an analysis of the individual features and identify differences existing between two corpora.

1 Introduction

As natural language systems continue to grow, so too does the importance of extracting temporal information from text. Narratives often contain a wealth of temporal information, linking specific events to each other and to individual named entities of importance, but such information is often implicitly conveyed, rather than explicitly stated. The continued interest in Question Answering and other data extraction systems has emphasized the need to better understand these relations to move past superficial understanding to a level of deeper comprehension. For native speakers, the temporal clues hidden in the text are relatively simple to comprehend. However, even for human annotators, the task of identifying and classifying the specific relationship between two events can be problematic. This complexity, of course, only exacerbates the problem of trying to automate the process for any information extraction system.

The creation of the TimeBank Corpus (Pustejovsky et al, 2003a), a fully-annotated newswire domain, opened up the possibility of applying machine learning techniques to the task of automatically extracting temporal relations. We look to the standards of the TimeBank Corpus to create a corpus of biographical accounts, and apply techniques that have been shown to work on TimeBank to the new domain.

2 Related Work

Domain-independent approaches have often focused on events that can be bound to a global timeline (Mani et al, 2003). This includes dates and times, but often neglects phrases that indicate events occurring in relative time (e.g. “during school,” “before the crash,” or “recently”). Research conducted on news articles attempted to identify the specific temporal relationships between two events, as seen in (Mani et al, 2006). Further work in that domain extended this start by identifying additional features that better predicted those temporal relations. (Lapata & Lascarides 2007; Chambers et al, 2007).

In this work, we are primarily interested in applying event ordering techniques to documents less structured than news articles, specifically biographies. It is the intention of our work to validate the efficacy of previous techniques in a different domain, and thus we attempt to extend the work completed by Chambers et al through application to a newly created corpus of biographical data. In the previous work, Chambers reports best results of 59.43% accuracy with gold standard features on TimeBank. We attempt to reproduce these results, and also adopt the policy of including incremental results against features selected based on the work

of Mani et al (2006), and Lapata & Lascarides (2007).

3 Data

For purposes of validation of our implementation, we adopt the use of the TimeBank corpus (v1.1), which consists of 186 newswire documents and 3,406 identified event pairs with temporal relationships. The number of identified event pairs differs slightly from the previous work, which reports only 3,345. We cannot account for this discrepancy.

Furthermore, we oversee the creation of the Bio Corpus, consisting of 17 biographical accounts and annotated with 1,594 event pairs. Despite the small size of the corpus, we feel that the greatly increased event relationship density of our samples compared to a similar number of TimeBank documents offsets the disadvantage of the small document count.

The accounts are drawn from those available at Biography.com, and describe multiple aspects of the subject's life. Because the style of the biographies tends to explore one aspect of life fully, before moving on to another, we frequently see references to events contained in previous sections. These relations, which are not only across sentence boundaries but often in entirely different paragraphs, are one of the most striking differences between TimeBank documents and those of the new corpus.

To prepare the corpus, each document was automatically event tagged through the adoption of EVITA, the Events in Text Analyzer (Sauri et al, 2005). EVITA was previously found to perform with 80.12% accuracy, a result comparable to the accuracy of graduate student annotators with basic training. The temporal relations between event pairs were then hand-annotated according to the TimeML standard (Pustejovsky et al, 2003b).

4 Methodology

In an attempt to reproduce the event relationship classification techniques of the previous work, we first implement the approach and test it on our version of the TimeBank corpus. We then demonstrate that the validated techniques are applicable to the biographical domain, and that where discrepancies do occur, the specific feature set can be

modified to elicit improvements not seen in the TimeBank data. In all possible cases we utilize the same techniques and tools as the earlier work, except where sufficient information is lacking, such as in the specific implementation of the machine learning techniques. In such situations, assumptions are made as deemed necessary.

Chambers' work attempts to identify the relationships between event pairs according to a previously defined set consisting of *Before*, *iBefore*, *Includes*, *Begins*, *Ends*, and *Simultaneous*. The set of event pairs are pre-selected and chosen for preexisting relationships, so a classification of *No Relation* is not required. In order to achieve classification, a support vector machine (SVM) is implemented via the Library for Support Vector Machines (Chang & Lin, 2011) and is trained on an extensive set of thirty-five features, as detailed below.

(1) Mani	Tense, Aspect, Class, Tense_Agree, Aspect_Agree, Event Words
(2) Lapata	Subord., Before, Synsets, Lemmas
(3) Chambers	POS, Class_Agree, Temporal Bigrams, Dominance, Prepositions, Same Sentence

Table 1. Features of classification at each stage.

The feature set was incrementally built by a number of previous experiments, as detailed in Table 1, above. Initially, five temporal attributes originally identified by TimeML as having temporal significance, are adopted. These include the tense, aspect, and class of each event, as well as the modality and polarity of each. However, per the previous work, which demonstrated modality and polarity performing with high majority baselines, we exclude them from consideration. While Chambers et al include the task of automating the identification of these features, we report results versus the gold standards taken from TimeBank.

Mani et al (2006) added features indicating an agreement between the two events in the case of tense and aspect, and Chambers extends this to include a class agreement variable. In addition to simple agreement, bigrams of tense, aspect, and class are first included by Chambers to more fully represent the relationship between the event attributes (e.g. "Past Present," "Perfect Prog").

Next to be included are the event strings themselves, extracted verbatim, and the corresponding

	Baseline	Mani	Lapata	Chambers
TimeBank – Chambers	37.22	50.97	52.29	60.45
TimeBank – New	37.11	51.97	53.79	58.22
Bio Corpus	45.67	53.14	52.89	56.65

Table 2: Accuracy of SVM classification for Temporal Relationships.

	Baseline – (Lapata)	Part-of-Speech	Prepositional Head	Class Agreement	Temporal Bigrams
TimeBank	53.79	55.99	56.48	55.02	54.84
Bio Corpus	55.40	54.77	57.34	55.71	55.49

Table 3: Accuracy of feature subset analysis. Includes all features attributed to Mani and Lapata.

Wordnet (Fellbaum, 1998) synsets and lemmas. Also included are the parts-of-speech for both event words, the two words immediately preceding each event, and that of the token immediately following the events. Bigrams for part-of-speech from each event and its preceding token are also included, as well as a bigram for the part-of-speech of the two events as related to each other.

Lapata and Lascarides (2006) first added a feature indicating whether or not two events were in a subordinate relationship, which Chambers' includes, and extends it with the addition of one indicating a dominating relationship. This information is extracted by considering the parse tree as defined by an intermediate stage of the Stanford Parser. Similar to these two linguistic ordering features, we include another feature indicating the textual ordering of the two events (true if Event 1 is before Event 2, and false if not), and one indicating whether the two events are intra- or inter-sentential (same sentence or different sentences). Finally, we adopt Chambers' use of a feature for identifying whether or not each event is a part of a prepositional phrase.

All of these features are extracted from the text via regular expressions and application of the aforementioned third-party tools (such as WordNet and the Stanford Parser). With the features extracted, the first experiment on TimeBank uses only those features identified by Mani et al. Experiments two and three incrementally grow the feature set with those identified by Lapata & Lascarides and Chambers, respectively. The feature sets can be seen in Table 1, above. Results of this reproduction of the previous work are used as a point of comparison to the results of classification on our own Bio Corpus, using the same incremental growth classification scheme as before.

Furthermore, we provide independent feature analysis of a selection of the new features added by Chambers over the Mani+Lapata set, leveraging the results to draw some conclusions as to the linguistic differences existing between the two corpora.

5 Results

We first perform classification on TimeBank with the feature set attributed to Mani, the results of which can be seen in Table 2. Our system returns an accuracy of 51.97%, outperforming Chambers' reported result by one full point. This over-performance is extended to the Lapata feature set in a 1.82 point increase over our results for Mani's features, versus the 1.32 increase seen in Chambers' reported results, which at least maintains a similar magnitude of improvement.

With the full set of features, including Chambers' additions, our system exhibits a reversal in the previous trend of over-performance. As seen in Table 2, when Chambers' reported results of 60.45%, our own system returns results of only 58.22%. Not only does this leave a void of over two percent between the expected and actual accuracies, but it represents a much smaller increase in performance between Lapata's and Chambers' feature sets on Bio. In an effort to identify an under-performing feature, although without point of comparison from previous work, we explore an independent analysis of the new features, and found all features to be performing with at least some measure of improvement, as can be seen in Table 3.

Mani's feature set, when applied to the Bio Corpus, returns similar results as on TimeBank, with slightly higher accuracy at 53.14%. This

translates to a smaller improvement over the baseline than we see in the newswire domain, but maintains approximately the same level of accuracy. Also following the same trend that is exhibited on TimeBank, the new features attributed to Lapata yield results with a small degree of improvement over the expected values at 55.4% versus TimeBank’s 53.79%.

The application of the full feature set returns the expected reversal of trend, but underperforms by an even greater degree at 56.65%, leading us to suspect linguistic differences between the two corpora. In an effort to confirm this, we perform the same independent feature analysis as we performed on TimeBank. Notable results of re-classification (seen in Table 3) came from the part-of-speech features, as well as from the prepositional phrase heads. Part-of-speech was found to degrade performance and drop accuracy from 55.40% to 54.77%. Omission of the part-of-speech from a full feature set classification does not, however, improve performance over the initial classification. The prepositional phrase feature, on the other hand, returned the opposite result from part-of-speech – an improvement over the full feature set accuracy at 57.34%, strongly suggesting the importance of prepositional phrases in classification in the Bio Corpus.

6 Discussion

On TimeBank, results of temporal relationship classification return results similar to what was expected. In the simpler feature sets of Mani and Lapata, our own experiments over-perform by a small margin in each case, maintaining a similar magnitude of improvement at each step. This small but interesting variation is likely the result of the 61 additional event pairs in our version of the TimeBank corpus. Given our lack of justification for the difference, this claim is merely speculative. On the final feature set, with the inclusion of all features set out by Chambers, we still see a small improvement over the prior feature sets, but a small magnitude of change, coming in at a high of 58.22% compared to Chambers’ 60.45%. While still reasonable, a sudden underperformance compared to the previous slight over-performances is unusual. Justification for this discrepancy could be attributed to the differences in the data set, but there is also a possibility that ambiguity in the de-

scription of the features led to improper extraction techniques. Our analysis of the individual feature fails to return what we can identify as an underperforming feature, however.

In the case of the Bio Corpus, we initially see a similar trend in performance, with the feature sets attributed to Mani and Lapata performing as expected, while the full Chambers set returns a less than impressive result. Additional analysis of the individual improvements from Chambers’ new features, however, identifies two outliers to performance on Bio. The underperformance of part-of-speech, and the surprising improvement based solely on the prepositional phrase feature, would suggest different linguistic trends between the two corpora.

In future explorations of this topic, we would like to expand the size of the biographical corpus and reaffirm its correctness through the use of cross-validation between multiple annotators. This would help to ensure that no unintentional biases have skewed our results. In addition, we would like to further investigate feature selection to find a best-case subset for performance on the Bio corpus. While we initially began such an analysis, the sheer number of potential combinations rendered it outside of the scope of this work.

Abstract

We examine predicative adjectives as an unsupervised criterion to extract subjective adjectives. We do not only compare this criterion with a weakly supervised extraction method but also with gradable adjectives, i.e. another highly subjective subset of adjectives that can be extracted in an unsupervised fashion. In order to prove the robustness of this extraction method, we will evaluate the extraction with the help of two different state-of-the-art sentiment lexicons (as a gold standard).

1 Introduction

Since the early work on sentiment analysis, it has been established that the part of speech with the highest proportion of subjective words are adjectives (Wiebe et al., 2004) (see Sentence (1)). However, not all adjectives are subjective (2).

- (1) A *grumpy* guest made some *impolite* remarks to the *insecure* and *inexperienced* waitress.
- (2) The *old* man wearing a *yellow* pullover sat on a *plastic* chair.

This justifies the exploration of criteria to automatically separate the subjective adjectives from the non-subjective adjectives.

In this work, we are interested in an out-of-context assessment of adjectives and therefore evaluate them with the help of sentiment lexicons. We examine the property of being a *predicative adjective* as an extraction criterion. Predicative adjectives are adjectives that do not modify the head of a noun

phrase, but which predicate a property of the referent of a noun phrase to which they are linked via a copula or a control predicate (3).

We show that adjectives that frequently occur as predicative adjectives are more likely to convey subjectivity (in general) than adjectives that occur non-predicatively, such as the pre-nominal (attributive) adjectives (4). A subjective adjective may occur both as a predicative (3) and a non-predicative (5) adjective and also convey subjectivity in both contexts. However, a large fraction of non-subjective adjectives do not occur as predicative adjectives (6).

- (3) Her idea was *brilliant*.
- (4) This is a *financial* problem.
- (5) She came up with a *brilliant* idea.
- (6) ?The problem is *financial*.

2 Related Work

The extraction of subjective adjectives has already attracted some considerable attention in previous research. Hatzivassiloglou and McKeown (1997) extract polar adjectives by a weakly supervised method in which subjective adjectives are found by searching for adjectives that are conjuncts of a pre-defined set of polar seed adjectives. Wiebe (2000) induces subjective adjectives with the help of distributional similarity. Hatzivassiloglou and Wiebe (2000) examine the properties of dynamic, gradable and polar adjectives as a means to detect subjectivity. Vagnaduzzo (2004) presents another bootstrapping method of extracting subjective adjectives with the help of head nouns of the subjective candidates and distributional similarity. Baroni and Vagnaduzzo

(2004) employ Web-based Mutual information for this task and largely outperform the results produced by Veginaduzzo (2004).

3 Method

In the following, we present different features with the help of which subjective adjectives can be extracted. For all resulting lists, the adjectives will be ranked according to their frequency of co-occurring with a particular feature.

3.1 Extracting Predicative Adjectives (PRD)

For the extraction of predicative adjectives, we exclusively rely on the output of a dependency parser. Predicative adjectives are usually connected to the subject of the sentence via the dependency label `nsubj` (Example (7) would correspond to Sentence (3)).

(7) `nsubj(brilliant, idea)`

3.2 Extracting Gradable Adjectives (GRD)

As an alternative extraction method, we consider morpho-syntactically *gradable adjectives*. Gradable adjectives, such as *nice* or *small*, are adjectives “that can be inflected to specify the degree or grade of something” (Wiktionary¹). It has been stated in previous work that if some adjective can build a comparative (e.g. *nicer*) or a superlative (e.g. *nicest*), then this adjective tends to be subjective (Hatzivasiloglou and Wiebe, 2000).

We employ the property of gradability, since, firstly, it is very predictive towards subjectivity and, secondly, it is the only other unsupervised criterion currently known to extract subjective adjectives. For the extraction of gradable adjectives, we rely, on the one hand, on the part-of-speech labels `JJR` (comparative) and `JJS` (superlative). On the other hand, we also consider adjectives being modified by either *more* or *most*. For the former case, we need to normalize the comparative (e.g. *nicer*) or superlative (e.g. *nicest*) word form to the canonical positive word form (e.g. *nice*) that is commonly used in sentiment lexicons.

3.3 Weakly-Supervised Extraction (WKS)

We also consider a weakly supervised extraction method in this paper, even though it is not strictly fair to compare such a method with our two previous extraction methods which are completely unsupervised. WKS considers an adjective subjective, if it co-occurs as a conjunct of a previously defined highly subjective (seed) adjective (8). In order to detect such conjunctions, we employ the dependency relation `conj`. By just relying on surface patterns, we would not be able to exclude spurious conjunctions in which other constituents than the two adjectives are coordinated, such as Sentence (10).

- (8) This approach is *ill-conceived and ineffective*.
- (9) `conj(ill-conceived, ineffective)`
- (10) [Evil witches are stereotypically dressed in *black*] and [good fairies in *white*].

We also experimented with other related weakly-supervised extraction methods, such as *mutual information* of two adjectives at the sentence level (or even smaller window sizes). However, using conjunctions largely outperformed these alternative approaches so we only pursue conjunctions here.

4 Experiments

As a large unlabeled (training) corpus, we chose the North American News Text Corpus (LDC95T21) comprising approximately 350 million words of news text. For syntactic analysis we use the Stanford Parser (Finkel et al., 2005). In order to decide whether an extracted adjective is subjective or not, we employ two sentiment lexicons, namely the *Subjectivity Lexicon (SUB)* (Wilson et al., 2005) and *SO-CAL (SOC)* (Taboada et al., 2011). According to the recent in-depth evaluation presented in Taboada et al. (2011), these two sentiment lexicons are the most effective resources for English sentiment analysis. By taking into account two different lexicons, which have also been built independently of each other, we want to provide evidence that our proposed criterion to extract subjective adjectives is not sensitive towards a particular gold standard (which would challenge the general validity of the proposed method).

¹<http://en.wiktionary.org/wiki/gradable>

ALL	other new last many first such next political federal own several few good* former same economic public major recent American second big* foreign high small local military financial little* national
PRD	able* likely available clear* difficult* important* ready* willing* hard* good* due possible* sure* interested unlikely necessary* high responsible* easy* strong* unable* different enough open aware happy impossible* right* wrong* confident*

Table 2: The 30 most frequent adjectives (ALL) and predicative adjectives (PRD); * marks matches with both sentiment lexicons SUB and SOC.

In order to produce the subjective seed adjectives for the weakly supervised extraction, we collect from the sentiment lexicon that we evaluate the n most frequent subjective adjectives according to our corpus. In order to further improve the quality of the seed set, we only consider *strong subjective* expressions from SUB and expressions with the intensity strength ± 5 from SOC.

Table 1 lists the size of the different sentiment lexicons and the rankings produced by the different extraction methods. Of course, the list of all adjectives from the corpus (**ALL**) is the largest list² while PRD is the second largest and GRD the third largest. The rankings produced by WKS are fairly sparse, in particular the ones induced with the help of SOC; apparently there are more frequently occurring strong subjective adjectives in SUB than there are high intensity adjectives in SOC.

4.1 Frequent Adjectives vs. Frequent Predicative Adjectives

Table 2 compares the 30 most frequent adjectives (ALL) and predicative adjectives (PRD). Not only does this table show that the proportion of subjective adjectives is much larger among the predicative adjectives but we may also gain some insight into what non-subjective adjectives are excluded. Among the high frequent adjectives are many quantifiers (*many, few* and *several*) and ordinal expressions (*first, next* and *last*). In principle, most of these expressions are not subjective. One may argue that these adjectives behave like function words. Since they occur

²It will also contain many words erroneously tagged as adjectives, however, this is unlikely to affect our experiments since we only focus on the highly ranked (i.e. most frequent) words. The misclassifications rather concern infrequent words.

very frequently, one might exclude some of them by just ignoring the most frequent adjectives. However, there are also other types of adjectives, especially pertainyms (*political, federal, economic, public, American, foreign, local, military, financial* and *national*) that appear on this list which could not be excluded by that heuristic. We found that these non-subjective content adjectives are present throughout the entire ranking and they are fairly frequent (on the ranking). On the list of predicative adjectives all these previous types of adjectives are much less frequent. Many of them only occur on lower ranks (and we assume that several of them only got on the list due to parsing errors).

4.2 Comparison of the Different Extraction Methods

Table 3 compares the precision of the different extraction methods at different cut-off values. It is interesting to see that for ALL in particular the higher ranks are worse than the lower ranks (e.g. rank 1000). We assume that this is due to the high-frequency adjectives which are similar to function words (see Section 4.1). At all cut-off values, however, this baseline is beaten by every other method, including our proposed method PRD. The two unsupervised methods PRD and GRD perform on a par with each other. On SUB, PRD even mostly outperforms GRD. The precision achieved by WKS is quite good. However, the coverage of this method is low. It would require more seed expressions to increase it, however, this would also mean considerably more manual guidance.

Table 3 also shows that the precision of all extraction methods largely drops on the lower ranks. However, one should not conclude from that the extraction methods proposed only work well for highly frequent words. The drop can be mostly explained by the fact that the two sentiment lexicons we use for evaluation are finite (i.e. SUB: 4396 words/SOC: 2827 words (Table 1)), and that neither of these lexicons (nor their union) represents the complete set of all English subjective adjectives. Both lexicons will have a bias towards frequently occurring subjective expressions.

Inspecting the ranks 3001-3020 produced by PRD as displayed in Table 4, for example, actually reveals that there are still many more subjective adjectives

Lexicons		Extraction Methods										
SUB	SOC	ALL	PRD	GRD	WKS-5		WKS-10		WKS-25		WKS-50	
4396	2827	212287	20793	7942	SUB	SOC	SUB	SOC	SUB	SOC	SUB	SOC

Table 1: Statistics regarding the size (i.e. number of adjectives) of the different sentiment lexicons and rankings.

artistic*	appealable	airtight	adjustable*	activist*	accommodating	acclimated	well-meaning	weakest	upsetting*	unsurpassed
unsatisfying*	unopposed	unobtrusive*	unobjectionable	unemployable	understanding*	uncharacteristic	submerged	speechless		

Table 4: A set of entries PRD produces on lower ranks (ranks 3001-3020); * marks matches with either of the sentiment lexicons SUB or SOC.

than the matches with our sentiment lexicons suggest (e.g. *appealable*, *accommodating*, *well-meaning*, *weakest*, *unsurpassed*, *unopposed*, *unobjectionable*, *unemployable*, *uncharacteristic* or *speechless*). In other words, these are less frequent words; many of them are actually subjective even though they are not listed in the sentiment lexicons. Moreover, irrespective of the drop in precision on the lower ranks, PRD and GRD still outperform ALL on both sentiment lexicons (Table 3). Despite the sparseness of our two gold standards on the lower ranks, we thus have some indication that PRD and GRD are more effective than ALL.

The problem of the evaluation of less-frequent words could not be solved by an extrinsic evaluation, either, e.g. by using the extracted lists for some text classification task (at the sentence/document level). The evaluation on contextual classification on corpora would also be biased towards high-frequency words (as the word distribution is typically Zipfian). For instance, on the MPQA-corpus (Wiebe et al., 2005), i.e. the standard dataset for (fine-grained) sentiment analysis, there is not a single mention of the subjective words *appealable*, *accommodating*, *unsurpassed*, *unopposed*, *unobtrusive* or *speechless*, which were found among the lower ranks 3001-3020.

4.3 How Different Are Gradable and Predicative Adjectives?

Since in the previous experiments the proportion of subjective adjectives was similar among the gradable adjectives and the predicative adjectives, we

may wonder whether these two extraction methods produce the same adjectives. In principle, the set of gradable adjectives extracted is much smaller than the list of extracted predicative adjectives (see Table 1). We found that the gradable adjectives are a proper subset of predicative adjectives, which is in line with the observation by (Bolinger, 1972, 21) that gradable adjectives (which he calls degree words) readily occur predicatively whereas non-gradable ones tend not to.

However, while gradability implies compatibility with predicative use, the reverse is not true. Accordingly, we found adjectives that are definitely not gradable among the predicative adjectives that are subjective, for instance *endless*, *insolvent*, *nonexistent*, *stagnant*, *unavailable* or *untrue*. This means that with the criterion of predicative adjectives one is able to extract relevant subjective adjectives that cannot be caught by the gradability criterion alone, namely *complementary* adjectives that refer to a simple binary opposition (Cruse, 1986, 198-99).

4.4 Intersecting the Different Unsupervised Criteria

In this section, we want to find out whether we can increase the precision by considering intersections of the two different unsupervised extraction criteria. (Due to the sparsity of WKS, it does not make sense to include that method in this experiment.) In our previous experiments it turned out that as far as precision is concerned, our new proposed extraction criterion was similar to the gradability criterion. If, however, the intersection of these two criteria produces better results, then we have provided some further proof of the effectiveness of our proposed criterion (even though we may sacrifice some exclusive subjective adjectives in PRD as pointed out in Section 4.3). It would mean that this criterion is also beneficial in the presence of the gradability criterion.

Figure 1 shows the corresponding results. We computed the intersection of PRD and GRD at var-

Rank n	ALL		PRD		GRD		WKS-5		WKS-10		WKS-25		WKS-50	
	SUB	SOC	SUB	SOC	SUB	SOC	SUB	SOC	SUB	SOC	SUB	SOC	SUB	SOC
10	10.00	30.00	90.00	90.00	80.00	60.00	80.00	90.00	80.00	90.00	90.00	70.00	90.00	70.00
25	20.00	32.00	88.00	60.00	64.00	60.00	92.00	80.00	91.00	80.00	92.00	80.00	92.00	84.00
50	30.00	34.00	88.00	64.00	70.00	68.00	82.00	78.00	92.00	78.00	92.00	84.00	90.00	86.00

3000	44.20	39.17	54.63	47.13	51.47	46.03	N/A	N/A	N/A	N/A	N/A	N/A	N/A	N/A

Table 3: Precision at rank n of the different extraction methods; $WKS-m$ denotes that for the extraction the m most frequent subjective adjectives from the respective sentiment lexicon were considered as seed expressions.

ious cut-off values of n . The resulting intersection comprises m ranks with $m < n$. The precision of the intersection was consequently compared against the precision of PRD and GRD at rank m . The figure shows that with the exception of the higher ranks on SUB (< 200) there is indeed a systematic increase in precision when the intersection of PRD and GRD is considered.

5 Conclusion

We examined predicative adjectives as a criterion to extract subjective adjectives. As this extraction method is completely unsupervised, it is preferable to weakly supervised extraction methods since we are not dependent on a manually designed high quality seed set and we obtain a much larger set of adjectives. This extraction method is competitive if not slightly better than gradable adjectives. In addition, combining these two unsupervised methods by assessing their intersection results mostly in an increase in precision.

Acknowledgements

This work was performed in the context of the Software-Cluster project EMERGENT. Michael Wiegand was funded by the German Federal Ministry of Education and Research (BMBF) under grant no. “01IC10S01”. The authors would like to thank Maite Taboada for providing her sentiment lexicon (SO-CAL) to be used for the experiments presented in this paper.

Abstract

Incorporating semantic structure into a linguistics-free translation model is challenging, since semantic structures are closely tied to syntax. In this paper, we propose a two-level approach to exploiting predicate-argument structure reordering in a hierarchical phrase-based translation model. First, we introduce linguistically motivated constraints into a hierarchical model, guiding translation phrase choices in favor of those that respect syntactic boundaries. Second, based on such translation phrases, we propose a predicate-argument structure reordering model that predicts reordering not only between an argument and its predicate, but also between two arguments. Experiments on Chinese-to-English translation demonstrate that both advances significantly improve translation accuracy.

1 Introduction

Hierarchical phrase-based (HPB) translation models (Chiang, 2005; Chiang, 2007) that utilize synchronous context free grammars (SCFG) have been widely adopted in statistical machine translation (SMT). Although formally syntactic, such models rarely respect linguistically-motivated syntax, and have no formal notion of semantics. As a result, they tend to produce translations containing both grammatical errors and semantic role confusions. Our goal is to take advantage of syntactic and semantic parsing to improve translation quality of HPB translation models. Rather than introducing semantic structure into the HPB model directly, we construct an improved translation model by incorporating linguistically motivated *syntactic constraints* into a standard HPB model. Once the

translation phrases are linguistically constrained, we are able to propose a *predicate-argument reordering model*. This reordering model aims to solve two problems: ensure that arguments are ordered properly after translation, and to ensure that the proper argument structures even *exist*, for instance in the case of PRO-drop languages. Experimental results on Chinese-to-English translation show that both the hard syntactic constraints and the predicate-argument reordering model obtain significant improvements over the syntactically and semantically uninformed baseline.

In principle, semantic frames (or, more specifically, predicate-argument structures: PAS) seem to be a promising avenue for translational modeling. While languages might diverge syntactically, they are less likely to diverge semantically. This has previously been recognized by Fung et al. (2006), who report that approximately 84% of semantic role mappings remained consistent across translations between English and Chinese. Subsequently, Zhuang and Zong (2010) took advantage of this consistency to jointly model semantic frames on Chinese/English bitexts, yielding improved frame recognition accuracy on both languages.

While there has been some encouraging work on integrating syntactic knowledge into Chiang’s HPB model, modeling semantic structure in a linguistically naive translation model is a challenge, because the semantic structures themselves are syntactically motivated. In previous work, Liu and Gildea (2010) model the reordering/deletion of source-side semantic roles in a tree-to-string translation model. While it is natural to include semantic structures in a tree-based translation model, the effect of semantic structures is presumably limited, since tree templates themselves have already encoded semantics to some

extent. For example, template $(VP (V\textit{BG} \textit{giving}) NP\#1 NP\#2)$ entails $NP\#1$ as *receiver* and $NP\#2$ as *thing given*. Xiong et al. (2012) model the reordering between predicates and their arguments by assuming arguments are translated as a unit. However, they only considered the reordering between arguments and their predicates.

2 Syntactic Constraints for HPB Translation Model

In this section, we briefly review the HPB model, then present our approach to incorporating syntactic constraints into it.

2.1 HPB Translation Model

In HPB models, synchronous rules take the form $X \rightarrow \langle \gamma, \alpha, \sim \rangle$, where X is the non-terminal symbol, γ and α are strings of lexical items and non-terminals in the source and target side, respectively, and \sim indicates the one-to-one correspondence between non-terminals in γ and α . Each such rule is associated with a set of translation model features $\{\phi_i\}$, including phrase translation probability $p(\alpha | \gamma)$ and its inverse $p(\gamma | \alpha)$, the lexical translation probability $p_{lex}(\alpha | \gamma)$ and its inverse $p_{lex}(\gamma | \alpha)$, and a rule penalty that affects preference for longer or shorter derivations. Two other widely used features are a target language model feature and a target word penalty.

Given a derivation d , its translation probability is estimated as:

$$P(d) \propto \prod_i \phi_i(d)^{\lambda_i} \quad (1)$$

where λ_i is the corresponding weight of feature ϕ_i . See (Chiang, 2007) for more details.

2.2 Syntactic Constraints

Translation rules in an HPB model are extracted from *initial phrase* pairs, which must include at least one word inside one phrase aligned to a word inside the other, such that no word inside one phrase can be aligned to a word outside the other phrase. It is not surprising to observe that initial phrases frequently are non-intuitive and inconsistent with linguistic constituents, because they are based only on statistical word alignments. Nothing in the framework actually requires linguistic knowledge.

Koehn et al. (2003) conjectured that such non-intuitive phrases do not help in translation. They tested this conjecture by restricting phrases to syntactically motivated constituents on both the source and target side: only those initial phrase pairs are subtrees in the derivations produced by the model. However, their phrase-based translation experiments (on Europarl data) showed the restriction to syntactic constituents is actually harmful, because too many phrases are eliminated. The idea of hard syntactic constraints then seems essentially to have been abandoned: it doesn't appear in later work.

On the face of it, there are many possible reasons Koehn et al. (2003)'s hard constraints did not work, including, for example, tight restrictions that unavoidably exclude useful phrases, and practical issues like the quality of parse trees. Although ensuing work moved in the direction of *soft* syntactic constraints (see Section 6), our ultimate goal of capturing predicate-argument structure requires linguistically valid syntactic constituents, and therefore we revisit the idea of hard constraints, avoiding problems with their strictness by relaxing them in three ways.

First, requiring source phrases to be subtrees in a linguistically informed syntactic parse eliminates many reasonable phrases. Consider the English-Chinese phrase pair $\langle \textit{the red car}, \textit{hongse de qiche} \rangle$.¹ It is easily to get a translation entry for the whole phrase pair. By contrast, the phrase pair $\langle \textit{the red}, \textit{hongse de} \rangle$ is typically excluded because it does not correspond to a complete subtree on the source side. Yet translating *the red* is likely to be more useful than translating *the red car*, since it is more general: it can be followed by any other noun translation. To this end, we relax the syntactic constraints by allowing phrases on the source side corresponding to either *one subtree* or *sibling subtrees* with a common parent node in the syntactic parse. For example, *the red* in Figure 1(a) is allowed since it spans two subtrees that have a common parent node *NP*.

Second, we might still exclude useful phrases because the syntactic parses of some languages, like Chinese, prefer deep trees, resulting in a head and its modifiers being distributed across multiple structural levels. Consider the English sentence *I still*

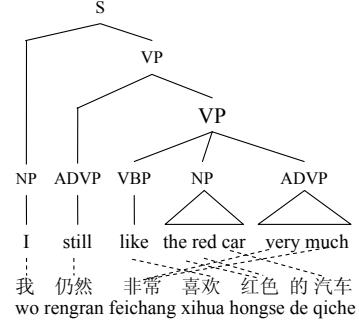

¹We use English as source language for better readability.

like the red car very much and its syntactic structure as shown in Figure 1(a). Phrases *I still, still like, I still like* are not allowed, since they don't map to either a subtree or sibling subtrees. Logically, however, it might make sense not just to include phrases mapping to (sibling) subtrees, but to include phrases mapping to subtrees with the same head. To this end, we flatten the syntactic parse so that a head and all its modifiers appear at the same level. Another advantage of this flattened structure is that flattened trees are more reliable than unflattened ones, in the sense that some bracketing errors in unflattened trees can be eliminated during tree flattening. Figure 1(b) illustrates flattening a syntactic parse by moving the head (*like*) and all its modifiers (*I, still, the red car, and very much*) to the same level.

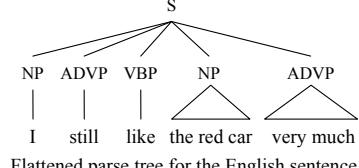

Third, initial phrase pair extraction in Chiang's HPB generates a very large number of rules, which makes training and decoding very slow. To avoid this, a widely used strategy is to limit initial phrases to a reasonable length on either side during rule extraction (e.g., 10 in Chiang (2007)). A corresponding constraint to speed up decoding prohibits any X from spanning a substring longer than a fixed length, often the same as the maximum phrase length in rule extraction. Although the initial phrase length limitation mainly keeps non-intuitive phrases out, it also closes the door on some useful phrases. For example, a translation rule $\langle I \text{ still like } X, wo \text{ rengrang xihuan } X \rangle$ will be prohibited if the non-terminal X covers 8 or more words. In contrast, our hard constraints have already filtered out dominating non-intuitive phrases; thus there is more room to include additional useful phrases. As a result, we can switch off the constraints on initial phrase length in both training and decoding.

2.3 Reorderable Glue Rules

In decoding, if no good rule (e.g., a rule whose left-hand side is X) can be applied or the length of the potential source span is larger than a pre-defined length, a glue rule (either $S \rightarrow \langle X_1, X_1 \rangle$ or $S \rightarrow \langle S_1 X_2, S_1 X_2 \rangle$) will be used to simply stitch two consequent translated phrases together in monotonic way. This will obviously prevent some reasonable translation derivations because in certain cases, the order of phrases may be inverted on the target side. Moreover, even that the syntactic constraints dis-

a. Word alignment for an English-Chinese sentence pair with the parse tree for the English sentence

b. Flattened parse tree for the English sentence

Figure 1: Example of flattening parse tree.

cussed above make translation node X s are syntactically informed, stitching translated phrases from left to right will unavoidably generate non-syntactically informed node S s. For example, the combination of X (*like*) and X (*the*) does not make much sense in linguistic perspective.

Alternatively, we replace glue rules of HPB with reorderable ones:

- $T \rightarrow \langle X_1, X_1 \rangle$
- $T \rightarrow \langle T_1 T_2, T_1 T_2 \rangle$
- $T \rightarrow \langle T_1 T_2, T_2 T_1 \rangle$

where the second (third) rule combines two translated phrases in a monotonic (inverted) way. Specifically, we set the translation probability of the first translation rule as 1 while estimating the probabilities of the other two rules from training data. In both training and decoding, we require the phrases covered by T to satisfy our syntactic constraints. Therefore, all translation nodes (both X s and T s) in derivations are syntactically informed, providing room to explore PAS reordering in HPB model.

3 PAS Reordering Model

Ideally, we aim to model PAS reordering based on the true semantic roles of both the source and target side, as to better cater not only consistence but

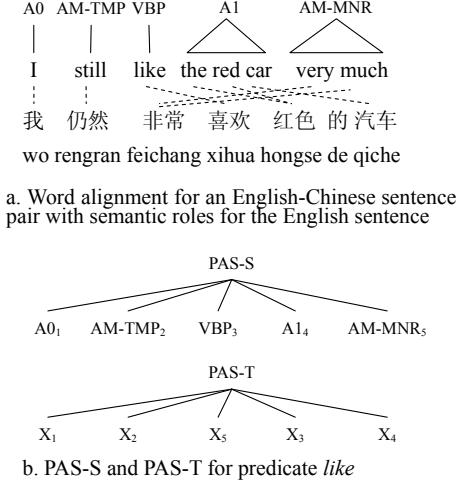

Figure 2: Example of PAS on both the source and target side. Items are aligned by indices.

divergence between semantic frames of the source and target language. However, considering there is no efficient way of jointly performing MT and SRL, accurate SRL on target side can only be done after translation. Similar to related work (Liu and Gildea, 2010; Xiong et al., 2012), we obtain the PAS of the source language (PAS-S) via a shallow semantic parser and project the PAS of the target language (PAS-T) using the word alignment derived from the translation process. Specifically, we use PropBank standard (Palmer et al., 2005; Xue, 2008) which defines a set of numbered core arguments (i.e., A0-A5) and adjunct-like arguments (e.g., AM-TMP for temporal, AM-MNR for manner). Figure 2(b) shows an example of PAS projection from source language to target language.² The PAS reordering model describes the probability of reordering PAS-S into PAS-T. Given a predicate p , it takes the following form:

$$P(\text{PAS-T} \mid \text{PAS-S}, \text{PRE}=p) \quad (2)$$

Note that cases for *untranslated roles* can be naturally reflected in our PAS reordering model. For example, if the argument I_{A0} is untranslated in Figure 2, its PAS-T will be $X_2X_5X_3X_4$.

²In PAS-S, we use parts-of-speech (POS) of predicates to distinguish different types of verbs since the semantic structures of Chinese adjective verbs are different from those of others.

3.1 Probability Estimation

While it is hard and unnecessary to translate a predicate and all its associated arguments with one rule, especially if the sentence is long, a practicable way, as most decoders do, is to translate them in multiple level rules. In addition, some adjunct-like arguments are optional, or structurally dispensable part of a sentence, which may result in data sparsity issue. Based on these observations, we decompose Formula 2 into two parts: *predicate-argument reordering* and *argument-argument reordering*.

Predicate-Argument Reordering estimates the reordering probability between a predicate and one of its arguments. Taking predicate *like* and its argument A1 *the red car* in Figure 2(a) as an example, the predicate-argument pattern on the source side (PA-S) is $VBP_1 A1_2$ while the predicate-argument pattern on the target side (PA-T) is $X_1 X_2$. The reordering probability is estimated as:

$$P_{p_A}(\text{PA-T} = X_1 X_2 \mid \text{PA-S} = VBP_1 A1_2, \text{PRE} = \text{like}) = \frac{\text{Count}(\text{PA-T} = X_1 X_2, \text{PA-S} = VBP_1 A1_2, \text{PRE} = \text{like})}{\sum_{T \in \Phi(\text{PA-S})} \text{Count}(\text{PA-T} = T, \text{PA-S} = VBP_1 A1_2, \text{PRE} = \text{like})} \quad (3)$$

where $\Phi(PA-S)$ enumerates all possible reorderings on the target side. Moreover, we take the predicate lexicon of predicate into account. To avoid data sparsity, we set a threshold (e.g., 100) to retain frequent predicates. For infrequent predicates, their probabilities are smoothed by replacing predicate lexicon with its POS. Finally, if source side patterns are infrequent (e.g., less than 10) for frequent predicates, their probabilities are smoothed as well with the same way.

Argument-Argument Reordering estimates the reordering probability between two arguments, i.e., argument-argument pattern on the source side (AA-S) and its counterpart on the target side (AA-T). However, due to that arguments are driven and pivoted by their predicates, we also include predicate in patterns of AA-S and AA-T. Let's revisit Figure 2(a). A1 *the red car* and AM-MNR *very much* are inverted on the target side, whose probability is estimated as:

$$P_{A-A}(\text{AA-T} = X_3 X_1 X_2 \mid \text{AA-S} = VBP_1 A1_2 \text{ AM-MNR}_3, \text{PRE} = \text{like}) \quad (4)$$

Similarly we smooth the probabilities by distinguishing frequent predicates from infrequent ones,

as well as frequent patterns from infrequent ones.

3.2 Integrating the PAS Reordering Model into the HPB Model

We integrate the PAS reordering model into the HPB SMT by adding a new feature into the log-linear translation model. Unlike the conventional phrase and lexical translation features whose values are phrase pair-determined and thus can be calculated offline, the value of the PAS reordering model can only be obtained with being aware of the predicate-argument structures a hypothesis may cover. Before we present the algorithm of integrating the PAS reordering model, we define a few functions by assuming p for a predicate, a for an argument, and H for a hypothesis:

- $\mathcal{A}(i, j, p)$: returns arguments of p which are fully located within the span from word i to j on the source side. For example, in Figure 2, $\mathcal{A}(4, 8, \text{like}) = \{\text{A1}, \text{AM-MRN}\}$.³
- $\mathcal{B}(i, j, p)$: returns *true* if p is located within $[i, j]$; otherwise returns *false*.
- $\mathcal{C}(a, p)$: returns *true* if predicate-argument reordering for a and p has not calculated yet; otherwise returns *false*.
- $\mathcal{D}(a_1, a_2, p)$: returns *true* if argument-argument reordering for p 's arguments a_1 and a_2 has not calculated yet; otherwise returns *false*.
- $\mathcal{P}_{P-A}(H, a, p)$: according to Eq. 3, returns the probability of predicate-argument reordering of a and p , given a and p are covered by H . The positional relation of a and p on the target side can be detected according to translation derivation of H .
- $\mathcal{P}_{A-A}(H, a_1, a_2, p)$: according to Eq. 4, returns the probability of argument-argument reordering of p 's arguments a_1 and a_2 , given a_1, a_2 and p are covered by H .

Algorithm 1 integrates the PAS reordering model into a CKY-style decoder whenever a new hypothesis is generated. Given a hypothesis H , it first looks for predicates and their arguments which are covered

³The hard constraints make sure a valid source text span would never fully cover some roles while partially cover other roles. For example, phrases *like the red, the read car very* in Figure 1 are invalid.

Algorithm 1: Integrating the PAS reordering model into a CKY-style decoder

Input: Sentence f in the source language
 Predicate-Argument Structures of f
 Hypothesis H spanning from word i to j
Output: Log-Probability of the PAS reordering model

1. set $prob = 0.0$
2. **for** predicate p in f , such that $\mathcal{B}(i, j, p)$ is *true*
3. $ARG = \mathcal{A}(i, j, p)$
4. **for** $a \in ARG$ such that $\mathcal{C}(a, p)$ is *true*
5. $prob += \log \mathcal{P}_{P-A}(H, a, p)$
6. **for** $a_1, a_2 \in ARG$ such that $a_1 \neq a_2$ and $\mathcal{D}(a_1, a_2, p)$ is *true*
7. $prob += \log \mathcal{P}_{A-A}(H, a_1, a_2, p)$
8. **return** $prob$

by H (line 2-3). Then it respectively calculates the probabilities of predicate-argument reordering and argument-argument reordering (line 4-7).

4 Experiments

We have presented our two-level approach to incorporating syntactic and semantic structures in a HPB system. In this section, we test the effect of such structural information on a Chinese-to-English translation task. The baseline system is a reproduction of Chiang's (2007) HPB system. The bilingual training data contains 1.5M sentence pairs with 39.4M Chinese words and 46.6M English words.⁴ We obtain the word alignments by running GIZA++ (Och and Ney, 2000) on the corpus in both directions and applying “grow-diag-final-and” refinement (Koehn et al., 2003). We use the SRI language modeling toolkit to train a 5-gram language model on the Xinhua portion of the Gigaword corpus and standard MERT (Och, 2003) to tune the feature weights on the development data.

To obtain syntactic parse trees for instantiating syntactic constraints and predicate-argument structures for integrating the PAS reordering model, we first parse the source sentences with the Berkeley Parser (Petrov and Klein, 2007) trained on Chinese TreeBank 6.0 and then ran the Chinese semantic role

⁴This dataset includes LDC2002E18, LDC2003E07, LDC2003E14, Hansards portion of LDC2004T07, LDC2004T08 and LDC2005T06

labeler (Li et al., 2010) on all source parse trees to annotate semantic roles for all verbal predicates.

We use the 2003 NIST MT evaluation test data (919 sentence pairs) as the development data, and the 2002, 2004 and 2005 NIST MT evaluation test data (878, 1788 and 1082 sentence pairs, respectively) as the test data. For evaluation, the NIST BLEU script (version 11b) is used to calculate the NIST BLEU scores, which measures case-insensitive matching of n -grams with n up to 4. To test whether a performance difference is statistically significant, we conduct significance tests following the paired bootstrapping approach (Koehn, 2004).

4.1 Effects of Syntactic Constraints

We have also tested syntactic constraints that simply require phrases on the source side to map to a subtree (called basic constraints). Similar to requiring initial phrases on the source side to satisfy the constraints in training process, we only perform chart parsing on text spans which satisfy the constraints in decoding process. Table 1 shows the results of applying syntactic constraints with different experimental settings. From the table, we have the following observations.

- Consistent with the conclusion in Koehn et al. (2003), using the basic constraints is harmful to HPB. Fortunately, our constraints consistently work better than the basic constraints.
- Relaxing maximum phrase length in training and maximum char span length in decoding, we obtain an average improvement of about 1.0~1.2 BLEU points for systems with both basic constraints and our constraints. It is worth noting that after relaxing the lengths, the system with our constraints performs on a par with the base HPB system (e.g., 36.21 vs. 36.10).

System	MT 02	MT 04	MT 05	Ave.

+our constraints	40.01	36.24 ⁺⁺	33.65 ⁺	36.71
with reorderable glue rules	40.70⁺	36.00 ⁺	33.67 ⁺	36.79
+PAS model	40.41 ⁺	36.73^{++**}	34.24^{++*}	37.13

Table 2: Effects of reorderable glue rules and the PAS reordering model. ^{+/++}: significant over base HPB at 0.05/0.01; ^{*/**}: significant over the system with reorderable glue rules at 0.05/0.01.

- Flattening parse trees further improves 0.4~0.5 BLEU points on average for systems with our syntactic constraints. Our final system with constraints outperforms the base HPB system with an average of 0.6 BLEU points improvement (36.71 vs. 36.10).

Another advantage of applying syntactic constraints is efficiency. By comparing the base HPB system and the system with our syntactic constraints (i.e., the last row in Table 1), it is not surprising to observe that the size of rules extracted from training data drops sharply from 193M in base HPB system to 60M in the other. Moreover, the system with constraints needs less decoding time than base HPB does. Observation on 2002 NIST MT test data (26 words per sentence on average) shows that basic HPB system needs to fill 239 cells per sentence on average in chart parsing while the other only needs to fill 108 cells.

4.2 Effects of Reorderable Glue Rules

Based on the system with our syntactic constraints and relaxed phrase lengths in training and decoding, we replace traditional glue rules with reorderable glue rules. Table 2 shows the results, from which we find that the effect of reorderable glue rules is elusive: surprisingly, it achieves 0.7 BLEU points

sentence length	1-10	11-20	21-30	31-40	41+	all
sentence count	337	1001	1052	768	590	3748
base HPB	32.21	37.51	36.71	34.96	35.00	35.73
+our constraints	31.70	37.57	37.10	36.20⁺⁺	35.78⁺⁺	36.39⁺⁺

Table 3: Experimental results over different sentence length on the three test sets. $+/++$: significant over base HPB at 0.05/0.01.

improvement on NIST MT 2002 test set while having negligible or even slightly negative impact on the other two test sets. The reason of reorderable glue rules having limited influence on translation results over monotonic only glue rules may be due to that the monotonic reordering overwhelms the inverted one: estimated from training data, the probability of the monotonic glue rule is 95.5%.

4.3 Effects of the PAS Reordering Model

Based on the system with reorderable glue rules, we examine whether the PAS reordering model is capable of improving translation performance. The last row in Table 2 presents the results. It shows the system with the PAS reordering model obtains an average of 0.34 BLEU points over the system without it (e.g., 37.13 vs. 36.79). It is interesting to note that it achieves significant improvement on NIST MT 2004 and 2005 test sets ($p < 0.05$) while slightly lowering performance on NIST MT 2002 test set ($p > 0.05$): the surprising improvement of applying reorderable glue rules on NIST MT 2002 test set leaves less room for further improvement. Finally, it shows we obtain an average improvement of 1.03 BLEU points on the three test sets over the base HPB system.

5 Discussion and Future Work

The results in Table 1 demonstrate that significant and sometimes substantial gains over baseline can be obtained by incorporating hard syntactic constraints into the HPB model. Due to the capability of translation phrases of arbitrary length, we conjecture that the improvement of our system over the baseline HPB system mostly comes from long sentences. To test the conjecture, we combine all test sentences in the three test sets and group them in terms of sentence length. Table 3 presents the sentence distribution and BLEU scores over different length. The results validate our assumption that the system with

constraints outperforms the base systems on long sentences (e.g., sentences with 20+ words).

Figure 3 displays a translation example which shows the difference between the base HPB system and the system with constraints. The inappropriate translation of the base HPB system can be mainly blamed on the rule $\langle X_{[2,5]} \rightarrow \text{的}_2 \text{发展}_3 X_{[4,5]}, X_{[4,5]} \text{ the development of} \rangle$, where $\text{的}_2 \text{发展}_3$, a part of the subtree $[0, 3]$ spanning from word 0 to 3, is translated immediately to the right of $X_{[2,5]}$, making a direct impact that subtree $[0, 3]$ is translated discontinuously on the target side. On the contrary, we can see that our constraints are able to help select appropriate phrase segments with respect to its syntactic structure.

Although our syntactic constraints apply on the source side, they are completely ignorant of syntax on the target side, which might result in excluding some useful translation rules. Let's revisit the sentence in Figure 3, where we can see that a transition rule spanning from word 0 to 5, say $\langle X_{[0,5]} \rightarrow X_{[0,3]} \text{ 是}_4 \text{ 取决于}_5, X_{[0,3]} \text{ depends on} \rangle$ is intuitive: the syntactic structure on the target side satisfies the constraints, although that of the source side doesn't. One natural extension of this work, therefore, would be to relax the constraints by including translation rules whose syntactic structure of either the source side or the target side satisfies the constraints.

To illustrate how the PAS reordering model impacts translation output, Figure 4 displays two translation examples of systems with or without it. The predicate *传递/convey* in the first example has three core arguments, i.e., A0, A2, and A1. The difference between the two outputs is the reordering of A1 and A2 while the PAS reordering model gives priority to pattern VVA1 A2. In the second example, we clearly observe two serious translation errors in the system without PAS reordering model: *他们/them*_{A1} is untranslated; *中国/china*_{A0} is moved to the immediate right of predicate *允许/allow* and plays as direct object.

Including the PAS reordering model improves the BLEU scores. One further direction to refine the approach is to alleviate verb sparsity via verb classes. Another direction is to include useful context in estimating reordering probability. For example, the content of a temporal argument AM-TMP can be a

short/simple phrase (e.g., *friday*) or a long/complex one (e.g., *when I was 20 years old*), which has impact on its reordering in translation.

6 Related Work

While there has been substantial work on linguistically motivated SMT, we limit ourselves here to several approaches that leverage syntactic constraints yet still allow cross-constituent translations. In terms of tree-based SMT with cross-constituent translations, Cowan et al. (2006) allowed non-constituent sub phrases on the source side and adopted phrase-based translation model for modifiers in clauses. Marcu (2006) and Galley et al. (2006) inserted artificial constituent nodes in parsing tree as to capture useful but non-constituent phrases. The parse tree binarization approach (Wang et al., 2007; Marcu, 2007) and the forest-based approach (Mi et al., 2008) would also cover non-constituent phrases to some extent. Shen et al. (2010) defined well-formed dependency structure to cover uncompleted dependency structure in

translation rules. In addition to the fact that the constraints of Shen et al. (2010) and this paper are based on different syntactic perspectives (i.e., dependency structure vs. constituency structure), the major difference is that in this work we don't limit the length of phrases to a fixed maximum size (e.g., 10 in Hiero). Consequently, we obtain some translation rules that are not found in Hiero systems constrained by the length. In terms of (hierarchical) phrase-based SMT with syntactic constraints, particular related to constituent boundaries, Koehn et al. (2003) tested constraints allowing constituent matched phrases only. Chiang (2005) and Cherry (2008) used a soft constraint to award or penalize hypotheses which respect or violate syntactic boundaries. Marton and Resnik (2008) further explored the idea of soft constraints by distinguishing among constituent types. Xiong et al. (2009; 2010) presented models that learn phrase boundaries from aligned dataset.

On the other hand, semantics motivated SMT has also seen an increase in activity recently. Wu and

Fung (2009) re-ordered arguments on the target side translation output, seeking to maximize the cross-lingual match of the semantic frames of the reordered translation to that of the source sentence. Liu and Gildea (2010) added two types of semantic role features into a tree-to-string translation model. Although Xiong et al. (2012) and our work are both focusing on source side PAS reordering, our model differs from theirs in two main aspects: 1) we consider reordering not only between an argument and its predicate, but also between two arguments; and 2) our reordering model can naturally model cases of untranslated arguments or predicates.

7 Conclusion

In this paper, we have presented an approach to incorporating syntactic and semantic structures for the HPB translation model. To accommodate the close tie of semantic structures to syntax, we first revisited the idea of hard syntactic constraints, and we demonstrated that hard constraints can, in fact, lead to significant improvement in translation quality when applied to Chiang’s HPB framework. Then our PAS reordering model, thanks to the constraints which guided translation phrases in favor of syntactic boundaries, made further improvements by predicting reordering not only between an argument and its predicate, but also between two arguments. In the future work, we will extend the PAS reordering model to include useful context, e.g., the head words and the syntactic categories of arguments.

Abstract

This paper discusses the extension of a system developed for automatic discovery of treebank annotation inconsistencies over an entire corpus to the particular case of evaluation of inter-annotator agreement. This system makes for a more informative IAA evaluation than other systems because it pinpoints the inconsistencies and groups them by their structural types. We evaluate the system on two corpora - (1) a corpus of English web text, and (2) a corpus of Modern British English.

1 Introduction

This paper discusses the extension of a system developed for automatic discovery of treebank annotation inconsistencies over an entire corpus to the particular case of evaluation of inter-annotator agreement (IAA). In IAA, two or more annotators annotate the same sentences, and a comparison identifies areas in which the annotators might need more training, or the annotation guidelines some refinement. Unlike other IAA evaluation systems, this system application results in a precise pinpointing of inconsistencies and the grouping of inconsistencies by their structural types, making for a more informative IAA evaluation.

Treebank annotation, consisting of syntactic structure with words as the terminals, is by its nature more complex and therefore more prone to error than many other annotation tasks. However, high annotation consistency is crucial to providing reliable training and testing data for parsers and linguistic research. Error detection is therefore an important

area of research, and the importance of work such as Dickinson and Meurers (2003) is that errors and annotation inconsistencies might be automatically discovered, and once discovered, be targeted for subsequent quality control.

A recent approach to this problem (Kulick et al., 2011; Kulick et al., 2012) (which we will call the KBM system) improves upon Dickinson and Meurers (2003) by decomposing the full syntactic tree into smaller units, using ideas from Tree Adjoining Grammar (TAG) (Joshi and Schabes, 1997). This allows the comparison to be based on small syntactic units instead of string n-grams, improving the detection of inconsistent annotation.

The KBM system, like that of Dickinson and Meurers (2003) before it, is based on the notion of comparing identical strings. In the general case, this is a problematic assumption, since annotation inconsistencies are missed because of superficial word differences between strings which one would want to compare.¹ However, this limitation is not present for IAA evaluation, since the strings to compare are, by definition, identical.² The same is also true of parser evaluation, since the parser output and the gold standard are based on the same sentences.

We therefore take the logical step of applying the KBM system developed for automatic discovery of annotation inconsistency to the special case of IAA.³

¹Boyd et al. (2007) and other current work tackles this problem. However, that is not the focus of this paper.

²Aside from possible tokenization differences by annotators.

³In this paper, we do not yet apply the system to parser evaluation, although it is conceptually the same problem as IAA evaluation. We wanted to first refine the system using annotator input for the IAA application before applying it to parser

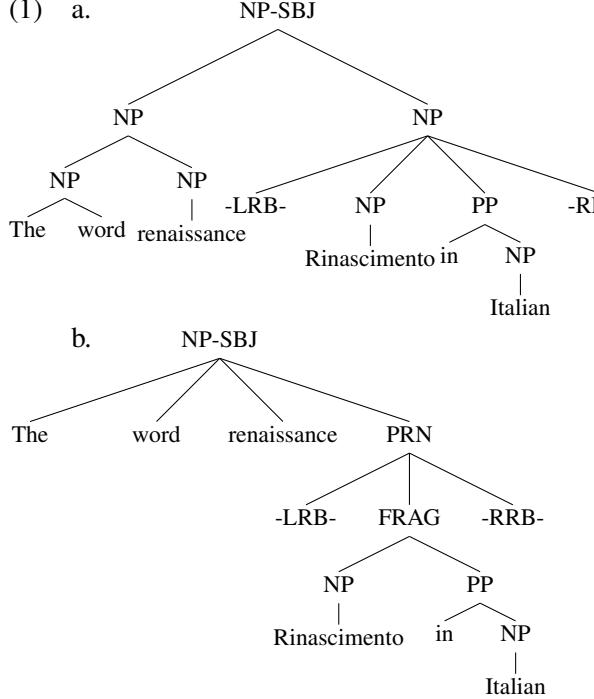

Figure 1: Two example trees showing a difference in IAA

To our knowledge, this work is the first to utilize such a general system for this special case.

The advantages of the KBM system play out somewhat differently in the context of IAA evaluation than in the more general case. In this context, the comparison of word sequences based on syntactic units allows for a precise pinpointing of differences. The system also retains the ability to group inconsistencies together by their structural type, which we have found to be useful for the more general case. Together, these two properties make for a useful and informative system for IAA evaluation.

In Section 2 we describe the basic working of our system. In Section 3 we discuss in more detail the advantages of this approach. In Section 4 we evaluate the system on two treebanks, a corpus of English web text and a corpus of Modern British English. Section 5 discusses future work.

2 System Overview

The basic idea of the KBM system is to detect word sequences that are annotated in inconsistent ways by evaluation.

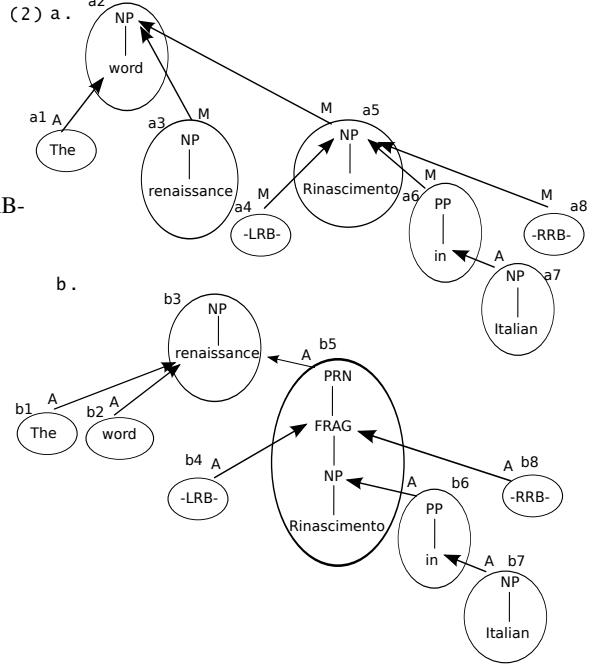

Figure 2: E-trees and derivation trees corresponding to (1ab)

comparing local syntactic units. Following Dickinson and Meurers (2003), we refer to sequences examined for inconsistent annotation as nuclei. The sentence excerpts (1ab) in Figure 1, from the test corpora used in this work, illustrate an inconsistency in the annotation of corresponding strings. We focus here on the difference in the annotation of the nucleus *The word renaissance*, which in (1a) is annotated as an appositive structure, while in (1b) it is flat.

Following the TAG approach, KBM decomposes the full phrase structure into smaller chunks called elementary trees (henceforth, e-trees). The relationship of the e-trees underlying a full phrase structure to each other is recorded in a derivation tree, in which each node is an e-tree, related to its parent node by a composition operation, as shown in (2ab).⁴

KBM uses two composition operations, each with left and right variants, shown in Figure 3: (1) ad-

⁴The decomposition is based on head-finding heuristics, with the result here that *word* is the head of (1a), while *renaissance* is the head of (1b), as reflected in their respective derivation trees (2a) and (2b). We omit the POS tags in (1ab) and (2ab) to avoid clutter.

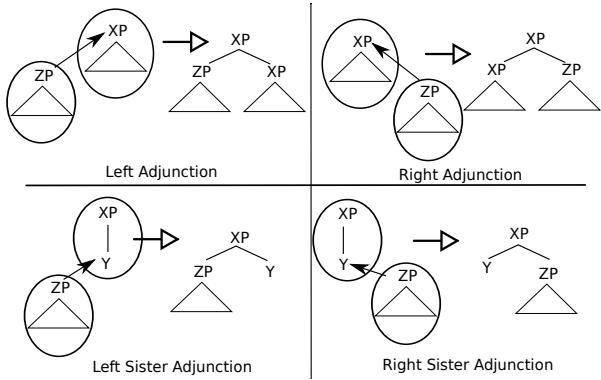

Figure 3: Composition operations (left and right)

junction, which attaches one tree to a target node in another tree by creating a copy of the target node, and (2) sister adjunction, which attaches one tree as a sister to a target node in another tree. Each arc in Figure 2 is labeled by an “M” for adjunction and “A” for sister-adjunction.⁵

The system uses the tree decomposition and resulting derivation tree for the comparison of different instances of the same nucleus. The full derivation tree for a sentence is not used, but rather only that slice of it having e-trees with words that are in the nucleus being examined, which we call a derivation tree fragment. That is, for a given nucleus with a set of instances, we compare the derivation fragments for each instance.

For example, for the nucleus *The word renaissance*, the derivation tree fragment for the instance in (1a) consists of the e-trees a1, a2, a3 (and their arcs) in (2a), and likewise the derivation tree from the instance in (1b) consists of the e-trees b1, b2, b3 in (2b). These derivation fragments have a different structure, and so the two instances of *The word renaissance* are recognized as inconsistent.

Two important aspects of the overall system require mention here: (1) Nuclei are identified by using sequences that occur as a constituent anywhere

⁵KBM is based on a variant of Spinal TAG (Shen et al., 2008), and uses sister adjunction without substitution. Space prohibits full discussion, but multiple adjunction to a single node (e.g., a4, a6, a8 to a5 in (2a)) does not create multiple levels of recursion, while a special specification handles the extra NP recursion for the apposition with a2, a3, and a5. For reasons of space, we also leave aside a precise comparison to Tree Insertion Grammar (Chiang, 2003) and Spinal TAG (Shen et al., 2008).

in the corpus, even if other instances of the same sequence are not constituents. Both instances of *The word renaissance* are compared, because the sequence occurs at least once as a constituent. (2) We partition each comparison of the instances of a nucleus by the lowest nonterminal in the derivation tree fragment that covers the sequence. The two instances of *The word renaissance* are compared because the lowest nonterminal is an NP in both instances.

3 Advantages of this approach

As Kulick et al. (2012) stressed, using derivation tree fragments allows the comparison to abstract away from interference by irrelevant modifiers, an issue with Dickinson and Meurers (2003). However, in the context of IAA, this advantage of KBM plays out in a different way, in that it allows for a precise pinpointing of the inconsistencies. For IAA, the concern is not whether an inconsistent annotation will be reported, since at some level higher in the tree every difference will be found, even if the context is the entire tree. KBM, however, will find the inconsistencies in a more informative way, for example reporting just *The word renaissance*, not some larger unit. Likewise, it reports *Rinascimento in Italian* as an inconsistently annotated sequence.⁶

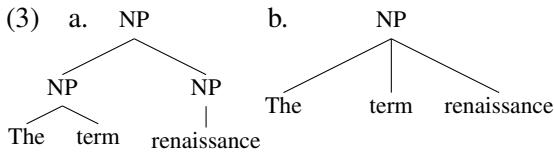

A critical desirable property of KBM that carries over from the more general case is that it allows for different nuclei to be grouped together in the system’s output if they have the same annotation inconsistency type. As in Kulick et al. (2011), each nucleus found to be inconsistent is categorized by an inconsistency type, which is simply the collection of different derivation tree fragments used for the comparison of its instances, including POS tags but not the words. For example, the inconsistency type of the nucleus *The word renaissance* in (1ab) is the pair of derivation tree fragments (a1,a2,a3) and (b1,b2,b3) from (2ab), with the POS tags. This nu-

⁶Note however that it does *not* report -LRB- *Rinascimento in Italian* -RRB- which is also a constituent, and so might be expected to be compared. The lowest nonterminal above this substring in the two derivation trees in Figure 2 is the NP in a5 and the FRAG in b5, thus exempting them from comparison. It is exactly this sort of case that motivated the “external check” discussed in Kulick et al. (2012), which we have not yet implemented for IAA.

Inconsistency type	# Found	# Accurate
Function tags only	53	53
POS tags only	18	13
Structural	129	122

Table 1: Inconsistency types found for system evaluation

cleus is then reported together with other nuclei that use the same derivation fragments. In this case, it therefore also reports the nucleus *The term renaissance*, which appears elsewhere in the corpus with the two annotations from the different annotators as in (3):

KBM reports *The word renaissance* and *The term renaissance* together because they are inconsistently annotated in exactly the same way, in spite of the difference in words. This grouping together of inconsistencies based on structural characteristics of the inconsistency is critically important for understanding the nature of the annotation inconsistencies.

It is the combination of these two characteristics - (1) pinpointing of errors and (2) grouping by structure - that makes the system so useful for IAA. This is an improvement over alternatives such as using evalb (Sekine and Collins, 2008) for IAA. No other system to our knowledge groups inconsistencies by structural type, as KBM does. The use of the derivation tree fragments greatly lessens the multiple reporting of a single annotation difference, which is a difficulty for using evalb (Manning and Schuetze, 1999, p. 436) or Dickinson and Meurers (2003).

4 Evaluation

4.1 English web text

We applied our approach to pre-release subset of (Bies et al., 2012), dually annotated and used for annotator training, from which the examples in Sections 2 and 3 are taken. It is a small section of the corpus, with 4,270 words dually annotated.

For this work, we also took the further step of characterizing the inconsistency types themselves,

allowing for an even higher-level view of the inconsistencies found. In addition to grouping together different strings as having the same inconsistent annotation, the types can also be grouped together for comparison at a higher level. For this IAA sample, we separated the inconsistency types into the three groups in Table 1, with the derivation tree fragments differing (1) only on function tags, (2) only on POS tags⁷, and (3) on structural differences. We manually examined each inconsistency group to determine if it was an actual inconsistency found, or a spurious false positive. As shown in Table 1, the precision of the reported inconsistencies is very high. It is in fact even higher than it appears, because the seven (out of 129) instances incorrectly listed as structural problems were actually either POS or function tag inconsistencies, that were discovered by the system only by a difference in the derivation tree fragment, and so were categorized as structural problems instead of POS or function tag inconsistencies.⁸

Because of the small size of the corpus, there are relatively few nuclei grouped into inconsistency types. The 129 structural inconsistency types include 130 nuclei, with the only inconsistency type with more than one nucleus being the type with *The word renaissance* and *The term renaissance*, as discussed above. There is more grouping together in the “POS tags only” case (37 nuclei included in the 18 inconsistency types), and the “function tags only” case (56 nuclei included in the 53 inconsistency types).

4.2 Modern British English corpus

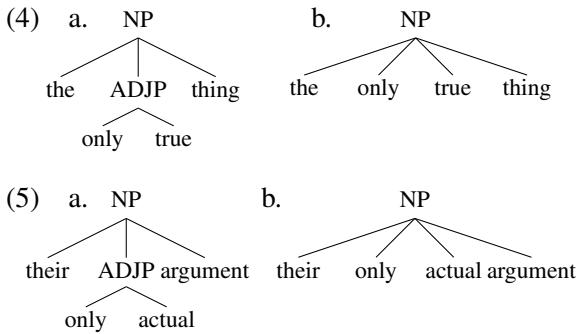

We also applied our approach to a supplemental section (Kroch and Santorini, in preparation) to a corpus of modern British English (Kroch et al., 2010), part of a series of corpora used for research into language change. The annotation style is similar to that of the Penn Treebank, although with some differences. In this case, because neither the function tags nor part-of-speech tags were part of the IAA work,

⁷As mentioned in footnote 4, although POS tags were left out of Figure 2 for readability, they are included in the actual e-trees. This allows POS differences in a similar syntactic context to be naturally captured within the overall KBM framework.

⁸A small percentage of inconsistencies are the result of linguistic ambiguities and not an error by one of the annotators.

we do not separate out the inconsistency types, as done in Section 4.1.

The supplement section consisted of 82,701 words dually annotated. The larger size, as compared with the corpus in Section 4.1, results in some differences in the system output. Because of the larger size, there are more substantial cases of different nuclei grouped together as the same inconsistency type than in Section 4.1. The first inconsistency type (sorted by number of nuclei) has 88 nuclei, and the second has 37 nuclei. In total, there are 1,532 inconsistency types found, consisting of 2,194 nuclei in total. We manually examined the first 20 inconsistency types (sorted by number of nuclei), consisting in total of 375 nuclei. All were found to be true instances of inconsistent annotation.

The trees in (4) and (5) show two of the 88 nuclei grouped into the first inconsistency type. As with *The word renaissance* and *The term renaissance* in the English web corpus, nuclei with similar (although not identical) words are often grouped into the same inconsistency type. To repeat the point, this is not because of any search for similarity of the words in the nuclei. It arises from the fact that the nuclei are annotated inconsistently in the same way. Of course not all nuclei in an inconsistency type have the same words. Nuclei found in this inconsistency type include *only true* and *only actual* as shown above, and also nuclei such as *new English*, *greatest possible*, *thin square*, *only necessary*. Taken together, they clearly indicate an issue with the annotation of multi-word adjective phrases.⁹

⁹Note that the inconsistencies discussed throughout this paper are not taken from the published corpora. These results are only from internal annotator training files.

5 Future work

There are several ways in which we plan to improve the current approach. As mentioned above, there is a certain class of inconsistencies which KBM will not pinpoint precisely, which requires adopting the “external check” from Kulick et al. (2012). The abstraction on inconsistency types described in Section 4 can also be taken further. For example, one might want to examine in particular inconsistency types that arise from PP attachment or that have to do with the PRN function tag.

One main area for future work is the application of this work to parser evaluation as well as IAA. For this area, there is some connection to the work of Goldberg and Elhadad (2010) and Dickinson (2010), which are both concerned with examining dependency structures of more than one edge. The connection is that those works are focused on dependency representations, and the KBM system does phrase structure analysis using a TAG-like derivation tree, which strongly resembles a dependency tree (Rambow and Joshi, 1997). There is much in this area of common concern that is worth examining further.

Embracing Ambiguity: A Comparison of Annotation Methodologies for Crowdsourcing Word Sense Labels

David Jurgens

Department of Computer Science
University of California, Los Angeles
jurgens@cs.ucla.edu

Abstract

Word sense disambiguation aims to identify which meaning of a word is present in a given usage. Gathering word sense annotations is a laborious and difficult task. Several methods have been proposed to gather sense annotations using large numbers of untrained annotators, with mixed results. We propose three new annotation methodologies for gathering word senses where untrained annotators are allowed to use multiple labels and weight the senses. Our findings show that given the appropriate annotation task, untrained workers can obtain at least as high agreement as annotators in a controlled setting, and in aggregate generate equally as good of a sense labeling.

1 Introduction

Word sense annotation is regarded as one of the most difficult annotation tasks (Artstein and Poesio, 2008) and building manually-annotated corpora with high-quality sense labels is often a time- and resource-consuming task. As a result, nearly all sense-tagged corpora in wide-spread use are created using trained annotators (Hovy et al., 2006; Passonneau et al., 2010), which results in a knowledge acquisition bottleneck for training systems that require sense labels (Gale et al., 1992). In other NLP areas, this bottleneck has been addressed through gathering annotations using many untrained workers on platforms such as Amazon Mechanical Turk (MTurk), a task commonly referred to as crowdsourcing. Recently, several works have proposed gathering sense annotations using crowdsourcing (Snow et al., 2008; Biemann and Nygaard, 2010; Passonneau et al., 2012b;

Rumshisky et al., 2012). However, these methods produce sense labels that are different from the commonly used sense inventories such as WordNet (Fellbaum, 1998) or OntoNotes (Hovy et al., 2006). Furthermore, while Passonneau et al. (2012b) did use WordNet sense labels, they found the quality was well below that of trained experts.

We revisit the task of crowdsourcing word sense annotations, focusing on two key aspects: (1) the annotation methodology itself, and (2) the restriction to single sense assignment. First, the choice in sense inventory plays an important role in gathering high-quality annotations; fine-grained inventories such as WordNet often contain several related senses for polysemous words, which untrained annotators find difficult to correctly apply in a given context (Chugur et al., 2002; McCarthy, 2006; Palmer et al., 2007; Rumshisky and Batiukova, 2008; Brown et al., 2010). However, many agreement studies have restricted annotators to using a single sense, which can significantly lower inter-annotator agreement (IAA) in the presence of ambiguous or polysemous usages; indeed, multiple studies have shown that when allowed, annotators readily assign multiple senses to a single usage (Véronis, 1998; Murray and Green, 2004; Erk et al., 2009; Passonneau et al., 2012b). Therefore, we focus on annotation methodologies that enable workers to use as many labels as they feel appropriate, asking the question: if allowed to make labeling ambiguity explicit, will annotators agree? Furthermore, we adopt the goal of Erk et al. (2009), which enabled annotators to weight each sense by its applicability to the given context, thereby quantifying the ambiguity.

This paper provides the following contributions. First, we demonstrate that the choice in annotation setup can significantly improve IAA and that the labels of untrained workers follow consistent patterns that enable creating high quality labeling from their aggregate. Second, we find that the sense labeling from crowdsourcing matches performance with annotators in a controlled setting.

2 Related Work

Given the potential utility of a sense-labeled corpus, multiple studies have examined how to efficiently gather high quality sense annotations. Snow et al. (2008) had MTurk workers, referred to as Turkers, disambiguate uses of “president.” While they reported extremely high IAA (0.952), their analysis was only performed on a single word.

Biemann and Nygaard (2010) and Biemann (2012) construct a sense-labeled corpus by concurrently constructing the sense inventory itself. Turkers used a lexical substitution task to identify valid substitutions of a target word. The contexts for the resulting substitutions were clustered based on their word overlap and the resulting clusters were labeled as senses. Biemann and Nygaard (2010) showed that the number of sense definitions for a word in their inventory was correlated with the number in WordNet, often with their inventory having fewer senses by combining related meanings and omitting rare meanings.

Hong and Baker (2011) evaluated multiple annotation strategies for gathering FrameNet sense annotations, ultimately yielding high (>90%) accuracy for most terms after filtering. They highlight ambiguous and polysemous usages as a notable source of errors, which the present work directly addresses.

In the most related work, Passonneau et al. (2012b) had Turkers annotate contexts using one or more senses, with the requirement that a worker labels all contexts. While they found that agreement between all workers was low, their annotations could be combined using the GLAD model (Whitehill et al., 2000) to obtain good performance, though not as good as trained annotators.

3 Annotation Methodologies

We consider three methodologies for gathering sense labels: (1) the methodology of Erk et al.

(2009) for gathering weighted labels, (2) a multi-stage strategy that uses both binary and Likert ratings, and (3) MaxDiff, a paired choice format.

Likert Ratings Likert rating scales provide the most direct way of gathering weighted sense labels; Turkers are presented with all senses of a word and then asked to rate each on a numeric scale. We adopt the annotation guidelines of Erk et al. (2009) which used a five-point scale, ranging from 1 to 5, indicating the sense does not apply or that it matches the contextual usage exactly, respectively.

Select and Rate Recent efforts in crowdsourcing have proposed multi-stage processes for accomplishing complex tasks, where efforts by one group of workers are used to create new subtasks for other workers to complete (Bernstein et al., 2010; Kittur et al., 2011; Kulkarni et al., 2012). We propose a two-stage strategy that aims to reduce the complexity of the annotation task, referred to as Select and Rate (S+R). First, Turkers are presented with all the senses and asked to make a binary choice of which senses apply. Second, a Likert rating task is created for only those senses whose selection frequency is above a threshold, thereby concentrating worker focus on a potentially smaller set of senses.

Our motivation for S+R is two-fold. First, the sense definitions of certain words may be unclear or misinterpreted by a minority of the Turkers, who then systematically rate inapplicable senses as applicable. The Select task can potentially remove such noise and therefore improve both IAA and rating quality in the subsequent Rate task. Second, while the present study analyzes words with 4–8 senses, we are ultimately interested in annotating highly polysemous words with tens of senses, which could present a significant cognitive burden for an annotator to rate concurrently. Here, the Select stage can potentially reduce the number of senses presented, leading to less cognitive burden in the Rate stage. Furthermore, as a pragmatic benefit, removing inapplicable senses reduces the visual space required for displaying the questions on the MTurk platform, which can improve annotation throughput.

MaxDiff MaxDiff is an alternative to scale-based ratings in which Turkers are presented with a only subset of all of a word’s senses and then asked to select (1) the sense option that *best* matches the mean-

	add.v	ask.v	win.v	argument.n	interest.n	paper.n	different.a	important.a

Table 1: IAA per word (top) and IAA between aggregate labelings and the GWS annotators (bottom)

ing in the example context and (2) the sense option that *least* matches (Louviere, 1991). In our setting, we presented three options at a time for words with fewer than seven senses, and four options for those with seven senses. For a single context, multiple subsets of the senses are presented and then their relative ranking is used to produce the numeric rating. The final applicability ratings were produced using a modification of the counting procedure of Orme (2009). First, all sense ratings are computed as the number of times the sense was rated *best* minus the number of times rated *least*. Second, all negatively-rated senses are assigned score of 1, and all positively ratings are normalized to be (1, 5].

4 Experiments

For measuring the difference in methodologies, we propose three experiments based on different analyses of comparing Turker and non-Turker annotations on the same dataset, the latter of which we refer to as the reference labeling. First, we measure the ability of the Turkers individually by evaluating their IAA with the reference labeling. Second, many studies using crowdsourcing combine the results into a single answer, thereby leveraging the wisdom of the crowds (Surowiecki, 2005) to smooth over inconsistencies in the data. Therefore, in the second experiment, we evaluate different methods of combining Turker responses into a single sense labeling, referred to as an *aggregate* labeling, and comparing that with the reference labeling. Third, we measure the replicability of the Turker annotations (Kilgarriff, 1999) using a sampling methodol-

ogy. Two equally-sized sets of Turker annotations are created by randomly sampling without replacement from the full set of annotations for each item. IAA is calculated between the aggregate labelings computed from each set. This sampling is repeated 50 times and we report the mean IAA as a measure of the expected degree of replicability when annotating using different groups of Turkers.

For the reference sense labeling, we use a subset of the GWS dataset of Erk et al. (2009), where three annotators rated 50 instances each for eight words. For clarity, we refer to these individuals as the GWS annotators. Given a word usage in a sentence, GWS annotators rated the applicability of all WordNet 3.0 senses using the same Likert scale as described in Section 3. Contexts were drawn evenly from the SemCor (Miller et al., 1993) and SENSEVAL-3 lexical substitution (Mihalcea et al., 2004) corpora. GWS annotators were apt to use multiple senses, with nearly all instances having multiple labels.

For each annotation task, Turkers were presented with an identical set of annotation guidelines, followed by methodology-specific instructions.¹ To increase the familiarity with the task, four instances were shown per task, with all instances using the same target word. Unlike Passonneau et al. (2012b), we did not require a Turker to annotate all contexts for a single word; however many Turkers did complete the majority of instances. Both the Likert, Select, and Rate tasks used ten Turkers each. Senses were passed from Select to Rate if they received at

¹Full guidelines are available at <http://cs.ucla.edu/~jurgens/sense-annotation/>

least three votes. For MaxDiff, we gathered at least $3n$ annotations per context where n is the number of senses of the target word, ensuring that each sense appeared at least once. Due to resource limitations, we omitted the evaluation of *argument.n* for MaxDiff. Following the recommendation of Kosinski et al. (2012), Turkers were paid \$0.05USD for each Likert, Select, and Rate task. For MaxDiff, due to their shorter nature and comparably high volume, Turkers were paid \$0.03USD per task.

To ensure fluency in English as well as reduce the potential for low-quality results, we prefaced each task with a simple test question that asked the Turker to pick out a definition of the target word from a list of four options. The incorrect options were selected so that they would be nonsensical for anyone familiar with the target word. Additionally, we rejected all Turker responses where more than one option was missing a rating. In the case of missing ratings, we infer a rating of 1. Approximately 20-30% of the submissions were rejected by these criteria, underscoring the importance of filtering.

For measuring IAA, we selected Krippendorff's α (Krippendorff, 1980; Artstein and Poesio, 2008), which is an agreement coefficient that handles missing data, as well as different levels of measurement, e.g., nominal data (Select and MaxDiff) and interval data (Likert and Rate).² Krippendorff's α adjusts for chance, ranging between $[-1, 1]$ for nominal data and $(-1, 1]$ for interval data, where 1 indicates perfect agreement and -1 indicates systematic disagreement; random labels would have an expected α of zero. We treat each sense and instance combination as a separate item to rate.

5 Results

The results of the first experiment appear in the top of Table 1. Two important aspects emerge. First, the word itself plays a significant role in IAA. Though Erk et al. (2009) reported a pair-wise IAA of the GWS annotators between 0.466 and 0.506 using Spearman's ρ , the IAA varies considerably between words for both Turkers and GWS annotators when measured using Krippendorff's α .

Second, the choice of annotation methodology

²We note that although the ratings are technically given on an ordinal scale (ranks), we use the interval scale to allow comparison with rational ratings from the aggregate solutions.

significantly impacts IAA. While both the Likert and S+R tasks have lower IAA than the GWS annotators do, the MaxDiff annotators achieve higher IAA for almost all words. We hypothesize that comparing senses for applicability is an easier task for the untrained worker, rather than having to construct a mental scale of what constitutes the applicability of each sense. Surprisingly, the binary Select task has a lower IAA than the more complex the Likert task. An analysis of the duration of median task completion times for the Likert and Select tasks showed little difference (with the exception of *paper.n*, which was on average 50 second faster for Likert ratings), suggesting that both tasks are equally as cognitively demanding. In addition, the Rate task has the lowest IAA, despite its similarity to the Likert task. An inspection of the annotations shows that the full rating scale was used, so the low value is not due to Turkers always using the same rating, which would yield an IAA near chance.

In the second experiment, we created a aggregate sense labeling and compared its IAA with the GWS annotators, shown in Table 1 (bottom). For scale-based ratings, we considered three arithmetic operations for selecting the final rating: mode, median, and mean. We found that the mode yielded the highest average IAA for the Likert ratings and median for S+R; however, the differences in IAA using each operation were often small. We compare the IAA with GWS annotators against two baselines: one generated by sampling from the GWS annotators' rating distribution, and a second generated by uniformly sampling in $[1, 5]$. By comparison, the aggregate labelings have a much larger IAA than the baselines, which is often at least as high as the IAA amongst the GWS annotators themselves, indicating that the Turkers in aggregate are capable of producing equivalent ratings. Of the three annotation methodologies, MaxDiff provides the highest IAA both within its annotators and with its aggregate key. Surprisingly, neither the Likert or S+R aggregate labeling appears better than the other.

Based on the second experiment, we measured the average IAA across all words between the aggregate Likert and MaxDiff solutions, which was 0.472. However, this IAA is significantly affected by the annotations for *win.v* and *different.a*, which had the lowest IAA among Turkers (Table 1) and there-

Corpus	Sense Inventory	IAA	Measurement
SensEval-1 (Kilgarriff and Rosenzweig, 2000)	HECTOR	0.950	Replicability experiment (Kilgarriff, 1999)
OntoNotes (Hovy et al., 2006)	OntoNotes	$\geq 0.90^{\dagger}$	Pair-wise agreement
SALSA (Burchardt et al., 2006)	FrameNet	0.86	Percentage agreement
SensEval-2 Lexical Sample (Kilgarriff, 2002)	WordNet 1.7	0.853, 0.710, 0.673 [‡]	Adjudicated Agreement
GWS with MaxDiff Replicability [◦]	WordNet 3.0	0.815	Krippendorff's α
SemCor (Fellbaum et al., 1998)	WordNet 1.6	0.786, 0.57 [*]	Percentage agreement
SensEval-3 (Snyder and Palmer, 2004)	WordNet 1.7	0.725	Percentage agreement
MASC (Passonneau et al., 2012a)	WordNet 3.1	-0.02 to 0.88 [△]	Krippendorff's α with MASCI (Passonneau et al., 2006)
MASC, single phase reported in Passonneau et al. (2010)	WordNet 3.1	0.515	Krippendorff's α
GWS with Likert Replicability	WordNet 3.0	0.409	Krippendorff's α
GWS with Erk et al. (2009) annotators	WordNet 3.0	0.349	Krippendorff's α

[†] Not all words achieved this agreement.

[‡] Kilgarriff (2002) uses a multi-stage agreement procedure where two annotators rate each item, and in the case of disagreement, a third annotator is added. If the third annotator agrees with either of the first two, the instance is marked as a case of agreement. However, the unadjudicated agreement for the dataset was 67.3 measured using pair-wise agreement. A re-annotation by Palmer et al. (2004) produced a similar pair-wise agreement of 71.0.

^{*} Tou et al. (1999) perform a re-annotation test of the same data using student annotators, finding substantially lower agreement

[◦] Excludes agreement for *argument.n*, which was not annotated

[△] IAA ranges for 37 words; no corpus-wide IAA is provided.

Table 2: IAA for sense-annotated corpora

fore produce noisy aggregate solutions. When *win.v* and *different.a* are excluded, the agreement between aggregate Likert and MaxDiff solutions is 0.649. While this IAA is still moderate, it suggests that Turkers can still produce similar annotations even when using different annotation methodologies.

For the third experiment, replicability is reported as the average IAA between the sampled aggregate labelings for all annotated words. Table 2 shows this IAA for Likert and MaxDiff methodologies in comparison to other sense annotation studies. Krippendorff (2004) recommends that an α of 0.8 is necessary to claim high-quality agreement, which is achieved by the MaxDiff methodology. In contrast, the average IAA between sampled Likert ratings is significantly lower, though the methodology does achieve an α of 0.812 for *paper.n*. However, when the two words with the lowest IAA, *win.v* and *different.a*, are excluded, the average α increases to 0.880 for MaxDiff and 0.649 for Likert. Overall, these results suggest that MaxDiff can generate highly replicable annotations with agreement on par with that of other high-quality sense-labeled corpora. Furthermore, the Likert methodology may in aggregate still

produce moderately replicable annotations in some cases.

6 Conclusion and Future Work

Word sense disambiguation is a difficult task, both for humans and algorithms, with an important bottleneck in acquiring large sense annotated corpora. As a potential solution, we proposed three annotation methodologies for crowdsourcing sense labels. Importantly, we relax the single sense assignment restriction in order to let annotators explicitly note ambiguity through weighted sense ratings. Our findings reveal that moderate IAA can be obtained using MaxDiff ratings, with IAA surpassing that of annotators in a controlled setting. Furthermore, our findings showed marked differences in rating difficulty per word, even in the weighted rating setting. In future work, we will investigate what factors influence annotation difficulty in order to improve IAA to what is considered expert levels, drawing from existing work analyzing difficulty in the single label setting (Murray and Green, 2004; Passonneau et al., 2009; Cinková et al., 2012).

Abstract

To solve data sparsity problem, recently there has been a trend in discriminative methods of NLP to use representations of lexical items learned from unlabeled data as features. In this paper, we investigated the usage of word representations learned by neural language models, i.e. word embeddings. The direct usage has disadvantages such as large amount of computation, inadequacy with dealing word ambiguity and rare-words, and the problem of linear non-separability. To overcome these problems, we instead built compound features from continuous word embeddings based on clustering. Experiments showed that the compound features not only improved the performances on several NLP tasks, but also ran faster, suggesting the potential of embeddings.

1 Introduction

Supervised learning methods have achieved great successes in the field of *Natural Language Processing (NLP)*. However, in practice most methods are usually limited by the problem of data sparsity, since it is impossible to obtain sufficient labeled data for all NLP tasks. In these situations semi-supervised learning can help to make use of both labeled data and easy-to-obtain unlabeled data.

The semi-supervised framework that is widely applied to NLP is to first learn word representations, which are feature vectors of lexical items, from unlabeled data and then plug them into a supervised system. These methods are very effective in utilizing large-scale unlabeled data and have successfully improved performances of state-of-

the-art supervised systems on a variety of tasks (Koo et al., 2008; Huang and Yates, 2009; Täckström et al., 2012).

With the development of *neural language models (NLM)* (Bengio et al., 2003; Mnih and Hinton, 2009), recently researchers become interested in word representations (also called **word embeddings**) learned by these models. Word embeddings are dense low dimensional real-valued vectors. They are composed of some latent features, which are expected to capture useful syntactic and semantic properties. Word embeddings are usually served as the first layer in deep learning systems for NLP (Collobert and Weston, 2008; Socher et al., 2011a, 2011b) and help these systems perform comparably with the state-of-the-art models based on hand-crafted features. They also have been directly added as features to the state-of-the-art models of chunking and NER, and have achieved significant improvements (Turian et al. 2010).

Although the direct usage of continuous embeddings has been proved to be an effective method for enhancing the state-of-the-art supervised models, it has some disadvantages, which made them be out-performed by simpler Brown cluster features (Turian et al, 2010) and made them computationally complicated. Firstly, embeddings of rare words are insufficiently trained since they are only updated few times and are close to their random initial values. As shown in (Turian et al, 2010), this is the main reason that models with embedding features made more errors than those with Brown cluster features. Secondly, in NLMs, each word has its unique representation, so it is difficult to represent different senses for ambiguous words. Thirdly, word embeddings are unsuitable for linear models in some tasks as will be proved in Section

4.2. This is possibly because in these tasks, either the target labels are correlated with combinations of different dimensions of word embeddings, or discriminative information may be coded in different intervals in the same dimension. So treating embeddings directly as inputs to a linear model could not fully utilize them. Moreover, since embeddings are dense vectors, it will introduce large amount of computations when they are directly used as inputs, making the method impractical.

In this paper, we first introduced the idea of clustering embeddings to overcome the last two disadvantages discussed above. The high-dimensional cluster features make samples from different classes better separated by linear models. And models with these features can still run fast because the clusters are sparse and discrete.

Second, we proposed the compound features based on clustering. Compound features, which are conjunctive features of neighboring words, have been widely used in NLP models for improving the performances because they are more discriminative. Compound features of embeddings can also help a model to better predict labels associated with rare-words and ambiguous words, because compound features composed of embeddings of nearby words can help to better describe the property of these words. Compound features are difficult to build on dense embeddings. However they are easy to induce from the sparse embedding clusters proposed in this paper.

Experiments on chunking and NER showed that based on the same embeddings, the compound features managed to achieve better performances. Moreover, we proposed analyses to reveal the reasons for the improvements of embedding-clusters and compound features. They suggest that these features can better deal with rare-words and word ambiguity, and are more suitable for linear models.

In addition, although Brown clustering was considered better in (Turian et al 2010), our experiment results and comparisons showed that our compound features from embedding clustering is at least comparable with those from Brown clustering. Since embeddings can greatly benefit from the improvement and developing of deep learning in the future, we believe that our proposed method has a large space of performance growth and will benefit more applications in NLP.

In the rest of the paper, Section 2 introduces how compound embedding features were obtained.

Section 3 gives experimental results. In Section 4, we give analysis about the advantages of compound features. Section 5 gives the conclusions.

2 Clustering of Word Embeddings

2.1 Learning Word Embeddings

Word embeddings in this paper were trained by NLMs (Bengio et al., 2003). The model predicts the scores of probabilities of words given their context information in the sentences. It first converts the current word and its context words (e.g. n-1 words before it as in n-gram models) into embeddings. Then these embeddings are put together and propagate forward on the network to compute the score of current word. After minimizing the loss on training data, embeddings are learned and can be further used as smoothing representations for words.

2.2 Clustering of embeddings

In order to get compound features of embeddings, we first induce discrete clusters from the embeddings. Concretely, the k -means clustering algorithm is used. Each word is treated as a single sample. A cluster is represented as the mean of the embeddings of words assigned to it. Similarities between words and clusters are measured by Euclidean distance. As discussed and experimented later, different numbers of ks contain information of different granularity. So we combine clustering results achieved by different ks as features to better utilize the embeddings.

2.3 Compound features

Based on embedding clusters, more powerful compound features can be built. Compound features are conjunctions between basic features of words and their contexts, which are widely used in NLP. Koo et al. (2008) also observed that compound features of Brown clusters achieved more improvements on parsing.

It is also necessary to build compound embedding features since they can better deal with rare-words and ambiguous words. For example, although embedding of a rare-word is not fully trained and hence inaccurate, embeddings of its context words can still be accurate as long as they

are not rare and are fully trained. So we could utilize the combination of embeddings before and after the word to predict its tag correctly. We conducted analysis to verify our theory in Section 4.

We combined the compound features together with other state-of-the-art human-craft features in supervised models. Examples of the resulted feature templates in chunking and NER are shown in Table 1 & 2. The feature $y_{-1}/y_0/c_{-1}/c_1$ in the last row is an example of compound feature made up of the embedding clusters of words before and after current word. Compound feature extraction can similarly be applied to form compound features of Brown clusters. For example, Brown clusters can replace embedding clusters in 3th row of Table 1.

Words	$w_{i,\in\{-2:2\}}, w_{i-1}/w_{i,\in\{0,1\}}$
POS	$p_{i,\in\{-2:2\}}, p_{i-1}/p_{i,\in\{-1,2\}}$
Cluster	$c_{i,\in\{-2:2\}}, c_{i-1}/c_{i,\in\{0,1\}}, c_{-1}/c_1$
Transition	$y_{-1}/y_0/\{w_0, p_0, c_0, c_{-1}/c_1\}$

Table 1: Chunking features. Cluster features are suitable for both Brown clusters and embedding clusters. Symbol y_i is the tag predicted on word w_i .

Words	$w_{i,\in\{-2:2\}}, w_{i-1}/w_{i,\in\{0,1\}}$
Pre/suffix	$w_{0,\in\{2:4\}}^i, w_{0,\in\{1:4\}}^{-i-1}$
Orthography	$Hyp(w_0), Cap(w_0)$
POS	$p_{i,\in\{-2:2\}}, p_{i-1}/p_{i,\in\{-1,2\}}$
Chunking	$b_{i,\in\{-2:2\}}, b_{i-1}/b_{i,\in\{-1,2\}}$
Cluster	$c_{i,\in\{-2:2\}}, c_{i-1}/c_{i,\in\{0,1\}}, c_{-1}/c_1$
Transition	$y_{-1}/y_0/\{w_0, p_0, c_0, c_{-1}/c_1\}$

Table 2: NER features. Hyp indicates if word contains hyphen and Cap indicates if first letter is capitalized.

3 Experiments

3.1 Experimental settings

We tested our compound features on the same chunking (CoNLL2000) and NER (CoNLL2003) tasks in (Turian et al., 2010). The Brown cluster features were used for comparison, which shared the same feature template used by clusters of embeddings. To compare with the work of (Turian et al., 2010), which aimed to solve the same problem but using embedding directly, we used the same word embeddings (CW 50) and Brown clusters (1000 clusters) they provided. The embeddings in (Turian et al., 2010) are trained on RCV corpus, while the CoNLL2000 data is a part of the WSJ corpus. Since we believe that word representations

trained on similar domain may better help to improve the results, we also used embeddings and Brown clusters trained on unlabeled WSJ data from (Nivre et al, 2007) for comparison.

Moreover, we wish to find out whether our method extends well to languages other than English. So we conducted experiments on Chinese NER, where large amount of training data exists, which makes improving accuracies more difficult. We used data from People’s Daily (Jan.-Jun. 1998) and converted them following the style of Penn CTB (Xue et al, 2005). Data from April was chosen as test set (1,309,616 words in 55,177 sentences), others for training (6,119,063 words in 255,951 sentences). The Chinese word representations were trained on Chinese Wikipedia until March 2011. The features used in Chinese NER are similar to those in English, except for the orthography, pre/suffixes, and chunking features.

We did little pre-processing work for the training of word representations on WSJ data. The datasets were tokenized and capital words were kept. For training of Chinese Wikipedia, we retained the bodies of all articles and replaced words with frequencies lower than 10 as an “UK_WORD” token. On each dataset, we induced embeddings with 64 dimensions based on 7-gram models and 1000 Brown clusters. The method in (Schwenk, 2007) was used to accelerate the training processes of NLMs. All the NLMs were trained for 5 epochs.

For clustering of embeddings we choose k=500 and 2500 since such combination performed best on development set as shown in the next section. We chose the Sofia-ml toolkit (Sculley 2010) for clustering of embeddings in order to save time.

In the experiments CRF models were used and were optimized by ASGD (implemented by Léon Bottou). For comparison we re-implemented the direct usage of embeddings in (Turian et al, 2010) with CRFsuite (Okazaki, 2007) since their features contain continuous values.

3.2 Performances

Table 3 shows the chunking results. The results reported in (Turian et al. 2010) were denoted as “direct”. Based on the same word representations, our compound features got better performances in all cases. The embedding features trained on unlabeled WSJ data yield further improvements, show-

ing that word representations from similar domains can better help the supervised tasks.

System	Direct	Compound
Baseline	93.75	
+Embedding (RCV)	94.10	94.19
+Brown (RCV)	94.11	94.24
+Brown&Emb (RCV)	94.35	94.42
+Embedding (WSJ)	94.20	94.37
+Brown (WSJ)	94.25	94.36
+Brown&Emb (WSJ)	94.43	94.58

Table 3: F1-scores of chunking

In the experiments of NER, first we evaluated how the numbers of clusters k will affect the performances on development set (Figure 1). The results showed that both the cluster features (excluding all compound embedding features) and compound features could achieve better results than direct usage of the same embeddings. It also showed that the performances did not vary much when k was between 500 and 3000. When $k=2500$, the result was a little higher than others. We finally chose combination of $k=500$ and 2500, which achieved best results on development set.

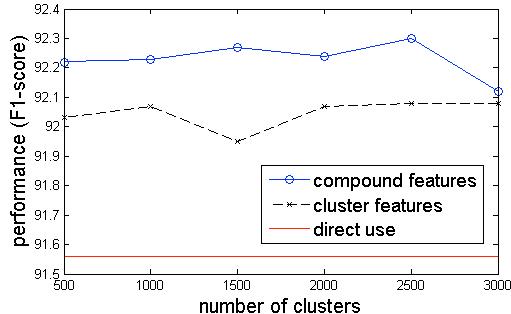

Figure 1: Relation between numbers of clusters k and performances on development set.

The performances of NER on test set are shown in Table 4. Our baseline is slightly lower than that in (Turian et al, 2010), because the first-order CRF cannot utilize context information of NE tags. Despite of this, same conclusions with chunking held.

System	Direct	Compound
Baseline	83.78	
+Embedding	87.38	88.46
+Brown	88.14	88.23
+Brown&Embedding	88.85	89.06

Table 4: F1-scores of English NER on test data

Performances on Chinese NER are shown in Table 5. Similar results were observed as in English NER, showing that our method extends to other languages as well.

System	Direct	Compound
Baseline	88.24	
+Embedding	89.98	90.37
+Brown	90.24	90.55
+Brown&Embedding	90.66	90.96

Table 5: F1-scores of Chinese NER on test data

Above results gave evidences that although clustering embeddings may lose some information, the derived compound features did have better performances. The compound features can also improve the performances of Brown clusters, but not as much as they did on embeddings. And the combination of embedding-clusters and Brown-clusters could further improve the performances, since they made use of different type of context information.

The compound features also reduced the time cost of using embedding features. For example, the time for tagging one sentence in English NER was reduced from 5.6 ms to 1.6 ms, shown in Table 6.

Embedding	Time (ms)
Baseline	1.2
Embeddings (direct)	5.6
Embeddings (compound)	1.6

Table 6: Running time of different features

4 Analysis

Our compound embedding features greatly outperformed the direct usage of same embeddings on English NER. In this section we conducted analyses to show the reasons for the improvements.

4.1 Rare-words and ambiguous words

To show the compound features have stronger abilities to handle rare words, we counted the numbers of errors made on words with different frequencies on unlabeled data. Here the word frequencies are from the results of Brown clustering provided by (Turian et al. 2010). We compared our compound embedding features with direct usage of embeddings as well as Brown clusters, which is believed to work better on rare words. Figure 2(a) shows that the compound features indeed resulted in fewer errors than the two baseline methods in most cases. Errors of embeddings occurred on words with frequencies lower than 2K and those in the range of 16 to 256 were reduced by 10.55% and 24.44%, respectively.

Our compound features also reduced the errors caused by ambiguous words, as shown in Figure

2(b), where the numbers of senses for a word are measured by the numbers of different POS tags it has in Penn Treebank. 12.1% of the errors on ambiguous words were reduced, comparing to 8.4% of the errors on unambiguous ones.

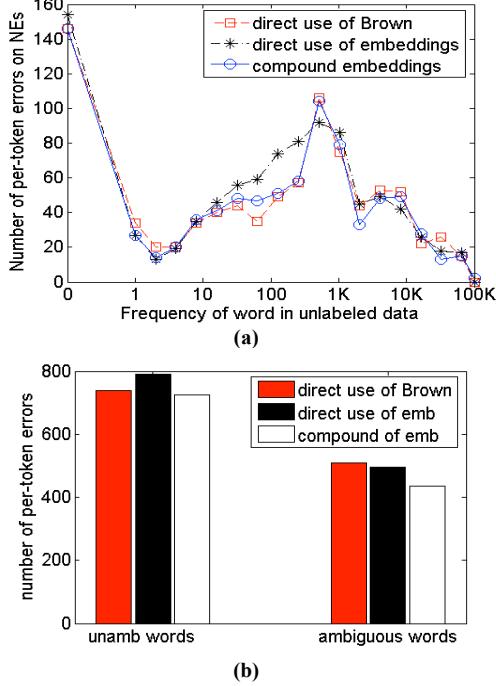

Figure 2: Errors incurred on words with different frequencies (a) and ambiguous words (b) in NER.

4.2 Linear separability of embeddings

Another reason for the good performances of compound features on NER is that they made linear models better separate ***named entities (NEs)*** and ***non-NEs***, which are more difficult to be linearly separated when embeddings are directly used as features. Here we designed an experiment to prove this. Based on training data of CoNLL2003, a classification task was built to tell whether a word belongs to NE or not. Linear SVM and a non-linear model ***Multilayer Perceptron (MLP)*** were used to build the classifiers. As shown in Table 7, when embeddings were directly used as features, MLP performed much better than linear SVM. And the linear model was under-fitting on this task since it had similar accuracies on both training set and development set. Above observations showed that linear models could not separate NEs and non-NEs well in the space of embeddings.

When clusters of embeddings were used as features, the accuracies of linear models increased even when there were only one or two non-zero

features for each sample. At the same time the performances of MLP decreased because of the loss of information during clustering. The gaps between accuracies of linear models and non-linear ones decreased in the spaces of clusters, showing that cluster features are more suitable for linear models. At last, the compound features made the linear model out-perform all non-linear ones, since extra context information could be utilized.

Embeddings	Models	Accuracy
direct	linear	94.38
direct	MLP	96.87
cluster 1000	linear	95.31
cluster 1000	MLP	95.32
cluster 500+2500	linear	96.10
cluster 500+2500	MLP	96.02
compound	linear	97.30

Table 7: Performances of linear and non-linear models on development set with different embedding features.

5 Conclusion and perspectives

In this paper, we first introduced the idea of clustering embeddings and then proposed the compound features based on clustering, in order to overcome the disadvantages of the direct usage of continuous embeddings. Experiments showed that the compound features built on the same original word representation features (either embeddings or Brown clusters) achieve better performances on the same tasks. Further analyses showed that the compound features reduced errors on rare-words and ambiguous words and could be better utilized by linear models.

The usage of word embeddings also has some limitations, e.g. they are weak in capturing structural information of languages, which is necessary in NLP. In the future, we will research on task-specific representations for sub-structures, such as phrases and sub-trees based on word embeddings and documents representations (Xu et al., 2012).

On Quality Ratings for Spoken Dialogue Systems – Experts vs. Users

Stefan Ultes, Alexander Schmitt, and Wolfgang Minker

Abstract

In the field of Intelligent User Interfaces, Spoken Dialogue Systems (SDSs) play a key role as speech represents a true intuitive means of human communication. Deriving information about its quality can help rendering SDSs more user-adaptive. Work on automatic estimation of subjective quality usually relies on statistical models. To create those, manual data annotation is required, which may be performed by actual users or by experts. Here, both variants have their advantages and drawbacks. In this paper, we analyze the relationship between user and expert ratings by investigating models which combine the advantages of both types of ratings. We explore two novel approaches using statistical classification methods and evaluate those with a pre-existing corpus providing user and expert ratings. After analyzing the results, we eventually recommend to use expert ratings instead of user ratings in general.

1 Introduction and Motivation

In human-machine interaction it is important that user interfaces can adapt to the specific requirements of its users. Handicapped persons or angry users, for example, have specific needs and should be treated differently than regular users.

Speech is a major component of modern user interfaces as it is the natural means of human communication. Therefore, it seems logical to use Spoken Dialogue Systems (SDS) as part of Intelligent User Interfaces enabling speech communication of different complexity reaching from simple spoken

commands up to complex dialogues. Besides the spoken words, the speech signal also may be used to acquire information about the user state, e.g., about their emotional state (cf., e.g., (Polzehl et al., 2011))). By additional analysis of the human-computer-dialogues, even more abstract information may be derived, e.g., the quality of the system (cf., e.g., (Engelbrecht and Möller, 2010)). System quality information may be used to adapt the system’s behavior online during the ongoing dialogue (cf. (Ultes et al., 2012)).

For determining the quality of Spoken Dialogue Systems, several aspects are of interest. Möller et al. (2009) presented a taxonomy of quality criteria. They describe quality as a bipartite issue consisting of Quality of Service (QoS) and Quality of Experience (QoE). Quality of Service describes objective criteria like dialogue duration or number of turns. While these are well-defined items that can be determined easily, Quality of Experience, which describes the user experience with subjective criteria, is more vague and without a sound definition, e.g., User Satisfaction (US).

Subjective aspects like US are either determined by using questionnaires like SASSI (Hone and Graham, 2000) or the ITU-standard augmented framework for questionnaires (Möller, 2003), or by using single-valued ratings, i.e., a rater only applies one single score. In general, two major categories of work on determining single-valued User Satisfaction exist. The satisfaction ratings are applied either

- by **users** during or right after the dialogue or
- by **experts** by listening to recorded dialogues.

In this work, users or *user raters* are people who actually perform a dialogue with the system and apply ratings while doing so. There is no constraint about their expertise in the field of Human Computer Interaction or Spoken Dialogue Systems: They may be novices or have a high expertise. With experts or *expert raters*, we refer to people who are not participating in the dialogue thus constituting a completely different set of people. Expert raters listen to recorded dialogues after the interactions and rate them by assuming the point of view of the actual person performing the dialogue. These experts are supposed to have some experience with dialogue systems. In this work, expert raters were “advanced students of computer science and engineering” (Schmitt et al., 2011a).

For *User Satisfaction*, ratings applied by the users seem to be clearly the better choice over ratings applied by third persons. However, determining true User Satisfaction is only possible by asking real users interacting with the system. Ideally, the ratings are applied by users talking to a system employed in the field, e.g., commercial systems, as these users have real concerns.

For such Spoken Dialogue Systems, though, it is not easy to get users to apply quality ratings to the dialogue – especially for each system-user exchange. The users would have to rate either by pressing a button on the phone or by speech, which would significantly influence the performance of the dialogue. Longer dialogues imply longer call durations which cost money. Further, most callers only want to quickly get some information from the system. Therefore, it may be assumed that most users do not want to engage in dialogues which are artificially made longer. This also inhabits the risk that users who participated in long dialogues do not want to call again. Therefore, collecting ratings applied by users are considered to be expensive. One possible way of overcoming the problem of rating input would be to use some special installation which enables the users to provide ratings more easily (cf. (Schmitt et al., 2011b)). However, this is also expensive and the system’s usability would be very restricted. Further, this setup could most likely only be used in a lab situation.

Expert raters, on the other hand, are able to simply listen to the recorded dialogues and to apply ratings,

e.g., by using a specialized rating software. This process is much easier and does not require the same amount of effort needed for acquiring user ratings. Further, as already pointed out, we refer to experts as people who have some basic understanding of dialogue systems but are not required to be high-level experts in the field. That is why we believe that these people can be found easily.

As both categories of ratings have their advantages and disadvantages, this contribution aims at learning about the differences and similarities of user and expert ratings with the ultimate goal of either being able to predict user ratings more efficiently or of advocating for replacing the use of user ratings by using only expert ratings in general.

Therefore, this work analyzes the relation between quality ratings applied by user and expert raters by analyzing approaches which take advantage of both categories: Using the less expensive rating process with expert raters and still predicting *real User Satisfaction* ratings. Moreover, this works’ goal is to shed light on the question whether information about one rating (in this case the less expensive expert ratings) may be used to predict the other rating (the more expensive user ratings). For this, we present two approaches applying two different statistical classification methods for a showcase corpus. Results of both methods are compared to a given baseline.

The remainder of this paper is organized as follows. First, we give a brief overview of work done in both categories (user ratings vs. expert ratings) in Section 2 and present our choice of data the analysis in this paper is based on in Section 3. Further, evaluation metrics are illustrated in Section 4 and approaches on facilitating prediction of user rater scores by expert rater information are presented in Section 5 followed by an evaluation and discussion of the results in Section 6.

2 Significant Related Work

Predicting User Satisfaction for SDSs has been in the focus of research for many years, most famously the PARADISE framework by Walker et al. (1997). The authors assume a linear dependency between quantitative parameters derived from the dialogue and US, modeling this dependency using linear re-

gression. Unfortunately, for generating the regression model, weighting factors have to be computed for each system anew. This generates high costs as dialogues have to be performed with real users where each user further has to complete a questionnaire after completing the dialogue. Moreover, in the PARADISE framework, only quality measurement for the whole dialogue (or system) is allowed. However, this is not suitable for using quality information for online adaption of the dialogue (cf. (Ultes et al., 2012)). Furthermore, PARADISE relies on questionnaires while we focus on work using single-valued ratings.

Numerous work on predicting User Satisfaction as a single-valued rating task for each system-user-exchange has been performed in both categories. This work is briefly presented in the following.

2.1 Expert Ratings

Higashinaka et al. (2010a) proposed a model to predict turn-wise ratings for human-human dialogues (transcribed conversation) and human-machine dialogues (text from chat system). Ratings ranging from 1-7 were applied by two expert raters labeling “Smoothness”, “Closeness”, and “Willingness” not achieving a Match Rate per Rating (MR/R)¹ of more than 0.2-0.24. This results are only slightly above the random baseline of 0.14. Further work by Higashinaka et al. (2010b) uses ratings for overall dialogues to predict ratings for each system-user-exchange. Again, evaluating in three user satisfaction categories “Smoothness”, “Closeness”, and “Willingness” with ratings ranging from 1-7 achieved best performance of 0.19 MR/R.

Interaction Quality (IQ) has been introduced by Schmitt et al. (2011a) as an alternative performance measure to User Satisfaction. In their terminology, US ratings are only applied by users. As their presented measure uses ratings applied by expert raters, a different term is used. Each system-user exchange was annotated by three different raters using strict guidelines. The ratings ranging from 1-5 are used as target variable for statistical classifiers using a set of automatically derivable interaction parameters as input. They achieve a MR/R of 0.58.

¹MR/R is equal to Unweighted Average Recall (UAR) which is explained in Section 4.

2.2 User Ratings

An approach presented by Engelbrecht et al. (2009) uses Hidden Markov Models (HMMs) to model the SDS as a process evolving over time. User Satisfaction was predicted at any point within the dialogue on a 5 point scale. Evaluation was performed based on labels the users applied themselves during the dialogue.

Hara et al. (2010) derived turn level ratings from an overall score applied by the users after the dialogue. Using n-gram models reflecting the dialogue history, the achieved results for recognizing User Satisfaction on a 5 point scale showed to be hardly above chance.

Work by Schmitt et al. (2011b) deals with determining User Satisfaction from ratings applied by the users themselves during the dialogues. A statistical classification model was trained using automatically derived interaction parameter to predict User Satisfaction for each system-user-exchange on a 5-point scale achieving an MR/R of 0.49.

3 Corpus

The corpus used by Schmitt et al. (2011b) not only contains user ratings but also expert ratings which makes it a perfect candidate for our research presented in this paper. Adopting the terminology by Schmitt et al., user ratings are described as User Satisfaction (US) whereas expert ratings are referred to with the term Interaction Quality (IQ) (cf. (Schmitt et al., 2011a)). The data used for all experiments of this work was collected by Schmitt et al. (2011b) during a lab user study with 38 users in the domain of the “Let’s Go Bus Information” system (Raux et al., 2006) of the Carnegie Mellon University in Pittsburgh. 128 calls were collected consisting of a total of 2,897 system-user exchanges. Both ratings, IQ and US, are at a scale from 1 to 5 where 1 stands for “extremely unsatisfied” and 5 for “satisfied”. Each dialogue starts with a rating of 5 as the user is expected to be satisfied in the beginning because nothing unsatisfying has happened yet.

Further, the corpus also provides interaction parameters which may be used as input variables for the IQ and US recognition models. These parameters have been derived automatically from three dialogue modules: Automatic Speech Recog-

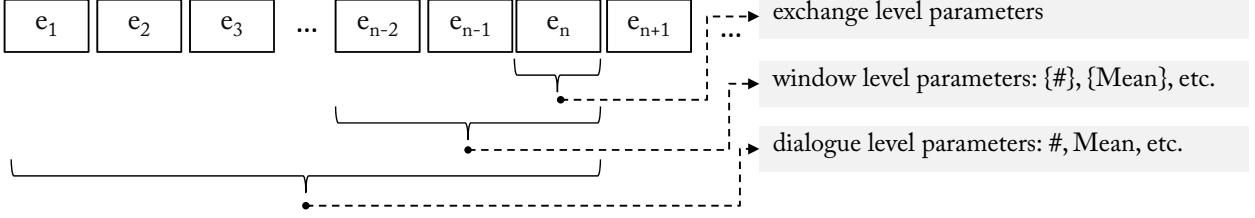

Figure 1: *The three different modeling levels representing the interaction at exchange e_n : The most detailed exchange level, comprising parameters of the current exchange; the window level, capturing important parameters from the previous n dialog steps (here $n = 3$); the dialogue level, measuring overall performance values from the entire previous interaction.*

nition, Spoken Language Understanding, and Dialogue Management. Furthermore, the parameters are modeled on three different levels (see Figure 1):

- *Exchange level* parameters can be derived directly from the respective dialogue modules, e.g., ASRConfidence.
- *Dialogue level* parameters consist of counts (#), means (Mean), etc. of the exchange level parameters calculated from all exchanges of the whole dialogue up to the current exchange, e.g., MeanASRConfidence.
- *Window level* parameters consist of counts (<{#}), means (<{Mean}), etc. of the exchange level parameters calculated from the last three exchanges, e.g., <{Mean}ASRConfidence.

4 Evaluation metrics

For measuring the performance of the classification algorithms, we rely on *Unweighted Average Recall (UAR)*, *Cohen's Kappa* and *Spearman's Rho*. The latter two also represent a measure for similarity of paired data. All measures will be briefly described in the following:

Unweighted Average Recall The Unweighted Average Recall (UAR) is defined as the sum of all class-wise recalls r_c divided by the number of classes $|C|$:

$$UAR = \frac{1}{|C|} \sum_{c \in C} r_c . \quad (1)$$

Recall r_c for class c is defined as

$$r_c = \frac{1}{|R_c|} \sum_{i=1}^{|R_c|} \delta_{h_i r_i} , \quad (2)$$

where δ is the Kronecker-delta, h_i and r_i represent the corresponding hypothesis-reference-pair of rating i , and $|R_c|$ the total number of all ratings of class c . In other words, UAR for multi-class classification problems is the accuracy corrected by the effects of unbalanced data.

Cohen's Kappa To measure the relative agreement between two corresponding sets of ratings, the number of label agreements corrected by the chance level of agreement divided by the maximum proportion of times the labelers could agree is computed. κ is defined as

$$\kappa = \frac{p_0 - p_c}{1 - p_c} , \quad (3)$$

where p_0 is the rate of agreement and p_c is the chance agreement (Cohen, 1960). As US and IQ are on an ordinal scale, a weighting factor w is introduced reducing the discount of disagreements the smaller the difference is between two ratings (Cohen, 1968):

$$w = \frac{|r_1 - r_2|}{|r_{max} - r_{min}|} . \quad (4)$$

Here, r_1 and r_2 denote the rating pair and r_{max} and r_{min} the maximal and minimal rating. This results in $w = 0$ for agreement and $w = 1$ if the ratings have maximal difference.

Spearman's Rho The correlation of two variables describes the degree by that one variable can be expressed by the other. *Spearman's Rank Correlation Coefficient* is a non-parametric method assuming a monotonic function between the

two variables (Spearman, 1904). It is defined by

$$\rho = \frac{\sum_i (x_i - \bar{x})(y_i - \bar{y})}{\sqrt{\sum_i (x_i - \bar{x})^2} \sqrt{\sum_i (y_i - \bar{y})^2}}, \quad (5)$$

where x_i and y_i are corresponding ranked ratings and \bar{x} and \bar{y} the mean ranks. Thus, two sets of ratings can have total correlation even if they never agree. This would happen if all ratings are shifted by the same value, for example.

5 Recognition of US Using IQ Information

As discussed in Section 1, automatic recognition of ratings applied by users as performed by Schmitt et al. (2011b) for User Satisfaction is time-consuming and expensive. Therefore, approaches are presented which facilitate expert ratings, i.e., Interaction Quality, with the hope of making US recognition more feasible. IQ and US are strongly related as both metrics represent the same quantity applied by different rater groups. Results of the Mann-Whitney U test, which is used to test for significant difference between Interaction Quality and User Satisfaction, show their difference ($p < 0.05$) but values for Cohen's Kappa (Cohen, 1960) and Spearman's Rank Correlation Coefficient (Spearman, 1904) emphasize the that IQ and US are quite similar. Achieving $\kappa = 0.5$ can be considered as a *moderate* agreement according to Landis and Koch's Kappa Benchmark Scale (Landis and Koch, 1977). Furthermore, a correlation of $\rho = 0.66$ ($p < 0.01$) indicates a *strong* relationship between IQ and US (Cohen, 1988).

While it has been shown that user and expert ratings are similar, it is desirable nonetheless to being able to predict real user ratings. These ratings are the desired kind of ratings when it comes to subjective dialogue system assessment. Only users can give a rating about their satisfaction level, i.e., how they like the system and the interaction with the system. However, user ratings are expensive as elaborated in Section 1. Therefore, we investigate approaches to recognize US which rely on means of IQ recognition.

5.1 Belief-Based Sequential Recognition

Methods used for IQ and US recognition by Schmitt et al. (2011b; 2011a) suffer from the fact that the

sequential character of the data is modeled inadequately as they assume statistical independence between the single exchanges (recognition of IQ and US does *not* depend on the respective value of the previous exchange). Hence, we present a Markovian approach overcoming these issues. A probability distribution over all US states, called *belief state*, is updated after each system-user-exchange taking also into account the *belief state* of the previous exchange. This belief update² is equivalent to the Forward Algorithm known from Hidden Markov Models (cf. (Rabiner, 1989)). In doing so, the new US probabilities also depend on the US values of the previous exchange. Moreover, a latent variable is introduced in order to decouple the target variable *US* with the variable the observation probability depends on *IQ*. This results in an indirect approach for recognizing User Satisfaction that is based on the more affordable recognition of Interaction Quality assuming that a universal mapping between IQ and US exists.

Thus, to determine the probability $b(US)$ of having the true User Satisfaction label *US* after the current system-user-exchange, we rely on Interaction Quality recognition, whose observation probability is depicted as $P(o|IQ)$. Furthermore, for coupling both quantities, we introduce a coherence probability $P(IQ|US)$. Belief update for estimating the new values for $b'(US')$ is as follows:

$$b'(US') = \alpha \cdot \sum_{IQ'} P(o'|IQ') \cdot P(IQ'|US') \cdot \sum_{US} P(US'|US)b(US) \quad (6)$$

The observation probability $P(o'|IQ')$ is modeled using confidence scores of classifiers applied for IQ recognition. Further, we compute the sum over all previous US beliefs $b(US)$ weighted by the transition probability $P(US'|US)$. Both, transition and coherence probability have been computed by taking the frequency of their occurrences in the training data. The α factor is used for normalization only.

Since we are aiming at generating an estimate \hat{US}

²Terminology is taken from Partially Observable Markov Decision Processes, cf. (Kaelbling et al., 1998)

at each exchange, it is calculated by

$$\hat{U}S = \arg \max_{US'} b'(US') \quad (7)$$

generating a sequence of estimates for each dialogue.

As the action of the system a can be expected to influence the satisfaction level of the user, action-dependency is added to Equation 6 resulting in

$$b'(US') = \alpha \cdot \sum_{IQ'} P(o'|IQ') \cdot P(IQ'|US', a) \\ \cdot \sum_{US} P(US'|US, a)b(US). \quad (8)$$

Hence, each system action a influences coherence and transition probabilities. It should be noted that action-dependency can only be introduced as in a SDS each turn a system action is selected and executed by the dialogue manager.

5.2 Model Exchange

While in *Belief-Based Sequential Recognition*, probability models are used for coupling expert and user ratings explicitly, a simpler approach has also been examined. A statistical classifier trained on the target variable IQ is used to evaluate classification of the target variable US. This seems to be reasonable as the set of scores and meaning of the scores of both metrics are equivalent. Furthermore, necessary prerequisites are fulfilled: the sample corpus contains both labels, the labels for US and IQ correspond, and both recognition approaches are based on the same feature set.

6 Experiments and Results

For evaluating *Belief-Based Sequential Recognition*, not only the absolute performance is of interest but also how this performance is influenced by the characteristics of the observation probability, i.e., the performance of the applied statistical classification approach and the variance of their confidence scores. In order to obtain different confidence characteristics, multiple classification algorithms, or algorithm variants respectively, are needed. Hence, five statistical classifiers have been chosen arbitrarily to produce the observation probabilities for *Belief-Based Sequential Recognition*:

- SVM³ with cubic kernel
- SVM with RBF-kernel
- Naive Bayes
- Naive Bayes with kernel
- Rule Induction

In contrast to Schmitt et al. (2011b; 2011a), a reduced feature set was used consisting of 43 parameters as some textual parameters were removed which are very specific and take many different values, e.g., UTTERANCE (the system utterance) or INTERPRETATION (the interpretation of the speech input).

The resulting feature set consists of the following parameters (parameter names are in accordance with the parameter names of the LEGO corpus (Schmitt et al., 2012)):

Exchange Level ACTIVITY, ACTIVITYTYPE, UTD, BARGED-IN?, ASRCONFIDENCE, MEANASRCONFIDENCE, TURNNUMBER, MODALITY, LOOPNAME, ASRRECOGNITIONSTATUS, ROLEINDEX, ROLENAME, NOISE?, HELPREQUEST?, REPROMPT?, WPST, WPUT

Dialogue Level #BARGEINS #ASRSUCCESS, #HELPREQUESTS, #TIMEOUTS, #TIMEOUTS_ASRRJECTIONS, #ASRREJECTIONS, #REPROMPTS, #SYSTEMQUESTIONS, #SYSTEMTURNS, #USERTURNS, %BARGEINS, %ASRSUCCESS, %HELPREQUESTS, %TIMEOUTS, %TIMEOUTS_ASRRJECTIONS, %ASRREJECTIONS, %REPROMPTS

Window Level {#}TIMEOUTS_ASRRJECTIONS, {#}HELPREQUESTS, {#}ASRREJECTIONS, {MEAN}ASRCONFIDENCE, {#}TIMEOUTS, {#}REPROMPTS, {#}SYSTEMQUESTIONS, {#}ASRSUCCESS, {#}BARGEINS

All results are evaluated with respect to the reference experiment of direct US recognition (US recognition using models trained on US). This is performed in accordance to Schmitt et al. (2011b) using the statistical classification algorithms stated

³Support Vector Machine, cf. (Vapnik, 1995)

Table 1: Results (UAR, Cohen’s Kappa, and Spearman’s Rho) of 10-fold cross-validation for US recognition of US recognition using models trained on US

Naive Bayes (Kernel)	0.34	0.37	0.60
Rule Induction	0.34	0.42	0.59

above. The performance of the reference experiment is shown in Table 1.

Using the same feature set, these classification algorithms are also applied for the evaluation of the *Model Exchange* approach using 10-fold cross validation. Note that the parameters of the classifiers also remained the same. The data was partitioned randomly on exchange level, i.e., without regarding their belonging to a specific dialogue. The measured results of the *Model Exchange* approach for the five classification methods can be seen in Table 2.

While the results are significantly above chance⁴, comparing them to the reference experiment reveals that in terms of UAR the reference experiment outperforms *Model Exchange* for all five classifiers. The achieved κ and ρ values show similar scores for both the reference experiment and the *Model Exchange* approach. However, in the data used for the experiments, the amount of occurrences of the ratings was not balanced (equal for all classes) which has been identified as the most likely reason for this effect.

Experiments for *Belief-Based Sequential Recognition* have also been performed using 10-fold cross validation. As complete dialogues and the order

⁴UAR of 0.2 for five classes

Naive Bayes (Kernel)	0.34	0.44	0.60
Rule Induction	0.35	0.47	0.62

of exchanges within the dialogues are important for this approach, the data was partitioned randomly on the dialogue level. As previously explained, for the probability distributions of the observation probability model, classification results of IQ recognition with 10-fold cross validation has been used in order to get good estimates for the whole data set. Results for the action-independent version can be seen in Table 3.

For the action-dependent version, four different basic actions ANNOUNCEMENT, CONFIRMATION, QUESTION, and WAIT have been used, generating results presented in Table 4. The results illustrate that neither action-independent nor action-dependent *Belief-Based Sequential Recognition* can outperform the reference experiment (cf. Table 1). Still, both variants achieve results clearly above chance. Again, the unbalanced data causes κ and ρ to be similar to the reference experiment.

A comparison of the action-independent with the action-dependent approach shows almost no differences in their performances. Only a slight tendency towards better UARs for action-dependency can be spotted.

Figure 2 displays the performances of both variants of *Belief-Based Sequential Recognition* along with performance of IQ recognition and the variance σ^2 of the corresponding confidence distribu-

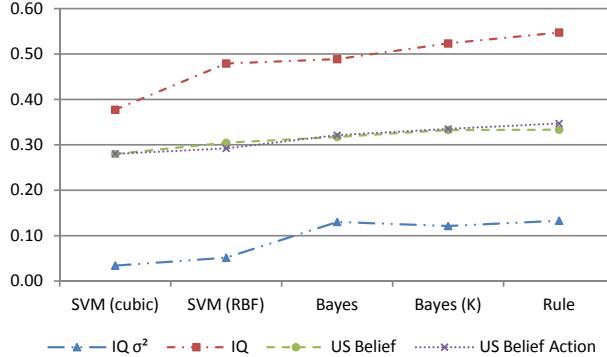

Figure 2: *UAR of IQ recognition and Belief-Based Sequential Recognition along with σ^2 of confidence distributions of IQ recognition*

Table 5: *Recognition performance and variance of confidence distributions for IQ recognition*

Classifier	σ^2	UAR	κ	ρ
SVM (cubic Kernel)	0.03	0.38	0.54	0.69
SVM (RBF-Kernel)	0.05	0.48	0.65	0.77
Naive Bayes	0.13	0.49	0.57	0.71
Naive Bayes (Kernel)	0.12	0.52	0.59	0.73
Rule Induction	0.13	0.55	0.68	0.79

tion (cf. Table 5). It can easily be seen that with rising UAR for IQ recognition, σ^2 also rises. This directly transfers to the performance of the *Belief-Based Sequential Recognition*. The more accurate the observation performance, the more accurate the belief prediction. Furthermore, when comparing the action-dependent to the action-independent variant of *Belief-Based Sequential Recognition*, better IQ performance and therefore a higher variance also causes slightly better results for the action-dependent variant. These differences, however, are only marginally. Therefore, they do not allow for drawing a conclusion.

7 Conclusions

For estimating User Satisfaction-like ratings, two categories exist: work relying on user ratings and work relying on expert ratings. To learn something about their differences and similarities, we explored the possibility of using the information encoded in the expert ratings to predict user ratings with the hope to get acceptable user rating prediction results. Therefore, we investigated if it is possible to determine the preferred true User Satisfaction value

based on less expensive expert ratings. For this, a corpus containing both kinds of ratings was chosen, i.e., User Satisfaction (US) and Interaction Quality (IQ) ratings. Furthermore, interaction parameters were used to create statistical recognition models for predicting IQ and US, respectively. Two approaches have been investigated: *Belief-Based Sequential Recognition*, which is based on an HMM-like structure with IQ as an additional latent variable, and *Model Exchange*, which uses statistical models trained on IQ to recognize US. Unfortunately, neither *Belief-Based Sequential Recognition* nor *Model Exchange* achieved results with an acceptable UAR.

The high correlation between expert and user ratings, depicted by high values for Cohen's κ and Spearman's ρ , already allow the conclusion that expert ratings can be used as a good replacement for user ratings. Moreover, the presented recognition results of the *Model Exchange* approach being clearly above chance underpin the strong similarity of IQ and US. Furthermore, IQ recognition is much more reliable and accurate than US recognition (shown by higher UAR, κ and ρ values).

While the experiments disproved the hope of getting acceptable user rating prediction results, the obtained results confirmed the similarity between both kinds of ratings. And as it is not necessary to use user ratings for most applications, e.g., for using the quality information to automatically improve the interaction (cf. (Ultes et al., 2012)), we believe that it suffices to use expert ratings as those can be acquired easier and less expensively and are similar enough to user ratings. Prompting the user to apply quality ratings in everyday situations with real-life systems will always be annoying to the user while recording of such interactions are always much easier to rate.

By providing a study for determining quality ratings of dialogues, we hope to encourage other researchers to look into this research for other parameters, e.g., emotion recognition.

Abstract

Large unsupervised latent variable models (LVMs) of text, such as Latent Dirichlet Allocation models or Hidden Markov Models (HMMs), are constructed using parallel training algorithms on computational clusters. The memory required to hold LVM parameters forms a bottleneck in training more powerful models. In this paper, we show how the memory required for parallel LVM training can be reduced by partitioning the training corpus to minimize the number of unique words on any computational node. We present a greedy document partitioning technique for the task. For large corpora, our approach reduces memory consumption by over 50%, and trains the same models up to three times faster, when compared with existing approaches for parallel LVM training.

1 Introduction

Unsupervised latent variable models (LVMs) of text are utilized extensively in natural language processing (Griffiths and Steyvers, 2004; Ritter et al., 2010; Downey et al., 2007; Huang and Yates, 2009; Li and McCallum, 2005). LVM techniques include Latent Dirichlet Allocation (LDA) (Blei et al., 2003), Hidden Markov Models (HMMs) (Rabiner, 1989), and Probabilistic Latent Semantic Analysis (Hofmann, 1999), among others.

LVMs become more predictive as they are trained on more text. However, training LVMs on massive corpora introduces computational challenges, in terms of both time and space complexity. The time complexity of LVM training has been addressed

through parallel training algorithms (Wolfe et al., 2008; Chu et al., 2006; Das et al., 2007; Newman et al., 2009; Ahmed et al., 2012; Asuncion et al., 2011), which reduce LVM training time through the use of large computational clusters.

However, the memory cost for training LVMs remains a bottleneck. While LVM training makes sequential scans of the corpus (which can be stored on disk), it requires consistent random access to model parameters. Thus, the model parameters must be stored in memory on each node. Because LVMs include a multinomial distribution over words for each latent variable value, the model parameter space increases with the number of latent variable values times the vocabulary size. For large models (i.e., with many latent variable values) and large corpora (with large vocabularies), the memory required for training can exceed the limits of the commodity servers comprising modern computational clusters. Because model accuracy tends to increase with both corpus size and model size (Ahuja and Downey, 2010; Huang and Yates, 2010), training accurate language models requires that we overcome the memory bottleneck.

We present a simple technique for mitigating the memory bottleneck in parallel LVM training. Existing parallelization schemes begin by partitioning the training corpus *arbitrarily* across computational nodes. In this paper, we show how to reduce memory footprint by instead partitioning the corpus to *minimize the number of unique words* on each node (and thereby minimize the number of parameters the node must store). Because corpus partitioning is a pre-processing step in parallel LVM training, our

technique can be applied to reduce the memory footprint of essentially any existing LVM or training approach. The accuracy of LVM training for a *fixed* model size and corpus remains unchanged, but intelligent corpus partitioning allows us to train larger and typically more accurate models using the same memory capacity.

While the general minimization problem we encounter is NP-hard, we develop greedy approximations that work well. In experiments with both HMM and LDA models, we show that our technique offers large advantages over existing approaches in terms of both memory footprint and execution time. On a large corpus using 50 nodes in parallel, our best partitioning method can reduce the memory required per node to less than 1/10th that when training without corpus partitioning, and to half that of a random partitioning. Further, our approach reduces the training time of an existing parallel HMM codebase by 3x. Our work includes the release of our partitioning codebase, and an associated codebase for the parallel training of HMMs.¹

2 Problem Formulation

In a distributed LVM system, a training corpus $D = \{d_1, d_2, \dots, d_N\}$ of documents is distributed across T computational nodes. We first formalize the memory footprint on each node n_t , where $t = \{1, \dots, T\}$. Let $D_t \subset D$ denote the document collection on node n_t , and V_t be the number of word types (i.e., the number of unique words) in D_t . Let K be the number of latent variable values in the LVM.

With these quantities, we can express how many parameters must be held in memory on each computational node for training LVMs in a distributed environment. In practice, the LVM parameter space is dominated by an *observation model*: a conditional distribution over words given the latent variable value. Thus, the observation model includes $K(V_t - 1)$ parameters. Different LVMs include various other parameters to specify the complete model. For example, a first-order **HMM** includes additional distributions for the initial latent variable and latent variable transitions, for a total of $K(V_t - 1) + K^2$ parameters. **LDA**, on the other hand, includes just a

¹<https://code.google.com/p/corpus-partition/>

single multinomial over the latent variables, making a total of $K(V_t - 1) + K - 1$ parameters.

The LVM parameters comprise almost all of the memory footprint for LVM training. Further, as the examples above illustrate, the number of parameters on each node tends to vary almost linearly with V_t (in practice, V_t is typically larger than K by an order of magnitude or more). Thus, in this paper we attempt to minimize memory footprint by limiting V_t on each computational node. We assume the typical case in a distributed environment where nodes are homogeneous, and thus our goal is to partition the corpus such that the *maximum* vocabulary size $V_{max} = \max_{t=1}^T V_t$ on any single node is minimized. We define this task formally as follows.

Definition CORPUSPART: Given a corpus of N documents $D = \{d_1, d_2, \dots, d_N\}$, and T nodes, partition D into T subsets D_1, D_2, \dots, D_T , such that V_{max} is minimized.

For illustration, consider the following small example. Let corpus C contain three short documents $\{c_1 = \text{"I live in Chicago"}, c_2 = \text{"I am studying physics"}, c_3 = \text{"Chicago is a city in Illinois"}\}$, and consider partitioning C into 2 non-empty subsets, i.e., $T = 2$. There are a total of three possibilities:

- $\{\{c_1, c_2\}, \{c_3\}\}$. $V_{max} = 7$
- $\{\{c_1, c_3\}, \{c_2\}\}$. $V_{max} = 8$
- $\{\{c_2, c_3\}, \{c_1\}\}$. $V_{max} = 10$

The decision problem version of **CORPUSPART** is NP-Complete, by a reduction from independent task scheduling (Zhu and Ibarra, 1999). In this paper, we develop greedy algorithms for the task that are effective in practice.

We note that **CORPUSPART** has a *submodular* problem structure, where greedy algorithms are often effective. Specifically, let $|S|$ denote the vocabulary size of a set of documents S , and let $S' \subseteq S$. Then for any document c the following inequality holds.

$$|S' \cup c| - |S'| \geq |S \cup c| - |S|$$

That is, adding a document c to the subset S' increases vocabulary size at least as much as adding c to S ; the vocabulary size function is submodular. The **CORPUSPART** task thus seeks a partition of the data that minimizes the maximum of a set of submodular functions. While formal approximation

guarantees exist for similar problems, to our knowledge none apply directly in our case. For example, (Krause et al., 2007) considers maximizing the minimum over a set of monotonic submodular functions, which is the opposite of our problem. The distinct task of minimizing a single submodular function has been investigated in e.g. (Iwata et al., 2001).

It is important to emphasize that data partitioning is a *pre-processing* step, after which we can employ precisely the same Expectation-Maximization (EM), sampling, or variational parameter learning techniques as utilized in previous work. In fact, for popular learning techniques including EM for HMMs (Rabiner, 1989) and variational EM for LDA (Wolfe et al., 2008), it can be shown that the parameter updates are *independent* of how the corpus is partitioned. Thus, for those approaches our partitioning is guaranteed to produce the same models as any other partitioning method; i.e., model accuracy is unchanged.

Lastly, we note that we target *synchronized* LVM training, in which all nodes must finish each training iteration before any node can proceed to the next iteration. Thus, we desire balanced partitions to help ensure iterations have similar durations across nodes. We achieve this in practice by constraining each node to hold at most 3% more than Z/T tokens, where Z is the corpus size in tokens.

3 Corpus Partitioning Methods

Our high-level greedy partitioning framework is given in Algorithm 1. The algorithm requires answering two key questions: How do we select which document to allocate next? And, given a document, on which node should it be placed? We present alternative approaches to each question below.

Algorithm 1 Greedy Partitioning Framework

INPUT: $\{D, T\}$
OUTPUT: $\{D_1, \dots, D_T\}$
Objective: Minimize V_{max}
 Initialize each subset $D_t = \emptyset$ for T nodes
repeat
 document selection: Select document d from D
 node selection: Select node n_t , and add d to D_t
 Remove d from D
until all documents are allocated

A **baseline** partitioning method commonly used in practice simply distributes documents across nodes randomly. As our experiments show, this baseline approach can be improved significantly.

In the following, set operations are interpreted as applying to the set of unique words in a document. For example, $|d \cup D_t|$ indicates the number of unique word types in node n_t after document d is added to its document collection D_t .

3.1 Document Selection

For document selection, previous work (Zhu and Ibarra, 1999) proposed a heuristic **DISSIMILARITY** method that selects the document d that is *least similar* to *any* of the node document collections D_t , where the similarity of d and D_t is calculated as: $Sim(d, D_t) = |d \cap D_t|$. The intuition behind the heuristic is that dissimilar documents are more likely to impact future node selection decisions. Assigning the dissimilar documents earlier helps ensure that more greedy node selections are informed by these impactful assignments.

However, **DISSIMILARITY** has a prohibitive time complexity of $\mathcal{O}(TN^2)$, because we must compare T nodes to an order of N documents for a total of N iterations. To scale to large corpora, we propose a novel **BATCH DISSIMILARITY** method. In **BATCH DISSIMILARITY**, we select the top L most dissimilar documents in each iteration, instead of just the most dissimilar. Importantly, L is altered dynamically: we begin with $L = 1$, and then increase L by one for iteration $i+1$ *iff* using a batch size of $L+1$ in iteration i would not have altered the algorithm's ultimate selections (that is, if the most dissimilar document in iteration $i+1$ is in fact the $L+1$ st most dissimilar in iteration i). In the ideal case where L is incremented each iteration, **BATCH DISSIMILAR** will have a reduced time complexity of $O(TN^{3/2})$.

Our experiments revealed two key findings regarding document selection. First, **BATCH DISSIMILARITY** provides a memory reduction within 0.1% of that of **DISSIMILARITY** (on small corpora where running **DISSIMILARITY** is tractable), but partitions an estimated 2,600 times faster on our largest evaluation corpus. Second, we found that document selection has *relatively minor* impact on memory footprint, providing a roughly 5% incremental benefit over random document selection. Thus, although

we utilize BATCH DISSIMILARITY in the final system we evaluate, simple random document selection may be preferable in some practical settings.

3.2 Node Selection

Given a selected document d , the **MINIMUM** method proposed in previous work selects node n_t having the minimum number of word types after allocation of d to n_t (Zhu and Ibarra, 1999). That is, **MINIMUM** minimizes $|d \cup D_t|$. Here, we introduce an alternative node selection method **JACCARD** that selects node n_t maximizing the Jaccard index, defined here as $|d \cap D_t| / |d \cup D_t|$.

Our experiments showed that our **JACCARD** node selection method outperforms the **MINIMUM** selection method. In fact, for the largest corpora used in our experiments, **JACCARD** offered an 12.9% larger reduction in V_{max} than **MINIMUM**. Our proposed system, referred to as **BJAC**, utilizes our best-performing strategies for document selection (BATCH DISSIMILARITY) and node selection (**JACCARD**).

4 Evaluation of Partitioning Methods

We evaluate our partitioning method against the baseline and **Z&I**, the best performing scalable method from previous work, which uses random document selection and **MINIMUM** node selection (Zhu and Ibarra, 1999). We evaluate on three corpora (Table 1): the *Brown* corpus of newswire text (Kucera and Francis, 1967), the Reuters Corpus Volume1 (*RCV1*) (Lewis et al., 2004), and a larger *Web-Sent* corpus of sentences gathered from the Web (Downey et al., 2007).

Corpus	N	V	Z
Brown	57339	56058	1161183
RCV1	804414	288062	99702278
Web-Sent	2747282	214588	58666983

Table 1: Characteristics of the three corpora. N = # of documents, V = # of word types, Z = # of tokens. We treat each sentence as a document in the Brown and Web-Sent corpora.

Table 2 shows how the maximum word type size V_{max} varies for each method and corpus, for $T = 50$ nodes. **BJAC** significantly decreases V_{max} over the

Corpus	baseline	Z&I	BJAC
Brown	6368	5714	4369
RCV1	49344	32136	24923
Web-Sent	72626	45989	34754

Table 2: Maximum word type size V_{max} for each partitioning method, for each corpus. For the larger corpora, **BJAC** reduces V_{max} by over 50% compared to the baseline, and by 23% compared to **Z&I**.

random partitioning baseline typically employed in practice. Furthermore, the advantage of **BJAC** over the baseline is maintained as more computational nodes are utilized, as illustrated in Figure 1. **BJAC** reduces V_{max} by a larger factor over the baseline as more computational nodes are employed.

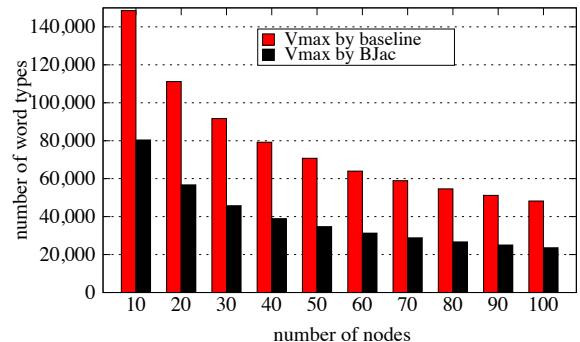

Figure 1: Effects of partitioning as the number of computational nodes increases (Web-Sent corpus). With 100 nodes, **BJAC**'s V_{max} is half that of the baseline, and 1/10th of the full corpus vocabulary size.

5 Evaluation in Parallel LVM Systems

We now turn to an evaluation of our corpus partitioning within parallel LVM training systems.

Table 3 shows the memory footprint required for HMM and LDA training for three different partitioning methods. We compare **BJAC** with the random partitioning baseline, Zhu's method, and with *all-words*, the straightforward approach of simply storing parameters for the entire corpus vocabulary on every node (Ahuja and Downey, 2010; Asuncion et al., 2011). *All-words* has the same memory footprint as when training on a single node.

For large corpora, **BJAC** reduces memory size per node by approximately a factor of two over the random baseline, and by a factor of 8-11 over all-

LVM	Corpus	all-words	baseline	BJAC
HMM	Brown	435.3	56.2	40.9
	RCV1	2205.4	384.1	197.8
	Web-Sent	1644.8	561.7	269.7
LDA	Brown	427.7	48.6	33.3
	RCV1	2197.7	376.5	190.1
	Web-Sent	1637.2	554.1	262.1

Table 3: Memory footprint of computational nodes in megabytes(MB), using 50 computational nodes. Both models utilize 1000 latent variable values.

words. The results demonstrate that in addition to the well-known savings in computation time offered by parallel LVM training, distributed computation *also* significantly reduces the memory footprint on each node. In fact, for the RCV1 corpus, BJAC reduces memory footprint to less than 1/10th that of training with all words on each computational node.

We next evaluate the *execution time* for an iteration of model training. Here, we use a parallel implementation of HMMs, and measure iteration time for training on the Web-sent corpus with 50 hidden states as the number of computational nodes varies. We compare against the random baseline and against the all-words approach utilized in an existing parallel HMM codebase (Ahuja and Downey, 2010). The results are shown in Table 4. Moving beyond the all-words method to exploit corpus partitioning reduces training iteration time, by a factor of two to three. However, differences in partitioning methods have only small effects in iteration time: BJAC has essentially the same iteration time as the random baseline in this experiment.

It is also important to consider the additional time required to execute the partitioning methods themselves. However, in practice this additional time is negligible. For example, BJAC can partition the Web-sent corpus in 368 seconds, using a single computational node. By contrast, training a 200-state HMM on the same corpus requires over a hundred CPU-days. Thus, BJAC’s time to partition has a negligible impact on total training time.

6 Related Work

The *CORPUSPART* task has some similarities to the graph partitioning task investigated in other

T	all-words	baseline	BJAC
25	4510	1295	1289
50	2248	740	735
100	1104	365	364
200	394	196	192

Table 4: Average iteration time(sec) for training an HMM with 50 hidden states on Web-Sent. Partitioning with BJAC outperforms all-words, which stores parameters for all word types on each node.

parallelization research (Hendrickson and Kolda, 2000). However, our LVM training task differs significantly from those in which graph partitioning is typically employed. Specifically, graph partitioning tends to be used for scientific computing applications where communication is the bottleneck. The graph algorithms focus on creating balanced partitions that minimize the cut edge weight, because edge weights represent communication costs to be minimized. By contrast, in our LVM training task, memory consumption is the bottleneck and communication costs are less significant.

Zhu & Ibarra (1999) present theoretical results and propose techniques for the general partitioning task we address. In contrast to that work, we focus on the case where the data to be partitioned is a large corpus of text. In this setting, we show that our heuristics partition faster and provide smaller memory footprint than those of (Zhu and Ibarra, 1999).

7 Conclusion

We presented a general corpus partitioning technique which can be exploited in LVM training to reduce memory footprint and training time. We evaluated the partitioning method’s performance, and showed that for large corpora, our approach reduces memory consumption by over 50% and learns models up to three times faster when compared with existing implementations for parallel LVM training.

Processing Spontaneous Orthography

Abstract

In cases in which there is no standard orthography for a language or language variant, written texts will display a variety of orthographic choices. This is problematic for natural language processing (NLP) because it creates spurious data sparseness. We study the transformation of spontaneously spelled Egyptian Arabic into a conventionalized orthography which we have previously proposed for NLP purposes. We show that a two-stage process can reduce divergences from this standard by 69%, making subsequent processing of Egyptian Arabic easier.

1 Introduction

In areas with **diglossia**, vernacular spoken variants (“low”) of a language family co-exist with a largely written variant (“high”), which is often not spoken as a native language. Traditionally, the low variants have not been written: written language is reserved for formal occasions and in those formal occasions only the high variant is used. Prototypical examples of diglossia are the German speaking parts of Switzerland, and the Arab world. The advent of the internet has changed linguistic behavior: it is now common to find written informal conversations, in the form of email exchanges, text messages, Twitter exchanges, and interactions on blogs and in web forums. These written conversations are typically written in the low variants (or in a mixture of low and high), since conversations in the high variant seem unnatural to the discourse participants. For natural language processing (NLP), this poses many challenges, one of which is the fact that the low variants have not been written much in the past and

do not have a standard orthography which is generally agreed on by the linguistic community (and perhaps sanctioned by an authoritative institution). Instead, each discourse participant devises a **spontaneous orthography**, in which she chooses among conventions from the high variant to render the spoken language. We are thus faced with a large number of ways to spell the same word, none of which can be assumed as “standard” since there is no standard. As a result, the increased data sparseness adds to the challenges of NLP tasks such as machine translation, compared to languages for which orthography is standardized.

In this paper, we work on Egyptian Arabic (EGY). We follow the conventions which we have previously proposed for the normalized orthography for EGY (Habash et al., 2012), called CODA (Conventional Orthography for Dialectal Arabic). In this paper, we investigate how easy it is to convert spontaneous orthography of EGY written in Arabic script into CODA orthography automatically. We will refer to this process as “normalization” or “codafication”. We present a freely available system called CODAFY, which we propose as a preprocessor for NLP modules for EGY. We show that a “do nothing” baseline achieves a normalization performance of 75.5%, and CODAFY achieves a normalization performance of 92.4%, an error reduction of 69.2% over this baseline on an unseen test set.

The paper is structured as follows. We first review relevant linguistic facts in Section 2 and then present the conventionalized orthography we use in this paper. After reviewing related work in Section 4, we present our data (Section 5), our approach (Section 6), and our results (Section 7). We conclude

with a discussion of future work.

2 Linguistic Facts

2.1 Writing without a Standard Orthography

An **orthography** is a specification of how the words of a language are mapped to and from a particular script (in our case, the Arabic script). In cases when a standard orthography is absent, writers make decisions about spontaneous orthography based on various criteria. Most prominent among them is **phonology**: how can my pronunciation of the word be rendered in the chosen writing system, given some (language-specific) assumptions about grapheme-to-phoneme mapping? Often, these assumptions come from the “high” variant of the language, or some related language. Another criterion for choosing orthography is a cognate in a related language or language variant (Modern Standard Arabic or MSA, the high variant for EGY), where a cognate pair is a pair of words (or morphemes) in two languages or language variants which are related by **etymology** (in some unspecified manner) and which have roughly the same meaning. Finally, the chosen spontaneous orthography can be altered to reflect **speech effects**, notably the lengthening of syllables to represent emphasis or other effects (such as كثيير ktyyyyr¹ ‘very’).

It is important to distinguish typos from spontaneous orthography. We define **spontaneous orthography** to be an intentional choice of graphemes to render the words in a language or language variant. We define a **typographical error (typo)** to be an unintended sequence of graphemes. For example, كدا kda and ده kdh can be intended spellings for EGY /kida/ ‘like this’, while كـ krA is not a plausible intentional spelling since it neither relates /kida/ to an MSA cognate, nor does the sequence of graphemes represent the phonology of EGY using standard assumptions. Instead, we can explain the spelling by assuming that the writer accidentally substituted the grapheme ـ for the grapheme د, which look somewhat alike and are near each other on some Arabic keyboard layouts. Of course, when we encounter

a specific spelling in a corpus, it can be, in certain cases, difficult to determine whether it is a conscious choice or a typo.

2.2 Relevant Differences between EGY and MSA

Lexical Variations Lexically, the number of differences is quite significant. For example, EGY مرات *mrAt* ‘wife [of]’ corresponds to MSA زوجة *zwjħ*. In such cases of lexical difference, no cognate spelling is available.

Phonological Variations There is an extensive literature on the phonology of Arabic dialects (Watson, 2002; Holes, 2004; Habash, 2010). Several phonological differences exist between EGY and MSA which relate to orthography. Here, we discuss one representative difference. The MSA consonant ظ /θ/ is pronounced as /t/ in EGY (or /s/ in more recent borrowings from MSA). For example, MSA يكثُر *ykθr* ‘increase (imperfective)’ is pronounced /yakθur/ in MSA versus /yiktar/ in EGY, giving rise to the EGY phonological spelling يكتَر *yktr*.

Morphological Variations There are a lot of morphological differences between MSA and EGY. For orthography, two differences are most relevant. The MSA future proclitic /sa/+ (spelled +سـ s+) appears in EGY as /ha/+ or /Ha/+ . The two forms appear in free variation, and we have not been able to find a variable that predicts which form is used when. This variation is not a general phonological variation between /h/ and /H/, we find it only in this morpheme. Predictably, this leads to two spellings in EGY: +حـ H+ and +هـ h+. Negation in EGY is realized as the circum-clitic /mā/+ ... +/š/. The principal orthographic question is whether the prefix is a separate word or is part of the main word; both variants are found.

3 CODA

CODA is a conventionalized orthography for Arabic dialects (Habash et al., 2012). In this section, we summarize CODA so that the reader can understand the goals of this paper. CODA has five key properties.

1. CODA is an internally consistent and coherent convention for writing DA: every word has a

single orthographic rendering.

2. CODA is created for computational purposes.
3. CODA uses the Arabic script as used for MSA, with no extra symbols from, for example, Persian or Urdu.
4. CODA is intended as a unified framework for writing all dialects. In this paper, we only discuss the instantiation of CODA for EGY.
5. CODA aims to maintain a level of dialectal uniqueness while using conventions based on similarities between MSA and the dialects.

We list some features of CODA relevant to this paper.

Phonological Spelling CODA generally uses phonological spelling for EGY (as MSA spelling does for MSA).

Etymologically Spelled Consonants A limited number of consonants may be spelled differently from their phonology if the following two conditions are met: (1) the consonant must be an EGY root radical and (2) the EGY root must have a cognate MSA root. If the conditions are met, then we spell the consonant using the corresponding radical from the cognate MSA root of the dialectal word's root. One such example is the spelling of the EGY verb pronounced /kitir/ as كثّ kθr ‘it increased’.

Morphologically Faithful CODA preserves dialectal morphology and spells the dialectal morphemes (clitics and inflections) phonologically. For example, for the attachable future marker clitic, the variant +ح is chosen, not the MSA +س, so that EGY /Hatiktar/ (and its variant /hatiktar/) are both spelled حتّكثّ Htkθr. The negation prefix and indirect object pronoun (*I+pronoun*) suffixes are separated, e.g., مَا قلت لهاش mA qlt lhAš /ma'ultlhāš/ ‘I did not tell her’.

Alif-Maqṣura The letter ي y is often used in Egypt to write word-final ي y and *vice versa* (even when writing MSA). In CODA, all rules for using Alif-Maqṣura are the same as MSA. For example, EGY /maSrī/ ‘Egyptian’ can be seen in spontaneous orthography as مصرى mSrý, but in CODA it is مصرى mSrý.

Ta-Marbuta As in MSA, the Ta-Marbuta (ة h) is used morphemically in CODA. The Ta-Marbuta is

always written as ة h in CODA, e.g., /arbaṣa/ ‘four’ is أربعة Ārbṣh in CODA, though it can be found as أربعة Ārbṣh (or أربعه Arbsh) in spontaneous orthography.

Lexical Exceptions EGY CODA guidelines include a word list specifying ad hoc spellings of EGY words that may be inconsistent with the default mapping outlined above. An example is /kida/ ‘like this’, which we find as both كدا kdA and هدا kdh in spontaneous orthography; the CODA spelling is هدا kdh.

4 Related Work

To our knowledge, this paper is the first to discuss the task of automatically providing a conventionalized spelling for a written Arabic dialect text. While there is no direct precedent, we discuss here some related research.

Our proposed work has some similarity to **automatic spelling correction** (ASC) and related tasks such as post editing for optical character recognition (OCR). Our task is different from ASC since ASC work assumes a standard orthography that the writer is also assumed to aim for. Both supervised and unsupervised approaches to this task have been explored. Unsupervised approaches rely on improving the fluency of the text and reducing the percentage of out-of-vocabulary words using NLP tools, resources, and heuristics, e.g., morphological analyzers, language models, and edit-distance measure, respectively (Kukich, 1992; Oflazer, 1996; Ben Othmane Zribi and Ben Ahmed, 2003; Shaalan et al., 2003; Haddad and Yaseen, 2007; Hassan et al., 2008; Shaalan et al., 2010; Alkanhal et al., 2012). Supervised approaches learn models of correction by training on paired examples of errors and their corrections. This data is hard to come by naturally, though for applications such as OCR corpora can be created from the application itself (Kolak and Resnik, 2002; Magdy and Darwish, 2006; Abuhakema et al., 2008; Habash and Roth, 2011).

There has been some work on **conversion** of dialectal Arabic to MSA. Al-Gaphari and Al-Yadoumi (2010) introduced a rule-based method to convert Sanaani dialect to MSA, and Shaalan et al. (2007) used a rule-based lexical transfer approach to transform from EGY to MSA. Similarly, both Sawaf

(2010) and Salloum and Habash (2011) showed that translating dialectal Arabic to MSA can improve dialectal Arabic machine translation into English by pivoting on MSA. A common feature across these conversion efforts is the use of morphological analysis and morphosyntactic transformation rules (for example, Al-Gaphari and Al-Yadoumi (2010)). While all this work is similar to ours in that dialectal input is processed, our output is still dialectal, while the work on conversion aims for a transformation into MSA.

The work most closely related to ours is that of Dasigi and Diab (2011). They identify the spelling variants in a given document and normalize them. However, they do not present a system that converts spontaneous spelling to a pre-existing convention such as CODA, and thus their results cannot be directly related to ours. Furthermore, their technique is different. First, similarity metrics based on string difference are used to identify if two strings are similar. Also, a contextual string similarity is used based on the fact that if two words are orthographic variants of each other, then they are bound to appear in similar contexts. After identifying the similar strings, the strings of interest are modeled in a vector space and clustered according to the similarity of their vectors.

5 Data

In this work, we use a manually annotated EGY Arabic corpus, developed by the Linguistic Data Consortium (LDC), and labeled as “ARZ” (Maamouri et al., 2012), parts 1, 2, 3, 4 and 5. The corpus consists of about 160K words (excluding numbers and punctuations), and follows the part-of-speech (POS) guidelines used by the LDC for Egyptian Arabic. The corpus contains a full analysis of Egyptian Arabic text in spontaneous orthography. The analysis includes the correct CODA orthography of the raw text, in addition to the full morphological/POS annotations.

Data Preparation We divide the ARZ corpus into three parts: training, development and test, which are of about 122K, 19K and 19K words, respectively. We only consider the orthographic information in the ARZ corpus: for every word in the corpus, we retain the spontaneous orthographic form

and its CODA-compliant form.

We manually checked the CODA-compliant annotations for about 500 words in the development corpus. We found that the accuracy of the gold annotations in this subset is about 93%. We performed next an error analysis for the erroneous gold annotations. About one half of the gold errors are CODA phonological and orthographical errors. Examples of the CODA phonological errors include wrong additions and deletions of $\text{ا} A$ and $\text{ي} y$, in addition to the $\text{ث} / \text{ت} t/\theta$ transformations, and the transformations that correspond to the different phonological forms of pronouncing the letter $\text{ه} h$. The CODA orthographical errors are those errors where a word orthography looks the same as its pronunciation, while it should not be, such as the $\text{أ} \ddot{\text{o}} h/\text{ه} h$ transformations. One fifth of the gold errors are annotation typos, such as writing قطارات *qTwrAt* instead of *qTArAt* ‘trains’. Moreover, 9% of the gold errors are wrong merges for the negation particle $\text{لـ} mA$ and the indirect object pronouns (*l+pronouns*). Since we use the gold in our study, and given the error analysis for the gold, we expect a qualitatively better gold standard to yield better results.

Transformation Statistics We observe two types of transformations when converting from spontaneous orthography to CODA: character substitutions that do not affect the word length, and character additions/deletions that change the word length. Tables 1 and 2 show the most common character substitution and addition/deletion transformations, respectively, as they appear in the training corpus, associated with their frequencies relative to the occurrence of transformations. The character substitutions are dominant, and constitute about 84% of all the transformations in the training corpus. While the classification of the character substitutions is automatically generated, the classification of the character additions/deletions is done manually using a random sample of 400 additions/deletions in the training corpus. This is because many additions/deletions are ambiguous.

6 Approach

We describe next the various approaches for spontaneous orthography codification. Our codification techniques fall into two main categories: contex-

Transformation	Frequency %
$\tilde{V}\tilde{W}\tilde{Y} A/\bar{A}/\check{A}/\bar{\check{A}} \Leftrightarrow \tilde{W}\tilde{Y}\tilde{V} A/\bar{A}/\check{A}/\bar{\check{A}}$	38.5
$\text{ي } y \Leftrightarrow \text{ى } \check{y}$	29.7
$\text{ه } h \Leftrightarrow \text{ه } \check{h}$	16.9
$\text{ه } h \Leftrightarrow \text{ح } H$	2.5
$\text{س ات } \theta \Leftrightarrow \text{س t/s}$	1.0
$\text{ا } A \Leftrightarrow \text{ه } h$	0.7
$\text{ق } q \Leftrightarrow \tilde{V}\tilde{W}\tilde{Y} \text{ ايء } \check{A}/\bar{A}/\check{\bar{A}}/\bar{\check{A}}/\hat{Y}$	0.4
$\text{و } w \Leftrightarrow \text{ه } h$	0.3
$\text{ذ } \delta \Leftrightarrow \text{د } j d/z$	0.3
$\text{ة } \hbar \Leftrightarrow \text{ت } t$	0.3
$\text{ا } A \Leftrightarrow \text{ه } \check{h}$	0.2
$\text{ض } D \Leftrightarrow \text{ظ زاد } d/z/\check{D}$	0.2

Table 1: Spontaneous to CODA character substitution transformations

Transformation	Frequency %
Errors in closed class words	22.0
Missing space after \w\l\l mA/lA/yA	19.0
\A additions & deletions	16.8
Gold errors	10.3
Speech effects	8.5
Missing space before \l (+pron)	8.5
\w\l\l w/h/wA \Leftrightarrow \w\l\l w/h/wA	8.3
\y additions & deletions	3.0

Table 2: Spontaneous to CODA character addition/deletion transformations

tual and non-contextual, where the non-contextual approaches are a lot faster than the contextual ones.

6.1 Speech Effect Handling

Before applying any codification techniques, we perform a special preprocessing step for speech effects, which represent redundant repetitions of some letter in sequence. Sometimes people intend these repetitions to show affirmation or intensification. This is simply handled by removing the repetitions when a letter is repeated more than twice in a row, except for some letters whose repetitions for more than once indicates a speech effect; these letters are \A, \AA, \e, \i, \y and \o. Handling speech effects on its own corrects about 2% of the non-CODA spontaneous orthography to its CODA-compliant form, without introducing any new errors. In all experiments we report in this paper, we have initially processed speech effects.

6.2 Character Edit Classification (CEC)

In this approach, a set of transformations is applied on a character level, where a character may receive a change or not. As a result, a word changes if one or more of its characters is changed. The output of these transformations is what constitutes the CODA orthography. This is a surface modeling technique that does not depend on the word context (though it does depend on character context inside the word).

First, we train classifiers for the most frequent transformations from EGY spontaneous orthography to the corresponding CODA, listed in Tables 1 and 2 in Section 5. Second, we apply the trained classifiers to generate the CODA output.

Training the classifiers For each transformation listed in the data section, we train a separate classifier. The classifiers are trained on our training corpus using the k-nearest neighbor algorithm (k-NN) (Wang et al., 2000), which is a method for classifying objects based on the closest training examples in the feature space. We did experiments using the other classification methods included in the WEKA machine learning tool (Hall et al., 2009), including SVMs, Naïve Bayes, and decision trees. However, k-NN gives the best results for our problem.

In the training process, a set of nine static features is applied, which are the character that is queried for the transformation with its preceding and following two characters (a special token indicates a character position that does not exist because it is beyond the word boundary), along with the first two and the last two characters in the underlying word.

In this model, each data point is a character, where a classifier determines whether a character should receive a substitution, deletion, or addition of another character. The effect of each classifier is examined separately on the development set. We then determine for each classification whether it helps or weakens the process by comparing its effect to the baseline which is doing nothing, i.e., no change to a word occurs. Those classifiers that on their own perform worse than the baseline are eliminated. For eliminating the classifiers, we examine them in a descending order according to the frequencies of their corresponding transformations. We now discuss the seven classifiers we retain in our system:

1. The different $\text{|\text{A}}$ form ($\text{\textcircumflex} \text{V} \text{V} \text{\textcircumflex} \text{A}/\text{\textcircumflex} \text{A}/\text{\textcircumflex} \text{A}/\text{\textcircumflex} \text{A}$) classifier. The classifier can change any $\text{|\text{A}}$ form into any other $\text{|\text{A}}$ form. The arbitrary selection of the different $\text{|\text{A}}$ forms represents the most frequent divergence from CODA in Arabic spontaneous orthography.
2. The $\text{|\text{ي}}/\text{ي}\text{|\text{ي}}$ classifier. The classifier handles transformations between $\text{|\text{ي}}\text{y}$ and $\text{ي}\text{|\text{ي}}$ in both directions, as their selection is mostly arbitrary in EGY spontaneous orthography.
3. The $\text{|\text{o}}/\text{|\text{ø}}/\text{h}/\text{\textcircumflex} \text{h}/\text{w}$ classifier. The classifier handles transformations between $\text{|\text{o}}\text{h}$, $\text{|\text{ø}}\text{h}$ and $\text{|\text{w}}$ in both directions. These transformations are likely to happen at word endings, since they represent common misspellings in writing $\text{|\text{o}}\text{h}$, $\text{|\text{ø}}\text{h}$ and $\text{|\text{w}}$, where $\text{|\text{o}}\text{h}$ is often substituted for the graphically similar $\text{|\text{ø}}\text{h}$, and $\text{|\text{o}}\text{h}$ and $\text{|\text{w}}$ can both be used to represent the 3rd person masculine singular accusative or genitive clitic. (Note that in Table 1, we list transformations between $\text{|\text{o}}\text{h}$ and $\text{|\text{ø}}\text{h}$ as well as between $\text{|\text{o}}\text{h}$ and $\text{|\text{w}}$; the remaining transformations are not frequent.)
4. The $\text{|\text{o}}/\text{|\text{ح}}/\text{h}/\text{H}$ classifier. The transformation from $\text{|\text{o}}\text{h}$ to $\text{|\text{ح}}\text{H}$ is likely to happen at word beginnings, since it represents a common deviation in writing the $\text{|\text{ح}}\text{H}$ future particle.
5. The $\text{|\text{A}}$ deletion classifier. The classifier handles the deletion of extra $\text{|\text{A}}$ at some positions, which is a common deviation in EGY spontaneous orthography, where the CODA orthography requires only short vowels instead.
6. The $\text{|\text{A}}$ addition classifier. The classifier handles the addition of $\text{|\text{A}}$ in some positions, where it is mostly omitted in EGY spontaneous orthography, such as adding $\text{|\text{A}}$ after the $\text{|\text{ح}}\text{H}$ future particle and the $\text{|\text{ب}}\text{b}$ progressive particle (when used with the 1st person singular imperfective), as well as the $\text{|\text{و}}\text{w}$ plural pronoun at word endings. When training this classifier, we target the letter after which the $\text{|\text{A}}$ should be added.
7. The space addition classifier. The classifier handles the addition of spaces in the middle

of words, i.e., splitting a word into two words. This is required to add spaces after mA/lA/yA for negation and vocation, and before the indirect object $l+pronoun$, so that the text becomes CODA-compliant.

Generating CODA Orthography Next, we apply the trained classifiers on the spontaneous-orthography text. Each classifier determines a set of character corrections, where the characters may receive transformations corresponding to those on which the classifier is trained. The classifiers are independent of one another, so their order of application is irrelevant.

By way of example, we apply the classifiers on the word $\text{أربعه} \text{Arbsh}$, ‘four’. The first classifier, corresponding to the different $\text{|\text{A}}$ forms, determines the transformation of $\text{|\text{A}}$ to $\text{|\text{آ}}$, while the $\text{|\text{o}}/\text{|\text{ø}}$ classifier determines the correction of $\text{|\text{o}}\text{h}$ to $\text{|\text{ø}}\text{h}$. The other classifiers are either not involved since they do not work on any of the word characters, or they determine that no character transformation should happen for this word. Thus applying the CEC technique in this case changes the word $\text{أربعه} \text{Arbsh}$ to $\text{أربعة} \text{Arbsh}$, which is the correct CODA form.

6.3 Maximum Likelihood Estimate (MLE)

Another surface modeling approach for spontaneous orthography codification is to use a maximum likelihood model that operates on the word level. In this approach, we build a unigram model that replaces every word in the spontaneous orthography with its most likely CODA form as seen in the training data. This assumes that the underlying word exists in the training corpus. For unseen words, the technique keeps them with no change.

The MLE approach chooses the correct CODA form for most of the words seen in training, making this approach highly dependent on the training data. It is efficient at correcting common misspellings in frequent words, especially those that are from closed classes.

6.4 Morphological Tagger

In addition to the approaches discussed above, we use a morphological tagger, MADA_{ARZ} (Morphological Analysis and Disambiguation for Egyp-

tian Arabic) (Habash et al., 2013). Although MADA_{ARZ} is originally developed to work as a morphological tagger, it still can help the codafication process, since the choice of a full morphological analysis for a word in context determines its CODA spelling. Therefore, MADA_{ARZ} is able to correct many word misspellings that are common in spontaneous orthography. These corrections include (VV̄V̄ A/Ā/Ā/Ā), ي/ي y/y and ہ/ہ h/h transformations. However, MADA_{ARZ}, as a codafication technique, uses the context of the word, which makes it a contextual modeling approach unlike CEC and MLE. It is much slower than they are.

6.5 Combined Techniques

The CEC and MLE techniques can be applied alone, or they can be applied together in a pipeline in either order. This gives a total of four possible combinations. Next, we conducted experiments with MADA_{ARZ}, running alone and as a pre- or postprocessor for a combination of CEC and/or MLE. In all cases, when we first apply one module and then another on the output of the first, we train the second module on the training corpus which has been passed through the first module. The results of running the different codafication approaches are discussed next.

7 Evaluation

7.1 Accuracy Evaluation

The different codafication approaches, discussed in the previous section, are tested against the development set, which was not used as part of our training. The evaluation metric we use is a word accuracy metric, i.e., we evaluate how well we can correctly predict the CODA form of the input spontaneous orthography.

Table 3 lists the effects of using the different codafication approaches. For each approach, two numbers are reported; exact and normalized. In the exact evaluation, the output of the codafication approach is exactly matched against the correct CODA orthography, while in the normalized evaluation, the match is relaxed for the (VV̄V̄ A/Ā/Ā/Ā) and ي/ي y/y alternations, i.e., these differences do not count as errors. In many NLP applications (such

as machine translation), the input is normalized for these two phenomena, so that the normalized evaluation gives a sense of the relevance of codafication to downstream processes which normalize.

In this evaluation we compare our different codafication techniques, CEC, MLE, CEC+MLE and MLE+CEC, against the baseline. We also show the effect of using MADA_{ARZ} as a codafication system. We see that MLE on its own outperforms CEC. Running CEC first and then MLE gives us our best result using surface techniques, namely 91.5%, for an error reduction of 63.4% against the baseline. This configuration also gives the highest normalized accuracy of 95.2%, for an error reduction of 49.5% against the baseline.

We now turn to deep modeling techniques. The performance of MADA_{ARZ} on its own as a codafication system is close to the performance of CEC+MLE, by which it is outperformed in the exact-match accuracy by 0.4%.

The best deep modeling (and the best overall) performance is achieved when running MADA_{ARZ} on top of MLE. This gives the highest accuracy of 92.6% (exact) and 95.8% (normalized), for error reductions of 68.1% (exact) and 55.8% (normalized) against the baseline, respectively. Note that the non-contextual modeling techniques CEC (5,584 words/sec) and MLE (6,698 words/sec) are a lot faster than the deep modeling technique MADA_{ARZ} (53 words/sec), while their combination CEC+MLE+MADA_{ARZ} is the slowest among all the approaches, operating at a rate of 52 words/sec. Thus, a small drop in accuracy results in a large increase in speed.

We also evaluated using MADA_{MSA} (v 3.2) (Morphological Analysis and Disambiguation for MSA) (Habash and Rambow, 2005; Habash et al., 2010). MADA_{MSA} is able to do some codafication, but it performs far worse than our codafication approaches.

Table 4 lists the results of the best performing codafication surface approach, CEC+MLE, and deep approach, MLE+MADA_{ARZ}, when applied on the test set, which was not used as part of our training or development, i.e., a completely blind test. We see that on the test set, the addition of MADA_{ARZ} improves results relatively more as compared to the development set.

Approach	Exact Match		Norm Match		w/s
	Acc%	ER%	Acc%	ER%	
Baseline	76.8	—	90.5	—	—
MADA _{MSA}	83.6	29.3	91.7	12.6	70
CEC	90.0	56.9	93.9	35.8	5,584
MLE	90.5	59.1	94.6	43.2	6,698
CEC+MLE	91.5	63.4	95.2	49.5	4,284
MLE+CEC	90.7	59.9	94.7	44.2	4,284
MADA _{ARZ}	91.1	61.6	95.2	49.5	53
MADA _{ARZ} +CEC	91.5	63.4	95.4	51.6	53
MADA _{ARZ} +MLE	91.9	65.1	95.8	55.8	53
CEC+MADA _{ARZ}	92.2	66.4	95.6	53.7	53
MLE+MADA _{ARZ}	92.6	68.1	95.8	55.8	53
MADA _{ARZ} +CEC+MLE	91.8	64.7	95.6	53.7	52
CEC+MLE+MADA _{ARZ}	92.0	65.5	95.8	55.8	52

Table 3: Comparison of the performance of the different codification approaches on the development corpus. *Acc* stands for Accuracy; *ER* is error reduction against the Baseline. *w/s* is speed (words/sec).

Approach	Exact Match		Norm Match		
	Acc%	ER%	Acc%	ER%	
Baseline	75.5	—	89.7	—	
CEC+MLE	91.3	64.5	94.8	49.5	
MLE+MADA _{ARZ}	92.9	71.0	95.5	56.3	

Table 4: Comparison of the performance of the different codification approaches on the test corpus. *Acc* stands for Accuracy; *ER* is error reduction against the Baseline.

7.2 Extrinsic Evaluation

Morphological Analysis We tested the effect of codification on morphological tagging, specifically full POS and lemma determination in context by the morphological tagger MADA_{ARZ}. Here, we are evaluating MADA_{ARZ} not on its conversion to CODA (as above), but on its core functionality, namely morphological tagging. We compare the performance of MADA_{ARZ} against running CEC+MLE+MADA_{ARZ}. When tested on the development set, the initial CEC+MLE codification step helps MADA_{ARZ} improve the identification of the complete Arabic (Buckwalter) POS tag from 84% to 85.3%, for an error reduction of 8.1%, while the correct lemma choice increases from 85.2% to 85.7%, for an error reduction of 3.4%. When tested on the test set, we get improvements on the choice

of the complete Buckwalter POS tag and lemma from 84.5% to 85.4% (5.8% error reduction) and from 86.3% to 86.7% (2.9% error reduction), respectively.

Arabic to English MT The goal of this experiment is to test the effect of codification on machine translation from dialectal Arabic to English. We use the open-source Moses toolkit (Koehn et al., 2007) to build a phrase-based SMT system. We use MGIZA++ for word alignment (Gao and Vogel, 2008). Phrase translations of up to 8 words are extracted in the phrase table. We use SRILM (Stolcke, 2002) with modified Kneser-Ney smoothing to build two 4-gram language models. The first model is trained on the English side of the bitext, while the other is trained on the English Gigaword data. Feature weights are tuned to maximize BLEU (Papineni et al., 2002) on a development set using MERT (Och, 2003). We perform case-insensitive evaluation in terms of the BLEU metric.

We train the system on dialectal Arabic-English parallel data, obtained from several LDC corpora, which amounts to $\sim 500k$ sentences with 3.8M untokenized words on the Arabic side. The development set, used for tuning the parameters of the MT system, has 1,547 sentences with 15,585 untokenized Arabic words. The test set has 1,065 sentences with

12,116 untokenized Arabic words. Both development and test sets have two reference translations each. The English data is lower-cased and tokenized using simple punctuation-based rules.

We build two systems which vary in preprocessing of the Arabic text. The baseline system applies only simple punctuation-based rules. The second system applies our codification in addition to punctuation separation. The Arabic text is Alif/Ya normalized and is kept untokenized in both settings. The baseline system achieves a BLEU score of 22.1%. The system using codification obtains a BLEU score of 22.6%, and outperforms the baseline by 0.5% absolute BLEU points. This result shows that improvements observed in intrinsic evaluation of codification carry on to the extrinsic task of machine translation.

7.3 Error Analysis

We conducted an error analysis for the best performing codification approach on the development set. The most frequent error types are listed in Table 5. About two thirds of the errors are CODA phonological and orthographical errors, denoted by CODA-Phon and CODA-Orth, respectively. The wrong additions and deletions of $\text{ا} A$ and $\text{ي} y$ and the $\text{ت} / \text{ث} t/\theta$ transformations are examples of CODA phonological errors. The CODA orthographic errors include cases such as the $\text{ي} / \text{ي} y / \text{ي} \acute{y}$ transformations. 21% of the errors are not real errors in the codification output, but result from gold errors. Finally, about 13% of the errors are wrong merges and splits for the the negation particle $\text{لـ} mA$, the vocative particle $\text{لـ} yA$ and the indirect-object $l+$ pronouns.

8 Conclusion and Future Work

We have presented the problem of transforming spontaneous orthography of the Egyptian Arabic dialect into a conventionalized form, CODA. Our best technique involves a combination of character transformations, whole-word transformations, and the use of a full morphological tagger. The tagger can be omitted for a small decrease in performance and a large increase in speed.² In future work, we plan to extend our approach to other Arabic dialects. We

²Our system will be freely available. Please contact the authors for more information.

Error Type	Description	Percentage
Gold Error	<i>Annotation Error</i>	21.0
CODA-Orth	$\text{هـ} h \Leftrightarrow \text{هـ} \acute{h}$	13.7
CODA-Phon	$\text{ا} A \rightarrow \epsilon$	8.7
Merge	$\text{لـ} mA / \text{NEG_PART}$	7.3
CODA-Phon	$\epsilon \rightarrow \text{يـ} y$	6.8
CODA-Phon	$\epsilon \rightarrow \text{ا} A$	5.9
CODA-Orth	$\text{يـ} y \Leftrightarrow \text{يـ} \acute{y}$	4.1
Merge	$\text{لـ} yA / \text{VOC_PART}$	3.7
CODA-Phon	$\text{هـ} h \Leftrightarrow \text{حـ} H$	3.2
CODA-Phon	$\text{يـ} y \Leftrightarrow \text{يـ} \acute{y}$	3.2

Abstract

Bibliometric measures are commonly used to estimate the popularity and the impact of published research. Existing bibliometric measures provide “quantitative” indicators of how good a published paper is. This does not necessarily reflect the “quality” of the work presented in the paper. For example, when *h-index* is computed for a researcher, all incoming citations are treated equally, ignoring the fact that some of these citations might be negative. In this paper, we propose using NLP to add a “qualitative” aspect to bibliometrics. We analyze the text that accompanies citations in scientific articles (which we term *citation context*). We propose supervised methods for identifying citation text and analyzing it to determine the purpose (i.e. author intention) and the polarity (i.e. author sentiment) of citation.

1 Introduction

An objective and fair evaluation of the impact of published research requires both quantitative and qualitative assessment. Existing bibliometric measures such as *H-Index* (Hirsch, 2005; Hirsch, 2010), *G-index* (Egghe, 2006), and *Impact Factor* (Garfield, 1994) focus on the quantitative aspect of this evaluation which dose not always correlate with the qualitative aspect.

For example, the number of papers published by a researcher only tells how productive she or he is. It does not say anything about the quality or the impact of the work. Similarly, the number of citations that a paper receives should not be used to gauge the quality of the work as it really only measures the popularity of the work and the interest of other researchers in it (Garfield, 1979). Controversial papers or those based on fabricated data or experiments may receive a large number of citations. A popular

example of fraudulent research that deceived many researchers and caught media attention was the case of a South Korean research scientist, Hwang Woo-suk, who was found to have faked his research results in the area of human stem cell cloning. His research was published in *Science* and received close to 200 citations after the fraud was discovered. The vast majority of those citations were negative.

This suggests that the *purpose* of citation should be taken into consideration when bibliometric measures are computed. Negative citations should be weighted less than positive or neutral citations. This motivates the need to automatically distinguish between positive, negative, and neutral citations and to identify the purpose of a citation; i.e. the author’s intention behind choosing a published article and citing it.

This analysis of citation purpose and polarity can be useful for many applications. For example, it can be used to build systems that help funding agencies and hiring committees at universities and research institutions evaluate researchers’ work more accurately. It can also be used as a preprocessing step in systems that process scholarly data. For example, citation-based summarization systems (Qazvinian and Radev, 2008; Qazvinian et al., 2010; Abu-Jbara and Radev, 2011) and survey generation systems (Mohammad et al., 2009; Qazvinian et al., 2013) can benefit from citation purpose and polarity analysis to improve paper and content selection.

In this paper, we investigate the use of linguistic analysis techniques to automatically identify the purpose of citing a paper and the polarity of this citation. We first present a sequence labeling method for extracting the text that cites a given target reference; i.e. the text that appears in a scientific article and refers to another article and comments on it. We use the term *citation context* to refer to this text. Next,

we use supervised classification techniques to analyze this text and identify the purpose and polarity of citation.

The rest of this paper is organized as follows. Section 2 reviews the related work. We present our approach in Section 3. We then describe the data and experiments in Section 4. Finally, Section 5 concludes the paper and suggests directions for future work.

2 Related Work

Our work is related to a large body of research on citations. Studying citation patterns and referencing practices has interested researchers for many years (Hodges, 1972; Garfield et al., 1984). White (2004) provides a good survey of the different research directions that study or use citations. In the following subsections, we review three lines of research that are closely related to our work.

2.1 Citation Context Identification

The first line of related research addresses the problem of identifying citation context. The context of a citation that cites a given target paper can be a set of sentences, one sentence, or a fragment of a sentence.

Nanba and Okumura (1999) use the term *citing area* to refer to the same concept. They define the citing area as the succession of sentences that appear around the location of a given reference in a scientific paper and have connection to it. Their algorithm starts by adding the sentence that contains the target reference as the first member sentence in the citing area. Then, they use a set of cue words and hand-crafted rules to determine whether the surrounding sentences should be added to the citing area or not. In (Nanba et al., 2000), they use their algorithm to improve citation type classification and automatic survey generation.

Qazvinian and Radev (2010) addressed a similar problem. They proposed a method based on probabilistic inference to extract non-explicit citing sentences; i.e., sentences that appear around the sentence that contains the target reference and are related to it. They showed experimentally that citation-based survey generation produces better results when using both explicit and non-explicit citing sentences rather than using the explicit ones alone.

In previous work, we addressed the issue of identifying the scope of a given target reference in citing sentences that contain multiple references (2012). Our definition of *reference scope* was limited to fragments of the explicit citing sentence (i.e. the sentence in which actual citation appears). That method does not identify related text in surrounding sentences.

In this work, we propose a supervised sequence labeling method for identifying the citation context of given reference which includes the explicit citing sentence and the related surrounding sentences.

2.2 Citation Purpose Classification

Several research efforts have focused on studying the different purposes for citing a paper (Garfield, 1964; Weinstock, 1971; Moravcsik and Murugesan, 1975; and Moitra, 1975; Bonzi, 1982). Bonzi (1982) studied the characteristics of citing and cited works that may aid in determining the relatedness between them. Garfield (1964) enumerated several reasons why authors cite other publications, including “alerting researchers to forthcoming work”, paying homage to the leading scholars in the area, and citations which provide pointers to background readings. Weinstock (1971) adopted the same scheme that Garfield proposed in her study of citations.

Spiegel-Rosing (1977) proposed 13 categories for citation purpose based on her analysis of the first four volumes of Science Studies. Some of them are: Cited source is the specific point of departure for the research question investigated, Cited source contains the concepts, definitions, interpretations used, Cited source contains the data used by the citing paper. Nanba and Okumura (1999) came up with a simple schema composed of only three categories: *Basis*, *Comparison*, and other *Other*. They proposed a rule-based method that uses a set of statistically selected cue words to determine the category of a citation. They used this classification as a first step for scientific paper summarization. Teufel et al. (2006), in their work on citation function classification, adopted 12 categories from Spiegel-Rosing’s taxonomy. They trained an SVM classifier and used it to label each citing sentence with exactly one category. Further, they mapped the twelve categories to four top level categories namely: weakness, contrast

(4 categories), positive (6 categories) and neutral.

The taxonomy that we use in this work is based on previous work. We adopt a scheme that contains six categories. We selected the six categories after studying all the previously used citation taxonomies. We included the ones we believed are important for improving bibliometric measures and for the applications that we are planning to pursue in the future (Section 5).

2.3 Citation Polarity Classification

The polarity (or sentiment) of a citation has also been studied previously. Previous work showed that positive and negative citations are common, although negative citations might be expressed indirectly or in an implicit way (Ziman, 1968; MacRoberts and MacRoberts, 1984; THOMPSON and YIYUN, 1991). Athar (2011) addressed the problem of identifying sentiment in citing sentences. He used a set of structure-based features to train a machine learning classifier using annotated data. This work uses the citing sentence only to predict sentiment. Context sentences were ignored. Athar and Teufel (2012a) observed that taking the context into consideration when judging sentiment in citations increases the number of negative citations by a factor of 3. They proposed two methods for utilizing the context. In the first method, they treat the citing sentence and a fixed context (a window of four sentences around the citing sentence) as if they were a single sentence. They extract features from the merged text and train a classifier similar to what they did in their 2011 paper. In the second method, they use a four-class annotation scheme. Each sentence in a window of four sentences around the citation is labeled as positive, negative, neutral, or excluded (unrelated to the cited work). These experiments surprisingly gave negative results and showed that classifying sentiment *without* considering the context achieves better results. They attributed this to the small size of their training data and to the noise that including the context text introduces to the data. In (Athar and Teufel, 2012b), the authors present a method for automatically identifying all the mentions of the cited paper in the citing paper. They show that considering all the mentions improves the performance of detecting sentiment in citations.

In our work, we propose a sequence labeling

method for identifying the citation context first, and then use a supervised approach to determine the polarity of a given citation.

3 Approach

In this section, we describe our approach to three tasks: citation context identification, citation purpose classification, and citation polarity identification. We also describe a preprocessing stage that is applied to the citation text before performing any of the three tasks.

3.1 Preprocessing

The goal of the preprocessing stage is to clean and prepare the citation text for part-of-speech tagging and parsing. The available POS taggers and parsers are not trained on citation text. Citation text is different from normal text in that it contains references written in a special format (e.g., author names and publication year written in parentheses; or reference indices written in square brackets). Many citing sentences contain multiple references, some of which might be grouped together in a pair of parentheses and separated by a comma or a semi-colons. These references are usually not syntactic nor semantic constituents of the sentences they appear in. This results in many POS tagging and parsing errors. We address this issue in the pre-processing stage to improve the performance of the feature extraction component. We perform three pre-processing steps:

a. Reference Tagging: In the first step, we find and tag all the references that appear in the text. We use a regular expression to find references and replace each reference with a placeholder. The reference to the target paper is replaced by the placeholder *TREF*. Each other reference is replaced by *REF*.

b. Reference Grouping: In this step, we identify grouped references (i.e. multiple references listed between one pair of parentheses separated by semi-colons). Each such group is replaced by a placeholder, *GREF*. If the target reference is a member of the group, we use a different placeholder: *GTREF*.

c. Non-syntactic Reference Removal: A reference or a group of references could either be a syntactic constituent and has a semantic role in the sentence or not (Whidby, 2012; Abu Jbara and Radev, 2012). If the reference is not a syntactic compo-

Feature	Description
Demonstrative determiners	Takes a value of 1 if the current sentence contains a <i>demonstrative determiner</i> (this, these, etc.), and 0 otherwise.
Conjunctive adverbs	Takes a value of 1 if the current sentence starts with a <i>conjunctive adverb</i> (However, Furthermore, Accordingly, etc.), and 0 otherwise.
Position	Position of the current sentence with respect to the citing sentence. This feature takes one of four values: -1, 0, 1, and 2.
Contains Closest Noun Phrase	Takes a value of 1 if the current sentence contains closest noun phrase (if any) immediately before the reference position in the citing sentence, and 0 otherwise. This noun phrase often is the name of a method, a tool, or corpus originating from the cited reference.
2-3 grams	The first bigram and trigram in the sentence (<i>This approach</i> , <i>One problem with</i> , etc.).
Contains Other references	Takes a value of 1 if the current sentence contains references other than the target, and 0 otherwise.
Contains a Mention of target reference	Takes a value of 1 if the current sentence contains a mention (explicit or anaphoric) of the target reference, and 0 otherwise.
Multiple references	Takes a value of 1 if the citing sentence contains multiple references, and 0 otherwise. If the citing sentence contains multiple references, it becomes less likely that the surrounding sentences are related.

Table 1: Features used for citation context identification

ment in the sentence, we remove it to reduce parsing errors. Following our previous work (Abu Jbara and Radev, 2012), we use a rule-based algorithm to determine whether a reference should be removed from the sentence or kept. The algorithm uses stylistic and linguistic features such as the style of the reference, the position of the reference, and the surrounding words to make the decision. When a reference is removed, the head of the closest noun phrase (NP) immediately before the position of the removed reference is used as a representative of the reference. This is needed for feature extraction as shown later in the paper.

3.2 Citation Context Identification

The task of identifying the citation context of a given target reference can be formally defined as follows. Given a scientific article *A* that cites another article *B*, find a set of sentences in *A* that talk about the work done in *B* such that at least one of these sentences contains an explicit reference to *B*.

We treat this problem as a sequence labeling problem. The goal is to find the globally best sequence of labels for all the sentences that appear within a window around the *citing sentence*. The *citing sentence* is the one that contains an explicit reference to the cited paper. Each sentence within the window is labeled as *INCLUDED* or *EXCLUDED* from the citation context of the given target paper. To determine the size of the window, we examined a development set of 300 sentences. We noticed that the related context almost always falls within a window of

four sentences. The window includes the citing sentence, one sentence before the citing sentence, and two sentences after the citing sentence.

We use Conditional Random Fields (CRFs) for sequence labeling. In particular, we use a first-order chain-structured CRF. The chain consists of two sets of nodes: 1) a set of hidden nodes \mathbf{Y} which represent the context labels of sentences (INCLUDED or EXCLUDED), and 2) a set of observed nodes \mathbf{X} which represent the features extracted from the sentences. The task is to estimate the probability of a sequence of labels \mathbf{Y} given the sequence of observed features \mathbf{X} : $P(\mathbf{Y}|\mathbf{X})$

Lafferty et al. (2001) define this probability to be a normalized product of potential functions ψ :

$$P(\mathbf{y}|\mathbf{x}) = \prod_t \psi_k(y_t, y_{t-1}, \mathbf{x}) \quad (1)$$

Where $\psi_k(y_t, y_{t-1}, \mathbf{x})$ is defined as

$$\psi_k(y_t, y_{t-1}, \mathbf{x}) = \exp\left(\sum_k \lambda_k f(y_t, y_{t-1}, \mathbf{x})\right) \quad (2)$$

where $f(y_t, y_{t-1}, \mathbf{x})$ is a transition feature function of the label at positions $i-1$ and i and the observation sequence \mathbf{x} ; and λ_j is a parameter that the algorithm estimates from training data.

The features we use to train the CRF model include structural and lexical features that attempt to capture indicators of relatedness to the given target reference. The features that we used and their descriptions are listed in table 1.

Category	Description	Example
Criticizing	Criticism can be positive or negative. A citing sentence is classified as "criticizing" when it mentions the weakness/strengths of the cited approach, negatively/positively criticizes the cited approach, negatively/positively evaluates the cited source.	Chiang (2005) introduced a constituent feature to reward phrases that match a syntactic tree but did not yield significant improvement.
Comparison	A citing sentence is classified as "comparison" when it compares or contrasts the work in the cited paper to the author's work. It overlaps with the first category when the citing sentence says one approach is not as good as the other approach. In this case we use the first category.	Our approach permits an alternative to minimum error-rate training (MERT; Och, 2003);
Use	A citing sentence is classified as "use" when the citing paper uses the method, idea or tool of the cited paper.	We perform the MERT training (Och, 2003) to tune the optimal feature weights on the development set.
Substantiating	A citing sentence is classified as "substantiating" when the results, claims of the citing work substantiate, verify the cited paper and support each other.	It was found to produce automated scores, which strongly correlate with human judgements about translation fluency (Papineni et al., 2002).
Basis	A citing sentence is classified as "basis" when the author uses the cited work as starting point or motivation and extends on the cited work.	Our model is derived from the hidden-markov model for word alignment (Vogel et al., 1996; Och and Ney, 2000).
Neutral (Other)	A citing sentence is classified as "neutral" when it is a neutral description of the cited work or if it doesn't come under any of the above categories.	The solutions of these problems depend heavily on the quality of the word alignment (Och and Ney, 2000).

Table 2: Annotation scheme for citation purpose. Motivated by the work of (Spiegel-Rösing, 1977) and (Teufel et al., 2006)

3.3 Citation Purpose Classification

In this section, we describe the citation purpose classification task. Given a target paper B and its citation context (extracted using the method described above) in a given article A , we want to determine the purpose of citing B by A . The purpose is defined as intention behind selecting B and citing it by the author of A (Garfield, 1964).

We use a taxonomy that consists of six categories. We designed this taxonomy based on our study of similar taxonomies proposed in previous work. We selected the categories that we believe are more important and useful from a bibliometric point of view, and the ones that can be detected through citation text analysis. We also tried to limit the number of categories by grouping similar categories proposed in previous work under one category. The six categories, their descriptions, and an example for each category are listed in Table 2.

We use a supervised approach whereby a classification model is trained on a number of lexical and structural features extracted from a set of labeled citation contexts. Some of the features that we use to train the classifier are listed in table 3.

3.4 Citation Polarity Identification

In this section, we describe the citation polarity identification task. Given a target paper B and its citation

context in a given article A , we want to determine the polarity of the citation text with respect to B . The polarity can be: *positive*, *negative*, or *neutral (objective)*. Positive, negative, and neutral in this context are defined in a slightly different way than their usual sense. A citation is marked positive if it either explicitly states a strength of the target paper or indicates that the work done in the target paper has been used either by the author or a third-party. It is also marked as positive if it is compared to another paper (possibly by the same authors) and deemed better in some way. A citation is marked negative if it explicitly points to a weakness of the target paper. It is also marked as negative if it is compared to another paper and deemed worse in some way. A citation is marked as neutral if it is only descriptive.

Similar to citation purpose classification, we use a supervised approach for this problem. We train a classification model using the same features listed in Table 3. Due to the high skewness in the data (more than half of the citations are neutral), we use two setups for binary classification. In the first setup, the citation is classified as *Polarized (Subjective)* or *(Neutral) Objective*. In the second one, *Subjective* citations are classified as *Positive* or *Negative*. We find that this method gives more intuitive results than using a 3-way classifier.

Feature	Description
Reference count	The number of references that appear in the citation context.
Is Separate	Whether the target reference appears within a group of references or separate (i.e. single reference).
Closest Verb / Adjective / Adverb	The lemmatized form of the closest verb/adjective/adverb to the target reference or its representative or any mention of it. Distance is measure based on the shortest path in the dependency tree.
Self Citation	Whether the citation from the source paper to the target reference is a self citation.
Contains 1st/3rd PP	Whether the citation context contains a first/third person pronoun.
Negation	Whether the citation context contains a negation cue. The list of negation cues is taken from the training data of the *SEM 2012 negation detection shared task (Morante and Blanco, 2012).
Speculation	Whether the citation context contains a speculation cue. The list is taken from Quirk et al. (1985)
Closest Subjectivity Cue	The closest subjectivity cue to the target reference or its representative or any anaphoric mention of it. The list of cues is taken from OpinionFinder (Wilson et al., 2005)
Contrary Expressions	Whether the citation context contains a contrary expression. The list is taken from Biber (1988)
Section	The headline of the section in which the citation appears. We identify five title categorizes: 1) <i>Introduction, Motivation, etc.</i> 2) <i>Background, Prior Work, Previous Work, etc.</i> 3) <i>Experiments, Data, Results, Evaluation, etc.</i> 4) <i>Discussion, Conclusion, Future work, etc.</i> 5) All other section headlines. Headlines are identified using regular expressions.
Dependency Relations	All the dependency relations that appear in the citation context. For example, <i>nsubj(outperform, algorithm)</i> is one of the relations extracted from "This algorithm outperforms the one proposed by...". The arguments of the dependency relation are replaced by their lemmatized forms. This type of features has been shown to give good results in similar tasks (Athar and Teufel, 2012a).

Table 3: The features used for citation purpose and polarity classification

4 Evaluation

In this section, we describe the data that we used for evaluation and the experiments that we conducted.

4.1 Data

We use the ACL Anthology Network corpus (AAN) (Radev et al., 2009; Radev et al., 2013) in our evaluation. AAN is a publicly available collection of more than 19,000 NLP papers. It includes a manually curated citation network of its papers as well as the full text of the papers and the citing sentences associated with each edge in the citation network. From this set, we selected 30 papers that have different numbers of incoming citations and that were consistently cited since they were published. These 30 papers received a total of about 3,500 citations from within AAN (average = 115 citation/paper, Min = 30, and Max = 338). These citations come from 1,493 unique papers. For each of these citations, we extracted a window of 4 sentences around the reference position. This brings the number of sentences in our dataset to a total of roughly 14,000 sentences. We refer to this dataset as *training/testing dataset*.

In addition to this dataset, we created another dataset that contains 300 citations that cite 5 papers from AAN. We refer to this dataset as the *development* dataset. This dataset was used to determine the

size of the citation context window, and to develop the feature sets used in the three tasks described in Section 3 above.

4.2 Annotation

In this section, we describe the annotation process. We asked graduate students with good background in NLP (the topic of the annotated sentences) to provide three annotations for each citation example (a window of 4 sentences around the reference anchor) in the *training/testing dataset*. We asked them to mark the sentences that are related to a given target reference. In addition, we asked them to determine the purpose of citing the target reference by choosing from the six purpose categories that we described earlier. We also asked them to determine whether the citation is negative, positive, or neutral.

To estimate the inter-annotator agreement, we picked 400 sentences from the *training/testing dataset* and assigned them to two different annotators. We use the Kappa coefficient (Cohen, 1968) to measure the agreement. The Kappa coefficient is defined as follows:

$$K = \frac{P(A) - P(E)}{1 - P(E)} \quad (3)$$

where $P(A)$ is the relative observed agreement among annotators and $P(E)$ is the hypothetical prob-

ability of chance agreement. The agreement between the two annotators on the context identification task was $K = 0.89$. On Landis and Kochs (Landis and Koch, 1977) scale, this value indicates *almost perfect* agreement. The agreement on the purpose and the polarity classification task were $K = 0.61$ and $K = 0.66$, respectively; which indicates *substantial agreement* on the same scale.

The annotation shows that in 22% of the citation examples, the citation context consists of 2 or more sentences. The distribution of the purpose categories in the data was: 14.7% criticism, 8.5% comparison, 17.7% use, 7% substantiation, 5% basis, and 47% other. The distribution of the polarity categories was: 30% positive, 12% negative, and 58% neutral.

4.3 Experimental Setup

We use the CRF++¹ toolkit for CRF training and testing. We use the Stanford parser to parse the citation text and generate the dependency parse trees of sentences. We use Weka for classification experiments. We experimented with several classifiers including: SVM, Logistic Regression (LR), and Naive Bayes. All the experiments that we conducted used the *training/testing dataset* in a 10-fold cross validation mode. All the results have been tested for statistical significance using a 2-tailed paired t-test.

4.4 Evaluation of Citation Context Identification

We compare the CRF approach to three baselines. The first baseline (ALL) labels all the sentences in the citation window of size 4 as *INCLUDED* in the citation context. The second baseline (CS-ONLY) labels the citing sentence only as *INCLUDED* in the citation context. In the third baseline, we use a supervised classification method instead of sequence labeling. We use Support Vector Machines (SVM) to train a model using the same set of features as in the CRF approach.

Table 4 shows the precision, recall, and F1 score of the CRF approach and the baselines. The results show that our CRF approach outperforms all the baselines. It also asserts our expectation that addressing this problem as a sequence labeling problem leads to better performance than individual sen-

	Precision	Recall	F1
CRFs	98.5%	82.0%	89.5%
ALL	30.7%	100.0%	46.9%
CS-ONLY	88.0%	74.0%	80.4%
SVM	92.0%	76.4%	83.5%

Table 4: Results of citation context identification

tence classification, which is also clear from the nature of the task.

Feature Analysis: We evaluated the importance of the features listed in Table 1 by computing the chi-squared statistic for every feature with respect to the class. We found that the lexical features (such as determiners and conjunction adverbs) are generally more important than the structural features (such as position and reference count). The features shown in Table 1 are listed in the order of their importance based on this analysis.

4.5 Evaluation of Citation Purpose Classification

Our experiments with several classification algorithms showed that the SVM classifier outperforms Logistic Regression and Naive Bayes classifiers. Due to space limitations, we only show the results for SVM. Table 5 shows the precision, recall, and F1 for each of the six categories. It also shows the overall accuracy and the Macro-F measure.

Feature Analysis: The chi-squared evaluation of the features listed in Table 3 shows that both lexical and structural features are important. It also shows that among lexical features, the ones that are limited to the existence of a direct relation to the target reference (such as *closest* verb, adjective, adverb, subjective cue, etc.) are most useful. This can be explained by the fact that the restricting the features to having direct dependency relation introduces much less noise than other features (such as *Dependency Triplets*). Among the structural features, the number of references in the citation context showed to be more useful.

4.6 Evaluation of Citation Polarity Identification

Similar to the case of citation purpose classification, our experiments showed that the SVM classifier outperforms the other classifiers that we experimented with. Table 6 shows the precision, recall, and F1 for

¹<http://crfpp.googlecode.com/svn/trunk/doc/index.html>

	Criticism	Comparison	Use	Substantiating	Basis	Other
Precision	53.0%	55.2%	60.0%	50.1%	47.3%	64.0%
Recall	77.4%	43.1%	73.0%	57.3%	39.1%	85.1%
F1	63.0%	48.4%	66.0%	53.5%	42.1%	73.1%
Accuracy: 70.5%						
Macro-F: 58.0%						

Table 5: Summary of Citation Purpose Classification Results (10-fold cross validation, SVM: Linear Kernel, $c = 1.0$)

each of the three categories. It also shows the overall accuracy and the Macro-F measure. The analysis of the features used to train this classifier using chi-squared analysis leads to the same conclusions about the relative importance of the features as described in the previous subsection. However, we noticed that features that are related to subjectivity (*Subjectivity Cues, Negation, Speculation*) are ranked higher which makes sense in the case of polarity classification.

4.7 Impact of Context on Classification Accuracy

To study the impact of using citation context in addition to the citing sentence on classification performance, we ran two polarity classification experiments. In the first experiment, we used the citing sentence only to extract the features that are used to train the classifiers. In the second experiment, we used the gold context sentences (the ones labeled *INCLUDED* by human annotators). Table 6 shows the results of the first experiment between rounded parentheses and the results of the second experiments in square brackets. The results show that adding citation context improves the classification accuracy especially in the *subjective* categories, specially in the negative category if we want to be more specific. This supports our intuition about polarized citations that authors start their review of the cited work with an objective (neutral) sentence and then follow it with their criticism if they have any. We also reached to similar conclusions with purpose classification, but we are not showing the numbers due to space limitations.

4.8 Other Experiments

4.8.1 Can We Do Better?

In this section, we investigate whether it is possible to improve the performance in the two classification tasks. One factor that we believe could have an

	Negative %	Positive %	Neutral %
Precision	68.7 (66.4) [69.8]	54.9 (52.1) [55.4]	83.6 (82.8) [84.2]
Recall	79.2 (71.1) [81.1]	48.1 (45.6) [46.3]	95.5 (95.1) [95.3]
F1	73.6 (68.7) [75.0]	51.3 (48.6) [50.4]	89.1 (88.5) [89.4]
Accuracy: 81.4 (74.2) [84.2] %			
Macro-F: 71.3 (62.1) [74.2] %			

Table 6: Summary of Citation Polarity Classification Results (10-fold cross validation, SVM: Linear Kernel, $c = 1.0$). Numbers between rounded parentheses are when only the explicit citing sentence is used (i.e. no context). Numbers in square brackets are when the gold standard context is used.

impact on the result is the size of the training data. To examine this hypothesis, we ran the experiment on different sizes of data. Figure 1 shows the learning curve of the two classifiers for different sizes of training data. The accuracy increases as more training data is available so we can expect that with even more data, we can do even better.

4.8.2 Relation Between Citation Purpose/Polarity and Citation Count

The main motivation of this work is our hypothetical assumption that using NLP for analyzing citations gives a clearer picture of the impact of the cited work. As a way to check the validity of this assumption, we study the correlation between the counts of the different purpose and polarity categories. We also study the correlation between these categories and the total number of citations that a paper received since it was published. We use the *training/testing dataset* and the gold annotations for this study.

We compute the Pearson correlation coefficient between the counts of citations from the different categories that a paper received per year since its publication. We found that, on average, the correlation between positive and negative citations is negative (AVG P = -0.194) and that the correlation be-

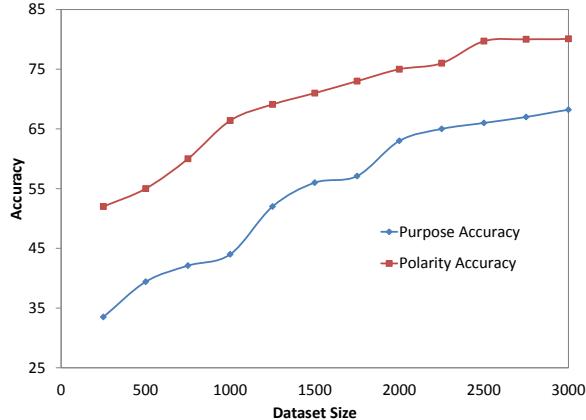

Figure 1: The effect of size of the data set size on the classifiers accuracy.

tween the count of positive citations and the total number of citations is higher than the correlation between negative citations and total citations (AVG P = 0.531 for positive vs. AVG P = 0.054 for negative).

Similarly, we noticed that there is a higher positive correlation between *Use* citations and total citations than in the case of both *Substantiation* and *Basis*. This can be explained by the intuition that publications that present new algorithms, tools, or corpora that are used by the research community become more and more popular with time and thus receive more and more citations.

Figure 2 shows the result of running our purpose classifier on all the citations to Papineni et al.’s (2002) paper about Bleu, an automatic metric for evaluating Machine Translation (MT) systems. The figure shows that this paper receives a high number of *Use* citations. This makes sense for a paper that describes an evaluation metric that has been widely used in the MT area. The figure also shows that in the recent years, this metric started to receive some *Criticizing* citations that resulted in a slight decrease in the number of *Use* citations. Such a temporal analysis of citation purpose and polarity is useful for studying the dynamics of research. It can also be used to detect the emergence or de-emergence of research techniques.

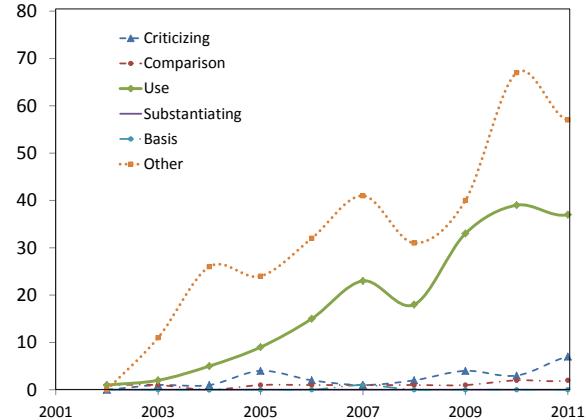

Figure 2: Change in the purpose of the citations to Papineni et al. (2002)

5 Conclusion

In this paper, we presented methods for three tasks: citation context identification, citation purpose classification, and citation polarity classification. This work is motivated by the need for more accurate bibliometric measures that evaluates the impact of research both qualitatively and quantitatively. Our experiments showed that we can classify the purpose and polarity of citation with a good accuracy. It also showed that using the citation context improves the classification accuracy and increases the number of polarized citations detected. For future work, we plan to use the output of this research in several applications such as predicting future prominence of publications, studying the dynamics of research, and designing more accurate bibliometric measures.

Estimating effect size across datasets

Anders Søgaard

Center for Language Technology
University of Copenhagen
soegaard@hum.ku.dk

Abstract

Most NLP tools are applied to text that is different from the kind of text they were evaluated on. Common evaluation practice prescribes significance testing across data points in available test data, but typically we only have a single test sample. This short paper argues that in order to assess the robustness of NLP tools we need to evaluate them on diverse samples, and we consider the problem of finding the most appropriate way to estimate the true effect size across datasets of our systems over their baselines. We apply *meta-analysis* and show experimentally – by comparing estimated error reduction over observed error reduction on held-out datasets – that this method is significantly more predictive of success than the usual practice of using macro- or micro-averages. Finally, we present a new parametric meta-analysis based on non-standard assumptions that seems superior to standard parametric meta-analysis.

1 Introduction

NLP tools and online services such as the Stanford Parser or Google Translate are used for a wide variety of purposes and therefore also on very different kinds of data. Some use the Stanford Parser to parse literature (van Cranenburgh, 2012), while others use it for processing social media content (Brown, 2011). The parser, however, was not necessarily evaluated on literature or social media content during development. Still, users typically expect reasonable performance on any natural language input. This paper asks what we as developers can do

to estimate the effect of a change to our system – not on the labeled test data that happens to be available to us, but on future, still unseen datasets provided by our end users.

The usual practice in NLP is to evaluate a system on a small sample of held-out labeled data. The observed effect size on this sample is then validated by significance testing across data points, testing whether the observed difference in performance means is likely to be due to mere chance. The preferred significance test is probably the non-parametric paired bootstrap (Efron and Tibshirani, 1993; Berg-Kirkpatrick et al., 2012), but many researchers also resort to Student’s *t*-test for dependent means relying on the assumption that their metric scores are normally distributed.

Such significance tests tell us nothing about how likely our change to our system is to lead to improvements on new datasets. The significance tests all rely on the assumption that our datapoints are sampled i.i.d. at random. The significance tests only tell us how likely it is that the observed difference in performance means would change if we sampled a bigger test sample the same way we sampled the one we have available to us right now.

In standard machine learning papers a similar situation arises. If we are developing a new perceptron learning algorithm, for example, we are interested in how likely the new learning algorithm is to perform better than other perceptron learning algorithms *across* datasets, and we may for that reason evaluate it on a large set of repository datasets.

Demsar (2006) presents motivation for using non-parametric methods such as the Wilcoxon signed

rank test to estimate significance across datasets. The t -test is based on means, and typically results across datasets are not commensurable. The t -test is also extremely sensitive to outliers. Notice also that typically we do not have enough datasets to do paired bootstrapping (van den Noortgate and Onghena, 2005).

In this paper we will assume that the Wilcoxon signed rank test provides a reasonable estimate of the significance of an observed difference in performance means across datasets, or of the significance of observed error reductions, but note that this still depends on the assumption that datasets are sampled i.i.d. at random. More importantly, a non-parametric test across data sets does not provide an actual estimate of the effect size. Estimating effect size is important, e.g. when there is a trade-off between performance gains and computational efficiency.

In evaluations across datasets in NLP we typically use the macro-average as an estimate of effect size, but in other fields such as psychology or medicine it is more common to use a weighted mean obtained using what is known as the **fixed effects model** or the **random effects model** for meta-analysis.

The experiments reported on in this paper focus on estimating error reduction and show that meta-analysis is generally superior to macro- and micro-average in terms of predicting future error reductions. Parametric meta-analysis, however, over-parameterizes the distribution of error reductions, leading to some instability. While meta-analysis is generally superior to macro-average, it is sometimes off by a large margin. We therefore introduce a new parametric meta-analysis that seems better suited to predicting error reductions. In our experiments test set sizes are balanced, so micro-averages will be near-identical to macro-averages.

2 Meta-analysis

Meta-analysis is the statistical analysis of the effect sizes of several studies and is very popular in fields such as psychology or medicine. Meta-analysis has not been applied very often to NLP. In NLP most people work on applying *new* methods to *old* datasets, and meta-analysis is designed to analyze series of studies applying *old* methods to *new* datasets, e.g. running the same experiments on

new subjects. However, meta-analysis *is* applicable to experiments with multiple datasets.

In psychology or medicine you often see studies running similar experiments on different samples with very different results. Meta-analysis stems from the observation that if we want to estimate an effect from a large set of studies, the average effect across all the studies will put too much weight on results obtained on small datasets in which you typically see more variance. The most popular approaches to meta-analysis are the fixed effects and the random effects model. The fixed effects model is applicable when you assume a true effect size (estimated by the individual studies). If you cannot make that assumption because the studies may differ in various aspects, leading the within-study estimates to be estimates of slightly different effect sizes, you need to use the random effects model. Both approaches to meta-analysis are parametric and rely on the effect sizes to be normally distributed.

2.1 Fixed effects model

In the fixed effects model we weight the effect sizes T_1, \dots, T_M – or error reductions, in our case – by the inverse of the variance v_i in the study, i.e. $w_i = \frac{1}{v_i}$. The combined effect size \hat{T} is then:

$$\hat{T} = \frac{\sum_{i=1}^M w_i T_i}{\sum_{i=1}^M w_i}$$

The variance of the combined effect is now:

$$v = \frac{1}{\sum_{i=1}^M w_i}$$

and the 95% confidence interval is then $\hat{T} \pm 1.96\sqrt{v}$.

2.2 Random effects model

In the random effects model we replace the variance v_i with the variance plus between-studies variance τ^2 :

$$\tau^2 = \frac{\sum_{i=1}^k w_i T_i^2 - \frac{(\sum_{i=1}^k w_i T_i)^2}{\sum_{i=1}^k w_i} - df}{\sum_{i=1}^k w_i - \frac{\sum_{i=1}^k w_i^2}{\sum_{i=1}^k w_i}} \quad (1)$$

with $df = N - 1$, except all negative values are replaced by 0.

Figure 2: Using macro-average and meta-analysis to predict error reductions on document classification datasets based on k observations. The scores are averages across 20 experiments. The p -values were computed using Wilcoxon signed rank tests.

The random effects model is obviously more conservative in its confidence intervals, and often we will not be able to obtain significance across datasets using a random effects model. If, for example, we apply a fixed effects model to test whether Bernoulli naive Bayes (NB) fairs better than a perceptron (P) model on 25 randomly extracted cross-domain document classification problem instances from the 20 Newsgroups dataset (see Sect. 4), the 95% confidence interval is [3.9%, 5.2%]. The weighted mean is 4.6% (macro-average 3.9%). Using a random effects model on the same 25 datasets, the 95% confidence interval becomes [-6.5%, 6.6%]. The weighted mean estimate is also slightly different from that of a fixed effects model. The first question we ask is which of these models provides the best estimate of effect size as observed on future datasets?

2.3 The error reductions distribution

Both the fixed effects and the random effects model assume that effect sizes are normally distributed. We

can apply Darling-Anderson tests to test whether error reductions in 20 Newsgroups are in fact normally distributed. Even a small sample of ten 20 Newsgroups datasets provides enough evidence to reject the hypothesis that error reductions (of NB over P) are normally distributed. The Darling-Anderson tests consistently tell us that the chance that our sample distributions of error reductions are normally distributed is below 1%. The over-paramaterization means that the estimates we get are unstable. While both models are superior to macro-average estimates, they may provide 'far-off' estimates.

Using Darling-Anderson tests we could also reject the hypothesis that error reductions were logically distributed, but we did not find evidence for rejecting the hypothesis that error reductions are Gumbel-distributed.¹ Gumbel distributions are used to model error distributions in the latent variable formulation of multinomial logit regression. A parametric meta-analysis model based on the assumption that error reductions are Gumbel distributed is an interesting alternative to non-parametric meta-analysis (Hedges and Olkin, 1984; van den Noortgate and Onghena, 2005), since there seems to be little consensus in the literature about the best way to approach non-parametric meta-analysis.

Gumbel distributions take the following form:

$$\frac{1}{\beta} e^{z - e^{-z}}$$

where $z = \frac{x-\alpha}{\beta}$ with α the location, and β the scale. We fit a Gumbel distribution to our weighted error reductions ($w_i T_i$) and compute the combined

¹Abidin et al. (2012) has shown that Darling-Anderson is superior to other goodness-of-fit tests for Gumbel distributions.

effect

$$\hat{T} = \frac{\alpha + 0.57721\beta}{\frac{1}{M} \sum_{i \geq 1}^M w_i}$$

where 0.57721 is the Euler-Mascheroni constant, and the variance of the combined effect $v = \frac{\pi^2}{6}\beta^2$.

3 Experiments in document classification and dependency parsing

Our first experiment makes use of the 20 Newsgroups document classification dataset.² The topics in 20 Newsgroups are hierarchically structured, which enables us to extract a large set of binary classification problems with considerable bias between source and target data (Chen et al., 2009; Sun et al., 2011). See the hierarchy in Figure 1. We extract 20 high-level binary classification problems by considering all pairs of top-level categories, e.g. COMPUTERS-RECREATIVE (comp-rec). For each of these 20 problems, we have different possible datasets, e.g. IBM-BASEBALL, MAC-MOTORCYCLES, etc. A *problem instance* takes training and test data from two *different* datasets belong to the same high-level problem. For example a problem instance could be learning to distinguish articles about Macintosh and motorcycles MAC-MOTORCYCLES (evaluated on the 20 Newsgroups test section) using labeled data from IBM-BASEBALL (the training section). In total we have 288 available problem instances in the 20 Newsgroups dataset.

In our first experiment we are interested in predicting the error reductions of a naive Bayes learner

over a perceptron model. We use publicly available implementations with default parameters.³ In each experiment we randomly select k datasets and estimate the true effect size using macro-average, a fixed effects model, a random effects model, and a corrected random effects model. In order to estimate the within-study variance we take 50 paired bootstrap samples of the system outputs. We evaluate our estimates against the observed average effect across 5 new randomly extracted datasets. For each k we repeat the experiment 20 times and report average error. We vary k to see how many observations are needed for our estimates to be reliable.

The results are presented in Figure 2. We note that meta-analysis provides much better estimates than macro-averages across the board. Our parametric meta-analysis based on the assumption that error reductions are Gumbel distributed performs best with more observations.

Our second experiment repeats the same procedure using available data from cross-lingual dependency parsing. We use the submitted results by participants in the CoNLL-X shared task (Buchholz and Marsi, 2006) and try to predict the error reduction of one system over another given k many observations. Given that we only have 12 submissions per system we use $k \in \{5, 7, 9\}$ randomly extracted datasets for observations and test on another five randomly extracted datasets. While results (Figure 3) are only statistically significant with $k = 7$, we see that meta-analysis estimates effect size across data sets better than macro-average in all cases.

4 Conclusions

We have argued that evaluation across datasets is important for developing robust NLP tools, and that meta-analysis can provide better estimates of effect size across datasets than macro-average. We also noted that parametric meta-analysis over-parameterizes error reduction distributions and suggested a new parametric method for estimating effect size across datasets.

Abstract

We present a systematic study of the effect of crowdsourced translations on Machine Translation performance. We compare Machine Translation systems trained on the same data but with translations obtained using Amazon’s Mechanical Turk vs. professional translations, and show that the same performance is obtained from Mechanical Turk translations at 1/5th the cost. We also show that adding a Mechanical Turk reference translation of the development set improves parameter tuning and output evaluation.

1 Introduction

Online crowdsourcing services have been shown to be a cheap and effective data annotation resource for various Natural Language Processing (NLP) tasks (Callison-Burch and Dredze, 2010; Zaidan and Callison-Burch, 2011a; Zaidan and Callison-Burch, 2011b). The resulting quality of annotations is high enough to be used for training statistical NLP models, with a saving in cost and time of up to an order of magnitude. Statistical Machine Translation (SMT) is one of the NLP tasks that can benefit from crowdsourced annotations. With appropriate quality control mechanisms, reference translations collected by crowdsourcing have been successfully used for training and evaluating SMT systems (Zbib et al., 2012; Zaidan and Callison-Burch, 2011b).

In this work, we used Amazon’s Mechanical Turk (MTurk) to obtain alternative reference translations of four Arabic-English parallel corpora previously released by the Linguistic Data Consortium (LDC)

for the DARPA BOLT program. This data, totaling over 500K Arabic tokens, was originally collected from web discussion forums and translated professionally to English. We used alternative MTurk translations of the same data to train and evaluate MT systems; and conducted the first systematic study that quantifies the effect of the reference translation process on MT output. We found that:

- Mechanical Turk can be used to translate enough data for training an MT system at 1/10th the price of professional translation, and at a much faster rate.
- Training MT systems on MTurk reference translations gives the same performance as training with professional translations at 20% of the cost.
- A second translation of the development set obtained via MTurk improves parameter tuning and output evaluation.

2 Previous Work

There have been several publications on crowdsourcing data annotation for NLP. Callison-Burch and Dredze (2010) give an overview of the NAACL-2010 Workshop on using Mechanical Turk for data annotation. They describe tasks for which MTurk can be used, and summarize a set of best practices. They also include references to the workshop contributions.

Zaidan and Callison-Burch (2011a) created a monolingual Arabic data set rich in dialectal content from user commentaries on newspaper websites. They hired native Arabic speakers on MTurk

to identify the dialect level and used the collected labels to train automatic dialect identification systems. They did not translate the collected data, however. Zaidan and Callison-Burch (2011b) obtained multiple translations of the NIST 2009 Urdu-English evaluation set using MTurk. They trained a statistical model on a set of features to select among the multiple translations. They showed that the MTurk translations selected by their model approached the range of quality of professional translations, and that the selected MTurk translations can be used reliably to score the outputs of different MT systems submitted to the NIST evaluation. Unlike our work, they did not investigate the use of crowdsourced translations for training or parameter tuning. Zbib et al. (2012) trained a Dialectal Arabic to English MT system using Mechanical Turk translations. But the data they translated on MTurk does not have professional translations to conduct the systematic comparison we do in this paper.

It is well known that scoring MT output against multiple references improves MT scores such as BLEU significantly, since it increases the chance of matching *n*-grams between the MT output and the references. Tuning system parameter with multiple references also improves machine translation for the same reason Madnani et al. (2007) and Madnani et al. (2008) showed that tuning on additional references obtained by automatic paraphrasing helps when only few tuning references are available.

3 Data Translation

The data we used are Arabic-English parallel corpora released by the LDC for the DARPA BOLT Phase 1 program¹. The data was collected from Egyptian online discussion forums, and consists of separate discussion threads, each composed of an initial user posting and multiple reply postings. The data tends to be bimodal: the first posting in the thread is often formal and expressed in Modern Standard Arabic, while the subsequent threads use a less formal style, and contain colloquial Egyptian dialect. The data was manually segmented into sentence units, and translated professionally.

We used non-professional translators hired on MTurk to get second translations. We used several

measures to control the quality of translations and detect cheaters. Those include the rendering of Arabic sentences as images, comparing the output to Google Translate and Bing Translator, and other automatic checks. The quality of individual worker’s translations was quantified by asking a native Arabic speaker judge to score a sample of the Turker’s translations. The translation task unit (aka Human Intelligence Task or HIT) consisted of a sequence of contiguous sentences from a discussion thread amounting to between 40 and 60 words. The instructions were simply to translate the Arabic source fully and accurately, and to take surrounding sentence segments into account to help resolve ambiguities. The HIT rewards were set to 2.5¢ per word.

At the end of the effort, we had 26 different workers translate 567K Arabic tokens in 4 weeks. The resulting translations were less fluent than their professional counterparts, and 10% shorter on average. The following section presents results of MT experiments using the MTurk translations.

4 MT Experiments

The MT system used is based on a string-to-dependency-tree hierarchical model of Shen et al. (2008). Sentence alignment was done using GIZA++ (Och and Ney, 2003). Decoder features include translation probabilities, smoothed lexical probabilities, and a dependency tree language model. Additionally, we used 50,000 sparse, binary-valued source and target features based on Chiang et al. (2009). The English language model was trained on 7 billion words from the LDC Gigaword corpus and from a web crawl. We used expected BLEU maximization (Devlin, 2009) to tune feature weights.

We defined a tuning set (3581 segments, 43.3K tokens) and a test set (4166 segments, 47.7K tokens) using LDC2012E30, the corpus designated as a development set by the LDC, augmented with around 50K Words held out from LDC2012E15 and LDC2012E19, to make a development set large enough to tune the large number of feature weights². The remaining data was used for training. We defined three nested training sets containing 100K, 200K and 400K Arabic tokens respectively, with

¹Corpora: LDC2012E15, LDC2012E19, LDC2012E55

Table 1: Comparison of the effect of web forum training data when using professional and MTurk reference translations. All results use professional references for the tuning and test sets.

two versions of each set: one with the professional reference translations for the target, and the other with the same source data, but the MTurk translations. We defined two versions of the test and tuning sets similarly. We report translation results in terms of lower-case BLEU scores (Papineni et al., 2002).

4.1 Training Data References

We first study the effect of training data references, varying the amount of training data and type of translations, while using the same professional translation references for tuning and scoring. The first set of baseline experiments were trained on web forum data only, using professional translations. The first line of Table 1 shows that doubling of the training data adds 2.5 then 2.3 BLEU points. We repeated the experiments, but with MTurk training references, and saw that the scores are lower by 1.3-2.5 BLEU points, depending on the size of training data, and that the gain obtained from doubling the training data decreases to 2.0 and 1.6 BLEU points.

The lower MT scores and slower learning curve of the MTurk systems are both due to the lower quality of the translations, and to the mismatch with the professional development set translations (we discuss this issue further in §4.3). However, by interpolation of the MT scores, we find that the same MT performance can be obtained by using twice the amount of MTurk translated data as professional data. Considering that the MTurk translations is 10 times cheaper than professional translations (2.5¢ versus 25-30¢), this constitutes a cost ratio of 5x.

We repeated the above experiments, but this time added 10 million words of parallel data from the NIST MT 2012 corpora (mostly news) for training. We weighted the web forum part of the training data by a factor of 5. Note from the results in the right half of Table 1 that the newswire data improves the

BLEU score by 2.5 to 6.3 BLEU points, depending on the size of the web forum data. This significant improvement is because some of the web forum user postings are formal and written in MSA (§3). More relevant to our aims is the comparison when we vary the web forum training references in the presence of the newswire training. The difference between the MTurk translation systems and the professional translation drops to 0.26-0.68 points. We conclude that in a domain adaptation scenario, where out-of-domain training data (i.e. newswire) already exists, crowdsourced translations for the in-domain (i.e. web forum) training data can be used with little to no loss in MT performance.

4.2 More Data vs. Multiple Translations

To our knowledge no previous work has compared using multiple reference translations for training data versus using additional training data of the same size. We studied this question by using both translations on the target side of the training data. Using the MTurk translations in addition to the professional translations in training gave a gain of 0.4 to 1.3 BLEU points (bottom half of Table 1). The gain was smaller in the presence of the GALE newswire data. When we compared with using the same amount of different training data instead of multiple references, we saw that training on new data with crowdsourced translations is better: training on two translations of 100KW gives 19.03, compared to 19.80 when training on a single translation of 200KW. The advantage of different-source data drops to 0.34 points when we start with 200KW. With a larger initial corpus, the additional source coverage of new data is not as critical, and the advantage of more variety on the target-side of the extracted translation rules becomes more competitive. This coverage is even less critical in the presence of the news data, where the ad-

Table 2: Effect of Tuning and Scoring References on MT.

vantage of new web forum source data disappears (lower-right quadrant of Table 1).

4.3 Development Data References

So far, we have focused on varying training data conditions, and kept the tuning and evaluation conditions fixed. But since we have re-translated the tuning and test sets on MTurk as well, we can study the effect of their reference translations on MT. As Table 2 shows, scoring the MT output using both reference translations, the BLEU scores increase by over 5 points (and more for the MTurk-trained system). This increase by itself is not remarkable. What is important to note is that the gain obtained by doubling the amount of training data is larger when measured using the multiple reference test set. We also ran experiments with 400KW training data, but with the lexical smoothing features (Koehn et al., 2003; Devlin, 2009) turned off. The bigger gains show that improvements in the MT output (from additional training or new features) can be better measured using a second MTurk reference of the test set.

Finally, we study the effect of tuning the system parameters using both translation references. Looking at the system trained on the professional translations, we see a gain of 2.5 to 2.7 BLEU points from adding the MTurk references to the tuning set. But as we mentioned earlier, the MTurk translations are shorter than the professional translations by around 10% on average. Tuning on both references, therefore, shortens the system output by around 5%. To neutralize the effect of length mismatch, we compared to a fairer baseline tuned on the professional references only, but we tuned the output-to-reference length ratio to be 0.95 (thus pro-

ducing a shorter output). In this case, we see a gain of 1.4 points from adding the MTurk references to the tuning set.

We also used the multiple-reference tuning set to retune the systems trained on MTurk translations. Comparing that to a baseline that is tuned and scored using MTurk references only, we see a gain of around 1%. Note, however, that in this case the length mismatch is reversed, and the output of the multiple-reference system is around 5% longer than that of the baseline. If we compare with a baseline that is tuned with a length ratio of 1.05 (to produce a longer output), we see the gain shrink only slightly.

To sum up this section, a second set of reference translations obtained via MTurk makes measurements of improvement on the test set more reliable. Also, a second set of references for tuning improves the output of the MT systems trained on either professional or MTurk references.

5 Conclusion

We compared professional and crowdsourced translations of the same data for training, tuning and scoring Arabic-English SMT systems. We showed that the crowdsourced translations yield the same MT performance as professional translations for as little as 20% of the cost. We also showed that a second crowdsourced reference translation of the development set allows for a more accurate evaluation of MT output.

Down-stream effects of tree-to-dependency conversions

Abstract

Dependency analysis relies on morphosyntactic evidence, as well as semantic evidence. In some cases, however, morphosyntactic evidence seems to be in conflict with semantic evidence. For this reason dependency grammar theories, annotation guidelines and tree-to-dependency conversion schemes often differ in how they analyze various syntactic constructions. Most experiments for which constituent-based treebanks such as the Penn Treebank are converted into dependency treebanks rely blindly on one of four-five widely used tree-to-dependency conversion schemes. This paper evaluates the down-stream effect of choice of conversion scheme, showing that it has dramatic impact on end results.

1 Introduction

Annotation guidelines used in modern dependency treebanks and tree-to-dependency conversion schemes for converting constituent-based treebanks into dependency treebanks are typically based on a specific dependency grammar theory, such as the Prague School’s Functional Generative Description, Meaning-Text Theory, or Hudson’s Word Grammar. In practice most parsers constrain dependency structures to be tree-like structures such that each word has a single syntactic head, limiting diversity between annotation a bit; but while many dependency treebanks taking this format agree on how to analyze many syntactic constructions, there are still many constructions these treebanks analyze differently. See Figure 1 for a standard overview of clear and more difficult cases.

The difficult cases in Figure 1 are difficult for the following reason. In the easy cases morphosyntactic and semantic evidence cohere. Verbs govern subjects morpho-syntactically and seem semantically more important. In the difficult cases, however, morpho-syntactic evidence is *in conflict* with the semantic evidence. While auxiliary verbs have the same distribution as finite verbs in head position and share morpho-syntactic properties with them, and govern the infinite main verbs, main verbs seem semantically superior, expressing the main predicate. There may be distributional evidence that complementizers head verbs syntactically, but the verbs seem more important from a semantic point of view.

Tree-to-dependency conversion schemes used to convert constituent-based treebanks into dependency-based ones also take different stands on the difficult cases. In this paper we consider four different conversion schemes: the Yamada-Matsumoto conversion scheme **yamada**,¹ the CoNLL 2007 format **conll07**,² the conversion scheme **ewt** used in the English Web Treebank (Petrov and McDonald, 2012),³ and the **lth** conversion scheme (Johansson

¹The Yamada-Matsumoto scheme can be replicated by running `penn2malt.jar` available at <http://w3.msi.vxu.se/~nivre/research/Penn2Malt.html>. We used Malt dependency labels (see website). The Yamada-Matsumoto scheme is an elaboration of the Collins scheme (Collins, 1999), which is not included in our experiments.

²The CoNLL 2007 conversion scheme can be obtained by running `pennconverter.jar` available at http://nlp.cs.lth.se/software/treebank_converter/ with the ‘`conll07`’ flag set.

³The EWT conversion scheme can be replicated using the Stanford converter available at <http://nlp.stanford.edu/software/stanford-dependencies.shtml>

Figure 1: Clear and difficult cases in dependency annotation.

and Nugues, 2007).⁴ We list the differences in Figure 2. An example of differences in analysis is presented in Figure 3.

In order to access the impact of these conversion schemes on down-stream performance, we need extrinsic rather than intrinsic evaluation. In general it is important to remember that while researchers developing learning algorithms for part-of-speech (POS) tagging and dependency parsing seem obsessed with accuracies, POS sequences or dependency structures have no interest on their own. The accuracies reported in the literature are only interesting insofar they correlate with the usefulness of the structures predicted by our systems. Fortunately, POS sequences and dependency structures *are* useful in many applications. When we consider tree-to-dependency conversion schemes, down-stream evaluation becomes particularly important since some schemes are more fine-grained than others, leading to lower performance as measured by intrinsic evaluation metrics.

Approach in this work

In our experiments below we apply a state-of-the-art parser to five different natural language processing (NLP) tasks where syntactic features are known to be effective: negation resolution, semantic role labeling (SRL), statistical machine translation (SMT), sentence compression and perspective classification. In all five tasks we use the four tree-to-dependency conversion schemes mentioned above and evaluate them in terms of down-stream performance. We also compare our systems to baseline systems not relying

⁴The LTH conversion scheme can be obtained by running pennconverter.jar available at http://nlp.cs.lth.se/software/treebank_converter/ with the 'oldLTH' flag set.

on syntactic features, when possible, and to results in the literature, when comparable results exist. Note that negation resolution and SRL are not end applications. It is not easy to generalize across five very different tasks, but the tasks will serve to show that the choice of conversion scheme has significant impact on down-stream performance.

We used the most recent release of the Mate parser first described in Bohnet (2010),⁵ trained on Sections 2–21 of the Wall Street Journal section of the English Treebank (Marcus et al., 1993). The graph-based parser is similar to, except much faster, and performs slightly better than the MSTParser (McDonald et al., 2005), which is known to perform well on long-distance dependencies often important for down-stream applications (McDonald and Nivre, 2007; Galley and Manning, 2009; Bender et al., 2011). This choice may of course have an effect on what conversion schemes seem superior (Johansson and Nugues, 2007). Sentence splitting was done using splitta,⁶, and the sentences were then tokenized using PTB-style tokenization⁷ and tagged using the in-built Mate POS tagger.

Previous work

There has been considerable work on down-stream evaluation of syntactic parsers in the literature, but most previous work has focused on evaluating parsing models rather than linguistic theories. No one has, to the best of our knowledge, compared the impact of choice of tree-to-dependency conversion scheme across several NLP tasks.

Johansson and Nugues (2007) compare the impact of **yamada** and **Ith** on semantic role labeling

performance, showing that **Ith** leads to superior performance.

Miyao et al. (2008) measure the impact of syntactic parsers in an information extraction system identifying protein-protein interactions in biomedical research articles. They evaluate dependency parsers, constituent-based parsers and deep parsers.

Miwa et al. (2010) evaluate down-stream performance of linguistic representations and parsing models in biomedical event extraction, but do not evaluate linguistic representations directly, evaluating representations and models jointly.

Bender et al. (2011) compare several parsers across linguistic representations on a carefully designed evaluation set of hard, but relatively frequent syntactic constructions. They compare dependency parsers, constituent-based parsers and deep parsers. The authors argue in favor of evaluating parsers on diverse and richly annotated data. Others have discussed various ways of evaluating across annotation guidelines or translating structures to a common format (Schwartz et al., 2011; Tsarfaty et al., 2012).

Hall et al. (2011) discuss optimizing parsers for specific down-stream applications, but consider only a single annotation scheme.

Yuret et al. (2012) present an overview of the SemEval-2010 Evaluation Exercises on Semantic

Evaluation track on recognition textual entailment using dependency parsing. They also compare several parsers using the heuristics of the winning system for inference. While the shared task is an example of down-stream evaluation of dependency parsers, the evaluation examples only cover a subset of the textual entailments relevant for practical applications, and the heuristics used in the experiments assume a fixed set of dependency labels (**ewt** labels).

Finally, Schwartz et al. (2012) compare the above conversion schemes and several combinations thereof in terms of learnability. This is very different from what is done here. While learnability may be a theoretically motivated parameter, our results indicate that learnability and downstream performance do not correlate well.

2 Applications

Dependency parsing has proven useful for a wide range of NLP applications, including statistical machine translation (Galley and Manning, 2009; Xu et al., 2009; Elming and Haulrich, 2011) and sentiment analysis (Joshi and Penstein-Rose, 2009; Johansson and Moschitti, 2010). This section describes the applications and experimental set-ups included in this study.

In the five applications considered below we

use syntactic features in slightly different ways. While our statistical machine translation and sentence compression systems use dependency relations as additional information about words and *on a par* with POS, our negation resolution system uses dependency paths, conditioning decisions on both dependency arcs and labels. In perspective classification, we use dependency triples (e.g. SUBJ(John, snore)) as features, while the semantic role labeling system conditions on a lot of information, including the word form of the head, the dependent and the argument candidates, the concatenation of the dependency labels of the predicate, and the labeled dependency relations between predicate and its head, its arguments, dependents or siblings.

2.1 Negation resolution

Negation resolution (NR) is the task of finding negation cues, e.g. the word *not*, and determining their *scope*, i.e. the tokens they affect. NR has recently seen considerable interest in the NLP community (Morante and Sporleder, 2012; Velldal et al., 2012) and was the topic of the 2012 *SEM shared task (Morante and Blanco, 2012).

The data set used in this work, the Conan Doyle corpus (CD),⁸ was released in conjunction with the *SEM shared task. The annotations in CD extend on cues and scopes by introducing annotations for in-scope events that are negated in factual contexts. The following is an example from the corpus showing the annotations for cues (bold), scopes (underlined) and negated events (italicized):

- (1) Since we have been so
unfortunate as to miss him [...]

CD-style scopes can be discontinuous and overlapping. Events are a portion of the scope that is semantically negated, with its truth value reversed by the negation cue.

The NR system used in this work (Lapponi et al., 2012), one of the best performing systems in the *SEM shared task, is a CRF model for scope resolution that relies heavily on features extracted from dependency graphs. The feature model contains token distance, direction, *n*-grams of word forms, lemmas, POS and combinations thereof, as well as the syntactic features presented in Figure 4. The results in our

Figure 4: Features used to train the conditional random field models

experiments are obtained from configurations that differ only in terms of tree-to-dependency conversions, and are trained on the training set and tested on the development set of CD. Since the negation cue classification component of the system does not rely on dependency features at all, the models are tested using gold cues.

Table 1 shows F₁ scores for scopes, events and full negations, where a true positive correctly assigns both scope tokens and events to the rightful cue. The scores are produced using the evaluation script provided by the *SEM organizers.

2.2 Semantic role labeling

Semantic role labeling (SRL) is the attempt to determine semantic predicates in running text and label their arguments with semantic roles. In our experiments we have reproduced the second best-performing system in the CoNLL 2008 shared task in syntactic and semantic parsing (Johansson and Nugues, 2008).⁹

The English training data for the CoNLL 2008 shared task were obtained from PropBank and NomBank. For licensing reasons, we used OntoNotes 4.0, which includes PropBank, but not NomBank. This means that our system is only trained to classify verbal predicates. We used the Clearparser conversion tool¹⁰ to convert the OntoNotes 4.0 and subsequently supplied syntactic dependency trees using our different conversion schemes. We rely on gold standard argument identification and focus solely on the performance metric semantic labeled F1.

⁹http://nlp.cs.lth.se/software/semantic_parsing:_propbank_nombank_frames

¹⁰<http://code.google.com/p/clearparser/>

2.3 Statistical machine translation

The effect of the different conversion schemes was also evaluated on SMT. We used the *reordering by parsing* framework described by Elming and Haulrich (2011). This approach integrates a syntactically informed reordering model into a phrase-based SMT system. The model learns to predict the word order of the translation based on source sentence information such as syntactic dependency relations. Syntax-informed SMT is known to be useful for translating between languages with different word orders (Galley and Manning, 2009; Xu et al., 2009), e.g. English and German.

The baseline SMT system is created as described in the guidelines from the original shared task.¹¹ Only modifications are that we use truecasing instead of lowercasing and recasing, and allow training sentences of up to 80 words. We used data from the English-German restricted task: ~3M parallel words of news, ~46M parallel words of Europarl, and ~309M words of monolingual Europarl and news. We use newstest2008 for tuning, newstest2009 for development, and newstest2010 for testing. Distortion limit was set to 10, which is also where the baseline system performed best. The phrase table and the lexical reordering model is trained on the union of all parallel data with a max phrase length of 7, and the 5-gram language model is trained on the entire monolingual data set.

We test four different experimental systems that only differ with the baseline in the addition of a syntactically informed reordering model. The baseline system was one of the tied best performing system in the WMT 2011 shared task on this dataset. The four experimental systems have reordering models that are trained on the first 25,000 sentences of the parallel news data that have been parsed with each of the tree-to-dependency conversion schemes. The reordering models condition reordering on the word forms, POS, and syntactic dependency relations of the words to be reordered, as described in Elming and Haulrich (2011). The paper shows that while reordering by parsing leads to significant improvements in standard metrics such as BLEU (Papineni et al., 2002) and METEOR (Lavie and Agarwal, 2007), improvements are more spelled out with hu-

man judgements. All SMT results reported below are averages based on 5 MERT runs following Clark et al. (2011).

2.4 Sentence compression

Sentence compression is a restricted form of sentence simplification with numerous usages, including text simplification, summarization and recognizing textual entailment. The most commonly used dataset in the literature is the Ziff-Davis corpus.¹² A widely used baseline for sentence compression experiments is Knight and Marcu (2002), who introduce two models: the noisy-channel model and a decision tree-based model. Both are tree-based methods that find the most likely compressed syntactic tree and outputs the yield of this tree. McDonald et al. (2006) instead use syntactic features to directly find the most likely compressed sentence.

Here we learn a discriminative HMM model (Collins, 2002) of sentence compression using MIRA (Crammer and Singer, 2003), comparable to previously explored models of noun phrase chunking. Our model is thus neither tree-based nor sentence-based. Instead we think of sentence compression as a sequence labeling problem. We compare a model informed by word forms and predicted POS with models also informed by predicted dependency labels. The baseline feature model conditions emission probabilities on word forms and POS using a ±2 window and combinations thereof. The augmented syntactic feature model simply adds dependency labels within the same window.

2.5 Perspective classification

Finally, we include a document classification dataset from Lin and Hauptmann (2006).¹³ The dataset consists of blog posts posted at bitterlemons.org by Israelis and Palestinians. The bitterlemons.org website is set up to "contribute to mutual understanding through the open exchange of ideas." In the dataset, each blog post is labeled as either Israeli or Palestinian. Our baseline model is just a standard bag-of-words model, and the system adds dependency triplets to the bag-of-words model in a way similar to Joshi and Penstein-Rose (2009). We do not remove stop words, since perspective classification is

similar to authorship attribution, where stop words are known to be informative. We evaluate performance doing cross-validation over the official training data, setting the parameters of our learning algorithm for each fold doing cross-validation over the actual training data. We used soft-margin support vector machine learning (Cortes and Vapnik, 1995), tuning the kernel (linear or polynomial with degree 3) and $C = \{0.1, 1, 5, 10\}$.

3 Results and discussion

Our results are presented in Table 1. The parsing results are obtained relying on predicted POS rather than, as often done in the dependency parsing literature, relying on gold-standard POS. Note that they comply with the result in Schwartz et al. (2012) that Yamada-Matsumoto-style annotation is more easily learnable.

The **negation resolution** results are significantly better using syntactic features in **yamada** annotation. It is not surprising that a syntactically oriented conversion scheme performs well in this task. Since Lapponi et al. (2012) used Maltparser (Nivre et al., 2007) with the freely available pre-trained parsing model for English,¹⁴ we decided to also run that parser with the gold-standard cues, in ad-

dition to Mate. The pre-trained model was trained on Sections 2–21 of the Wall Street Journal section of the English Treebank (Marcus et al., 1993), augmented with 4000 sentences from the QuestionBank,¹⁵ which was converted using the Stanford converter and thus similar to the **ewt** annotations used here. The results were better than using **ewt** with Mate trained on Sections 2–21 alone, but worse than the results obtained here with **yamada** conversion scheme. F_1 score on full negation was 66.92%.

The case-sensitive BLEU evaluation of the **SMT** systems indicates that choice of conversion scheme has no significant impact on overall performance. The difference to the baseline system is significant ($p < 0.01$), showing that the reordering model leads to improvement using any of the schemes. However, the conversion schemes lead to very different translations. This can be seen, for example, by the fact that the relative tree edit distance between translations of different syntactically informed SMT systems is 12% higher than within each system (across different MERT optimizations).

The reordering approach puts a lot of weight on the syntactic dependency relations. As a consequence, the number of relation types used in the conversion schemes proves important. Consider the

Figure 6: Examples of sentence compression output.

example in Figure 5. German requires the verb in second position, which is obeyed in the much better translations produced by the **ewt** and **lth** systems. Interestingly, the four schemes produce virtually identical structures for the source sentence, but they differ in their labeling. Where **conll07** and **yamada** use the same relation for the first two constituents (ADV and vMOD, respectively), **ewt** and **lth** distinguish between them (ADVMOD/PREP and ADV/LOC). This distinction may be what enables the better translation, since the model may learn to move the verb after the sentence adverbial. In the other schemes, sentence adverbials are not distinguished from locational adverbials. Generally, **ewt** and **lth** have more than twice as many relation types as the other schemes.

The schemes **ewt** and **lth** lead to better **SRL** performance than **conll07** and **yamada** when relying on gold-standard syntactic dependency trees. This supports the claims put forward in Johansson and Nugues (2007). These annotations also happen to use a larger set of dependency labels, however, and syntactic structures may be harder to reconstruct, as reflected by labeled attachment scores

(LAS) in syntactic parsing. The biggest drop in **SRL** performance going from gold-standard to predicted syntactic trees is clearly for the **lth** scheme, at an average 17.8% absolute loss (**yamada** 5.8%; **conll07** 6.8%; **ewt** 5.5%; **lth** 17.8%).

The **ewt** scheme resembles **lth** in most respects, but in preposition-noun dependencies it marks the preposition as the head rather than the noun. This is an important difference for **SRL**, because semantic arguments are often nouns embedded in prepositional phrases, like agents in passive constructions. It may also be that the difference in performance is simply explained by the syntactic analysis of prepositional phrases being easier to reconstruct.

The **sentence compression** results are generally much better than the models proposed in Knight and Marcu (2002). Their noisy channel model obtains an F_1 compression score of 14.58%, whereas the decision tree-based model obtains an F_1 compression score of 31.71%. While F_1 scores should be complemented by human judgements, as there are typically many good sentence compressions of any source sentence, we believe that error reductions of more than 50% indicate that the models used here

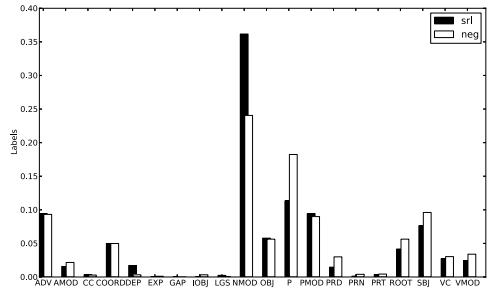

Figure 7: Distributions of dependency labels in the Yamada-Matsumoto scheme

(though previously unexplored in the literature) are fully competitive with state-of-the-art models.

We also see that the models using syntactic features perform better than our baseline model, except for the model using **conll07** dependency annotation. This may be surprising to some, since distributional information is often considered important in sentence compression (Knight and Marcu, 2002). Some output examples are presented in Figure 6. Unsurprisingly, it is seen that the baseline model produces grammatically incorrect output, and that most of our syntactic models correct the error leading to ungrammaticality. The model using **ewt** annotation is an exception. We also see that **conll07** introduces another error. We believe that this is due to the way the **conll07** tree-to-dependency conversion scheme handles coordination. While the word *Sweden* is not coordinated, it occurs in a context, surrounded by commas, that is very similar to coordinated items.

In **perspective classification** we see that syntactic features based on **yamada** and **lth** annotations lead to improvements, with **yamada** leading to slightly better results than **lth**. The fact that a syntactically oriented conversion scheme leads to the best results may reflect that perspective classification, like authorship attribution, is less about content than stylistics.

While **lth** seems to lead to the overall best results, we stress the fact that the five tasks considered here are incommensurable. What is more interesting is that, task to task, results are so different. The semantically oriented conversion schemes, **ewt** and **lth**, lead to the best results in SRL, but with a significant drop for **lth** when relying on predicted parses, while the **yamada** scheme is competitive in the other

four tasks. This may be because distributional information is more important in these tasks than in SRL.

The distribution of dependency labels seems relatively stable across applications, but differences in data may of course also affect the usefulness of different annotations. Note that **conll07** leads to very good results for negation resolution, but bad results for SRL. See Figure 7 for the distribution of labels in the **conll07** conversion scheme on the SRL and negation scope resolution data. Many differences relate to differences in sentence length. The negation resolution data is literary text with shorter sentences, which therefore uses more punctuation and has more root dependencies than newspaper articles. On the other hand we do see very few predicate dependencies in the SRL data. This may affect downstream results when classifying verbal predicates in SRL. We also note that the number of dependency labels have less impact on results in general than we would have expected. The number of dependency labels and the lack of support for some of them may explain the drop with predicted syntactic parses in our SRL results, but generally we obtain our best results with **yamada** and **lth** annotations, which have 12 and 41 dependency labels, respectively.

4 Conclusions

We evaluated four different tree-to-dependency conversion schemes, putting more or less emphasis on syntactic or semantic evidence, in five down-stream applications, including SMT and negation resolution. Our results show why it is important to be precise about exactly what tree-to-dependency conversion scheme is used. Tools like `pennconverter.jar` gives us a wide range of options when converting constituent-based treebanks, and even small differences may have significant impact on down-stream performance. The small differences are also important for more linguistic comparisons that also tend to gloss over exactly what conversion scheme is used, e.g. Ivanova et al. (2012).

The Life and Death of Discourse Entities: Identifying Singleton Mentions

Marta Recasens Linguistics Department Stanford University Stanford, CA 94305 recasens@google.com	Marie-Catherine de Marneffe Linguistics Department The Ohio State University Columbus, OH 43210 mcdm@ling.osu.edu	Christopher Potts Linguistics Department Stanford University Stanford, CA 94305 cgpotts@stanford.edu
--	---	---

Abstract

A discourse typically involves numerous entities, but few are mentioned more than once. Distinguishing discourse entities that die out after just one mention (**singletons**) from those that lead longer lives (**coreferent**) would benefit NLP applications such as coreference resolution, protagonist identification, topic modeling, and discourse coherence. We build a logistic regression model for predicting the singleton/coreferent distinction, drawing on linguistic insights about how discourse entity lifespans are affected by syntactic and semantic features. The model is effective in its own right (78% accuracy), and incorporating it into a state-of-the-art coreference resolution system yields a significant improvement.

1 Introduction

Not all discourse entities are created equal. Some lead long lives and appear in a variety of discourse contexts (**coreferent**), whereas others never escape their birthplaces, dying out after just one mention (**singletons**). The ability to make this distinction based on properties of the NPs used to identify these referents (mentions) would benefit not only coreference resolution, but also topic analysis, textual entailment, and discourse coherence.

The existing literature provides numerous generalizations relevant to answering the question of whether a given discourse entity will be singleton or coreferent. These involve the internal syntax and morphology of the target NP (Prince, 1981a; Prince, 1981b; Wang et al., 2006), the grammatical function

and discourse role of that NP (Chafe, 1976; Hobbs, 1979; Walker et al., 1997; Beaver, 2004), and the interaction of all of those features with semantic operators like negation, modals, and attitude predicates (Karttunen, 1973; Karttunen, 1976; Kamp, 1981; Heim, 1982; Heim, 1992; Roberts, 1990; Groenendijk and Stokhof, 1991; Bittner, 2001).

The first step in our analysis is to bring these insights together into a single logistic regression model — the *lifespan model* — and assess their predictive power on real data. We show that the features generally behave as the existing literature leads us to expect, and that the model itself is highly effective at predicting whether a given mention is singleton or coreferent. We then provide an initial assessment of the engineering value of making the singleton/coreferent distinction by incorporating our lifespan model into the Stanford coreference resolution system (Lee et al., 2011). This addition results in a significant improvement on the CoNLL-2012 Shared Task data, across the MUC, B³, CEAf, and CoNLL scoring algorithms.

2 Data

All the data used throughout the paper come from the CoNLL-2012 Shared Task (Pradhan et al., 2012), which included the 1.6M English words from OntoNotes v5.0 (Hovy et al., 2006) that have been annotated with different layers of annotation (coreference, parse trees, etc.). We used the training, development (dev), and test splits as defined in the shared task (Table 1). Since the OntoNotes coreference annotations do not contain singleton mentions, we automatically marked as singletons all the NPs

Dataset	Docs	Tokens	Mentions	
			Coreferent	Singletons
Training	2,802	1.3M	152,828	192,248
Dev	343	160K	18,815	24,170
Test	348	170K	19,392	24,921

Table 1: CoNLL-2012 Shared Task data statistics. We added singletons (NPs not annotated as coreferent).

not annotated as coreferent. Thus, our singletons include non-referential NPs but not verbal mentions.

3 Predicting lifespans

Our lifespan model makes a binary distinction between discourse referents that are not part of a coreference chain (singletons) and items that are part of one (coreferent). The distribution of lifespans in our data (Figure 1) suggests that this is a natural division. The propensity of singletons also highlights the relevance of detecting singletons for a coreference system. We fit a binary logistic regression model in R (R Core Team, 2012) on the training data, coding singletons as “0” and coreferent mentions as “1”. Throughout the following tables of coefficient estimates, positive values favor coreferents and negative ones favor singletons. We turn now to describing and motivating the features of this model.

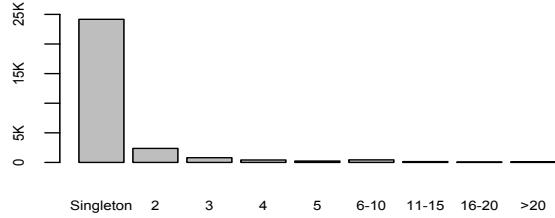

Figure 1: Distribution of lifespans in the dev set. Singletons account for 56% of the data.

Internal morphosyntax of the mention Table 2 summarizes the features from our model that concern the internal morphology and syntactic structure of the mention. Many are common in coreference systems (Recasens and Hovy, 2009), but our model highlights their influence on lifespans. The picture is expected on the taxonomy of given and new defined by Prince (1981b) and assumed throughout dynamic semantics (Kamp, 1981; Heim, 1982): pronouns depend on anaphoric connections to previous

mentions for disambiguation and thus are very likely to be coreferent. This is corroborated by the positive coefficient estimate for ‘Type = pronoun’ in Table 2. Few quantified phrases easily participate in discourse anaphora (Partee, 1987; Wang et al., 2006), accounting for the association between quantifiers and singletons (negative coefficient estimate for ‘Quantifier = quantified’ in Table 2). The one surprise is the negative coefficient for indefinites. In theories stretching back to Karttunen (1976), indefinites function primarily to establish new discourse entities, and should be able to participate in coreference chains, but here the association with such chains is negative. However, interactions explain this fact (see Table 4 and our discussion of it).

The person, number, and animacy values suggest that singular animates are excellent coreferent NPs, a previous finding of Centering Theory (Grosz et al., 1995; Walker et al., 1998) and of cross-linguistic work on obviative case-marking (Aissen, 1997).

Our model also includes named-entity features for all of the eighteen OntoNotes entity-types (omitted from Table 2 for space and clarity reasons). As a rule, they behave like ‘Type = proper noun’ in associating with coreferents. The exceptions are ORDINAL, PERCENT, and QUANTITY, which seem intuitively unlikely to participate in coreference chains.

	Estimate	P-value
Type = pronoun	1.21	< 0.001
Type = proper noun	1.88	< 0.001
Animacy = inanimate	-1.36	< 0.001
Animacy = unknown	-0.38	< 0.001
Person = 1	1.05	< 0.001
Person = 2	0.13	< 0.001
Person = 3	1.62	< 0.001
Number = singular	0.61	< 0.001
Number = unknown	0.17	< 0.001
Quantifier = indefinite	-1.49	< 0.001
Quantifier = quantified	-1.23	< 0.001
Number of modifiers	-0.39	< 0.001

Table 2: Internal morphosyntactic features.

Grammatical role of the mention Synthesizing much work in Centering Theory and information structuring, we conclude that coreferent mentions are likely to appear as core verbal arguments and will favor sentence-initial (topic-tracking) positions (Ward and Birner, 2004). The coefficient estimates

	Estimate	P-value
Sentence Position = end	-0.22	< 0.001
Sentence Position = first	0.04	0.07
Sentence Position = last	-0.31	< 0.001
Sentence Position = middle	-0.11	< 0.001
Relation = noun argument	0.56	< 0.001
Relation = other	-0.67	< 0.001
Relation = root	-0.61	< 0.001
Relation = subject	0.65	< 0.001
Relation = verb argument	0.32	< 0.001
In coordination	-0.48	< 0.001

Table 3: Grammatical role features.

in Table 3 corroborate these conclusions. To define the ‘Relation’ and ‘In coordination’ features, we used the Stanford dependencies (de Marneffe et al., 2006) on the gold constituents.

Semantic environment of the mention Table 4 highlights the complex interactions between discourse anaphora and semantic operators. These interactions have been a focus of logical semantics since Karttunen (1976), whose guiding observation is semantic: an indefinite interpreted inside the scope of a negation, modal, or attitude predicate is generally unavailable for anaphoric reference outside of the scope of that operator, as in *Kim didn’t understand [an exam question]_i. #It_i was too hard*. Of course, such discourses cohere if the indefinite is interpreted as taking wide scope (‘there is a question Kim didn’t understand’). Such readings are often disfavored, but they become more salient when modifiers like *certain* are included (Schwarzchild, 2002) or when the determiner is sensitive to the polarity or intensionality of its environment (Baker, 1970; Ladusaw, 1980; van der Wouden, 1997; Israel, 1996; Israel, 2001; Giannakidou, 1999). Subsequent research identified many other factors that further extend or restrict the anaphoric potential of an indefinite (Roberts, 1996).

We do not have direct access to semantic scope, but we expect syntactic scope to correlate strongly with semantic scope, so we used dependency representations to define features capturing syntactic scope for negation, modal auxiliaries, and a broad range of attitude predicates. These features tend to bias in favor of singletons because they so radically restrict the possibilities for intersentential anaphora.

Interacting these features with those for the internal syntax of mentions is also informative. Since proper names and pronouns are not scope-taking, they are largely unaffected by the environment features, whereas indefinites emerge as even more restricted, just as Karttunen and others would predict.

Attitude predicates seem initially anomalous, though. They share the relevant semantic properties with negation and modals, and yet they seem to facilitate coreference. Here, the findings of de Marneffe et al. (2012) seem informative. Those authors find that, in texts of the sort we are studying, attitude predicates are used predominantly to mark the source of information that is effectively asserted despite being embedded (Rooryck, 2001; Simons, 2007). That is, though *X said p* does not semantically entail *p*, it is often interpreted as a commitment to *p*, which correspondingly elevates mentions in *p* to main-clause status (Harris and Potts, 2009).

	Estimate	P-value
Presence of negation	-0.18	< 0.001
Presence of modality	-0.22	< 0.001
Under an attitude verb	0.03	0.01
AttitudeVerb * (Type = pronoun)	0.29	< 0.001
AttitudeVerb * (Type = proper noun)	0.14	< 0.001
Modal * (Type = pronoun)	0.12	0.04
Modal * (Type = proper noun)	0.35	< 0.001
Negation * (Type = pronoun)	1.07	< 0.001
Negation * (Type = proper noun)	0.30	< 0.001
Negation * (Quantifier = indefinite)	-0.37	< 0.001
Negation * (Quantifier = quantified)	-0.36	0.23
Negation * (Number of modifiers)	0.11	< 0.001

Table 4: Semantic environment features and interactions.

Results The model successfully learns to tease singletons and coreferent mentions apart. Table 5 summarizes its performance on the dev set. The STANDARD model uses 0.5 as the decision boundary, with 78% accuracy. The CONFIDENT model predicts singleton if $\text{Pr} < .2$ and coreferent if $\text{Pr} > .8$, which increases precision (P) at a cost to recall (R).

Prediction	STANDARD			CONFIDENT		
	R	P	F1	R	P	F1
Singleton	82.3	79.2	80.7	50.5	89.6	64.6
Coreferent	72.2	76.1	74.1	41.3	86.8	55.9

4 Application to coreference resolution

To assess the usefulness of the lifespan model in an NLP application, we incorporate it into the Stanford coreference resolution system (Lee et al., 2011), which we take as our baseline. This was the highest-scoring system in the CoNLL-2011 Shared Task, and was also part of the highest-scoring system in the CoNLL-2012 Shared Task (Fernandes et al., 2012). It is a rule-based system that includes a total of ten rules (or “sieves”) for entity coreference, such as exact string match and pronominal resolution. The sieves are applied from highest to lowest precision, each rule adding coreference links.

Incorporating the lifespan model The lifespan model can improve coreference resolution in two different ways: (i) mentions classified as singletons should not be considered as either antecedents or coreferent, and (ii) mentions classified as coreferent should be linked with another mention(s). By successfully predicting singletons (i), we can enhance the system’s precision; by successfully predicting coreferent mentions (ii), we can improve the system’s recall. Here we focus on (i) and use the lifespan model for detecting singletons. This decision is motivated by two factors. First, given the large number of singletons (Figure 1), we are more likely to see a gain in performance from discarding singletons. Second, the multi-sieve nature of the Stanford coreference system does not make it straightforward to decide which antecedent a mention should be linked to even if we know that it is coreferent.

We leave the incorporation of coreferent predictions for future work.

To integrate the singleton model into the Stanford coreference system, we let a sieve consider whether a pair of mentions is coreferent only if neither of the two mentions are classified as singletons by our CONFIDENT model. Experiments on the dev set showed that the model often made wrong predictions for NEs. We do not trust the model for NE mentions. Performance on coreference (on the dev set) was higher with the CONFIDENT model than with the STANDARD model.

Results and discussion To evaluate the coreference system with and without the lifespan model, we used the English dev and test sets from the CoNLL-2012 Shared Task, presented in Section 2. Although the CoNLL shared task evaluated systems on only multi-mention (i.e., non-singleton) entities, by stopping singletons from being linked to multi-mention entities, we expected the lifespan model to increase the system’s precision. Our evaluation uses five of the measures given by the CoNLL-2012 scorer: MUC (Vilain et al., 1995), B^3 (Bagga and Baldwin, 1998), CEAF- ϕ_3 and CEAF- ϕ_4 (Luo, 2005), and the CoNLL official score (Denis and Baldridge, 2009). We do not include BLANC (Recasens and Hovy, 2011) because it assumes gold mentions and so is not suited for the scenario considered in this paper, which uses automatically predicted mentions.

Table 6 summarizes the test set performance. All the scores are on automatically predicted mentions. We use gold POS, parse trees, and NEs. The base-

line is the Stanford system, and ‘w/Lifespan’ is the same system extended with our lifespan model to discard singletons, as explained above.

As expected, the lifespan model increases precision but decreases recall. Overall, however, we obtain a significant improvement of 0.5–1 points in the F1 score of MUC, CEAF- ϕ_3 , CEAF- ϕ_4 and CoNLL. The drop in B^3 traces to a bug in the CoNLL scorer’s implementation of Cai and Strube (2010)’s algorithm for aligning gold and automatically predicted mentions, which affects the computation of B^3 and CEAF- ϕ_3 .¹ Table 7 presents the results after modifying the CoNLL-2012 scorer to compute B^3 and CEAF- ϕ_3 according to Cai and Strube (2010).² We do see an improvement in the precision and F1 scores of B^3 , and the overall CoNLL score remains significant. The CEAF- ϕ_3 F1 score is no longer significant, but is still in the expected direction.

5 Conclusion

We built a model to predict the lifespan of discourse referents, teasing apart singletons from coreferent mentions. The model validates existing linguistic insights and performs well in its own right. This alone has ramifications for tracking topics, identifying protagonists, and modeling coreference and discourse coherence. We applied the lifespan model to coreference resolution, showing how to incorporate it effectively into a state-of-the-art rule-based coreference system. We expect similar improvements with machine-learning-based coreference systems, where incorporating all the power of the lifespan model would be easier.

Our lifespan model has been integrated into the latest version of the Stanford coreference resolution system.³

¹At present, if the system links two mentions that do not exist in the gold standard, the scorer adds two singletons to the gold standard. This results in a higher B^3 F1 score (when it should be lower) because recall increases instead of staying the same (precision goes up).

²In the modified scorer, twinless predicted mentions are added to the gold standard to compute precision but not to compute recall.

Automatic Generation of English Respellings

Abstract

A *respelling* is an alternative spelling of a word in the same writing system, intended to clarify pronunciation. We introduce the task of automatic generation of a respelling from the word’s phonemic representation. Our approach combines machine learning with linguistic constraints and electronic resources. We evaluate our system both intrinsically through a human judgment experiment, and extrinsically by passing its output to a letter-to-phoneme converter. The results show that the respellings generated by our system are better on average than those found on the Web, and approach the quality of respellings designed by an expert.

1 Introduction

Respellings are a widely employed method of conveying the pronunciation of English and foreign words, both in print and on the Web. For example, *Huatulco*, the name of a Mexican resort, is respelled as ‘wah-tool-koh’ in a travel guide (Noble, 2012). The advantage of using respellings lies in removing the need for a separately defined phonetic transcription system. Since they contain only the letters of the Latin alphabet, their phonetic interpretation relies exclusively on orthographic intuitions of readers. For this reason, respellings are widely used in travel phrase books, medical compendia, and drug name pronunciation guides, among others.

Despite their utility, good respellings are not easy to create. Respellings found on the Web often contain errors or ambiguities. For example, *Henoch-Schoenlein purpura*, a skin disease, is respelled both

as ‘heh-nok shoon-line purr-puh-ruh’ and ‘hen-awk sher-line purr-purr-ah’. Does ‘heh’ rhyme with *eh* [e] or with *Nineveh* [ə], or is it the same vowel as in *hen* [ɛ]? Clearly, if both respellings refer to the same pronunciation, at least one of them must be wrong. In addition, converting the pronunciation of a foreign name to English phonemes is in itself a non-trivial task.

In this paper, we focus on the task of generating respellings from the intended pronunciation given as a sequence of phonemes. We develop a stand-alone system that combines linguistic knowledge and resources with machine learning models trained on data mined from the Web and electronic dictionaries. One of our ultimate objectives is to aid writers by evaluating their respellings, improving them, or generating new candidates. Accordingly, we endeavour to maintain the generation and the evaluation stages as separate modules in our system.

The evaluation of respellings is a challenging problem. Since English spelling conventions are notoriously inconsistent, there is no algorithm for accurately predicting the pronunciation of an out-of-vocabulary word. The current state-of-the-art letter-to-phoneme (L2P) converters are typically reported with 10-30% error rates on dictionary words (Bisani and Ney, 2008). On the other hand, human readers often disagree on the details of the pronunciation implied by a respelling. In this paper, we conduct two kinds of evaluations: an automated verification with an independent L2P system, and an experiment with human participants that pass judgments on different respellings of the same word. We interpret the results as evidence that the output of our system compares favourably with typical respellings found on the Web.

2 Definitions and Conventions

Although Chomsky and Halle (1968) characterize English orthography as close to optimal, Kominek and Black (2006) estimate that it is about 3 times more complex than German, and 40 times more complex than Spanish. This is confirmed by lower accuracy of letter-to-phoneme systems on English (Bisani and Ney, 2008). A survey of English spelling (Carney, 1994) devotes 120 pages to describe phoneme-to-letter correspondences, and lists 226 letter-to-phoneme rules, almost all of which admit exceptions.

There is no consensus on how to best convey the pronunciation of an uncommon word in English. Most dictionaries employ either the International Phonetic Alphabet (IPA), or their own transcription schemes that incorporate special symbols and diacritics. Unfortunately, many readers are unfamiliar with phonetic transcription. Instead, respellings are often preferred by writers in the news and on the Web. In this section, we define the respelling task in detail.

2.1 Form of Respellings

A *respelling* is a non-standard spelling of a word, that is intended to better convey its pronunciation. We assume that the pronunciation is defined as a sequence of English phonemes, and that the respelling contains only the 26 letters of the alphabet, with optional hyphenation. Some transcription schemes combine respellings with special symbols for representing certain phonemes. For example, an otherwise purely alphabetic Wikipedia scheme employs the symbol \emptyset for the vowel *schwa*. In our opinion, such devices destroy the main advantage of respellings, which is their universality, without attaining the precision of a true phonetic transcription. In fact, Fraser (1997) identifies the *schwa* symbol as the cause of many pronunciation errors.

In our system, we consistently use hyphens to segment multi-syllable respellings. Each syllable-size segment contains the representation of exactly one vowel phoneme, so that the number of segments matches the number of syllables.¹ However, the hyphenation need not correspond exactly to the actual

¹Henceforth, we refer to “syllable-size segments” simply as “syllables”.

syllable breaks. This approach has several advantages. First, individual syllables are easier to pronounce than an entire unfamiliar word. Second, hyphens limit the context that affects the pronunciation of a given letter (e.g. *th* in *Beethoven* ‘bayt-hoe-ven’). Finally, hyphens indicate whether adjacent vowel letters, such as *oe* in ‘hoe’, represent one vowel phoneme or two.

Some respellings explicitly indicate the stressed syllable by expressing it in a different font. This is potentially helpful because unstressed vowels tend to be reduced, which changes their pronunciation. However, since the vowel reduction phenomenon is by no means universal, the readers may be unsure whether to apply it to, e.g. the final *o* in ‘KWAT-ro’. In this paper, we make no distinction between stressed and unstressed syllables; instead, we follow the principle that each syllable is to be pronounced as if it was a separate word. Nonetheless, it would be straightforward to project the stress indicators onto the appropriate syllables in the respellings generated by our system.

2.2 Quality of Respellings

There is no clear-cut distinction between good and bad respellings. The quality of a respelling is more of a subjective opinion rather than a verifiable fact. We propose to evaluate it according to the following three criteria: ambiguity, correctness, and preference.

A respelling is *ambiguous* if it is perceived as compatible with more than one pronunciation. Because most of the rules of English spelling have exceptions, it is rarely possible to demonstrate that a respelling is completely unambiguous. However, some respellings are clearly more ambiguous than others. For example, the digraph *ee* almost always represents the vowel [i], whereas the letter sequence *ough* can represent several different phonemes.² Respellings that contain highly ambiguous letter-phoneme mappings can be expected to be ambiguous themselves. Ambiguity is a property of a respelling itself, regardless of the intended pronunciation.

A respelling is *correct* if it accurately conveys the intended pronunciation to the reader. Unlike the am-

²Compare *bough*, *cough*, *dough*, *tough*, *lough*, *through*.

biguity, correctness can be verified objectively for a particular reader, by comparing the intended pronunciation with the pronunciation inferred by the reader. A respelling that is judged correct with respect to one pronunciation cannot be judged correct with respect to a different pronunciation. Nevertheless, it is entirely possible that different readers will derive different pronunciations from the same respelling.

A respelling can be classified as unambiguous and yet incorrect by a given reader, but it cannot be judged as simultaneously ambiguous and correct. Indeed, an ambiguous respelling is compatible with at least two pronunciations, only one of which can be the intended pronunciation. Therefore, for a given reader, unambiguity is a necessary but not sufficient condition for correctness.

Given two unambiguous and correct respellings, a reader may prefer one over the other, perhaps because of the ease of inferring the intended pronunciation. For example, ‘rode-ease-yew’ may be preferred to ‘roh-dee-zyoo’ because the former is entirely composed of actual English words with unique pronunciation, whereas the latter contains an unusual consonant cluster zy. Preference is also expressed implicitly if only one of the alternative respellings is judged as unambiguous (or correct),

3 Related Work

Fraser (1997) describes an experiment in which 15 human subjects were asked to pronounce uncommon words after being shown a representation of their pronunciation. The respellings designed by the author were much more effective for that purpose than either the IPA phonetic transcription or phonemic respelling (Section 4.3). However, the creation of respellings was described as labour-intensive, and at least one of them was found to be sub-optimal during the experiment.

Williams and Jones (2008) propose respellings as a way of extending pronunciation lexicons by informants who lack linguistic training. Galescu (2009) reports that the addition of respellings of medical terms from an on-line dictionary improves the accuracy of an L2P system. The author identifies an automatic pronunciation-to-respelling system as future work.

Ghoshal et al. (2009) extract a large number of respellings from the Web, and show that they can be exploited to improve the accuracy of the L2P conversion by supplementing the data in pronunciation dictionaries. Can et al. (2009) further analyze the effect of using respellings on the accuracy of spoken-term detection (STD) systems.

4 Direct Methods

In this section, we discuss three direct methods of generating respellings: manual design, dictionary lookup, and phonemic respelling.

4.1 Manual Design

Respellings found on the Web and in news articles are usually ad-hoc creations of the authors of those texts. Respellings designed by different writers for the same word are rarely identical.³ The quality of Web respellings vary.

The respellings found in specialized lexicons are more likely to be designed by experts, and are often guided by a set of respelling rules. Nevertheless, such respelling guides may also be ambiguous.⁴ Regardless of the source, since respellings are often used for names and foreign words, no lexicon can be expected to provide a complete coverage.

4.2 Dictionary Lookup

Pronunciation dictionaries can be helpful in generating respellings. Assuming that we have a method of dividing pronunciations into syllables, a complete respelling of an out-of-dictionary word can in some cases be automatically derived from the list of syllable pronunciations. For example, *hyphy* can be respelled as ‘high-fee’ by following such a procedure. If each of the syllables has a unique pronunciation, such respellings are arguably both unambiguous and correct.

Unfortunately, only a subset of potential phonemic syllables actually occur in a lexicon. Considering only the syllables of the CVC type (consonant-vowel-consonant), there are over ten thousand distinct possibilities (e.g., [bəb], [bəf], etc.), of which

³For example, the word *capoeira* is represented by 99 different respellings in the corpus of Ghoshal et al. (2009).

⁴For an example of a confusing respelling guide see <http://www.ama-assn.org/go/usan>.

fewer than three thousand can be found in the Com- bilex pronunciation dictionary (Richmond et al., 2009). While the dictionary lookup may produce attractive respellings, it is not sufficient for a stand-alone use.

4.3 Phonemic Respelling

A simple method that can produce a respelling for any word is to directly map each phoneme to a particular letter or a letter sequence that is frequently used to represent that phoneme. Phonemes such as [m], [d] and [f] are indeed closely associated with individual letters. This is not surprising since the Roman letters were originally created to represent single phonemes in Latin, and some of those phonemes also exist in English. However, many phonemes, especially vowels, have no obvious orthographic representation. One solution is to use digraphs such as *ee* and *aw*, but a number of phonemes, such as [aʊ] as in *loud*, have no mappings that work in all contexts.

The principal weakness of a phonemic respelling is its inflexibility, which often results in counter-intuitive respellings. For example, many readers are baffled by respelling such as ‘gee’ for *ghee* or ‘john’ for *Joan*. Phonemic respelling tends to fail in cases where it generates a sequence of letters that is inherently ambiguous, or which pronunciation changes because of the context. On the other hand, mappings such as *uu* for [ʊ] and *ahy* for [aɪ], which never occur in real English words, are difficult to interpret for some readers.

In this paper, we adopt a context-free phonemic respelling scheme as the baseline, with the mappings from the online dictionary *Dictionary.com*, which differs from the system used in Wikipedia only in a few details.

5 Candidate Generation

In this section, we present our syllabification approach, as well as two generation modules: a trained phoneme-to-letter (P2L) model and a rule-based re-speller.

5.1 Syllabification

Our respelling generation process is for the most part performed on the level of individual syllables.

	VOWEL	ONSET	LAX	CODA
nt	*			
ndən		*		
bæ			*	
dənm				*
bæn				

Table 1: Examples of syllables that violate phonotactic constraints.

Correct syllabification is by itself a non-trivial problem, but even if it was provided by an oracle, it might not correspond to the optimal segmentation of a respelling. For example, the word *trigonal* [trɪgənəl] is usually syllabified as *tri-go-nal*, but a better segmentation for the purposes of respelling is *trig-on-al*. We adopt an overgenerate-and-rank approach, whereby instead of committing to a specific word segmentation at the start of the process, we process multiple syllabification alternatives in parallel, one of which is ultimately selected at the respelling evaluation stage.

Ideally, syllabification should conform to the phonotactic constraints of English, so that the resulting respellings are easy to pronounce. The consonant sonority should be rising in onsets, and falling in codas (Kenstowicz, 1994). We verify that syllables follow the sonority principle by following the formulation of Bartlett et al. (2009). The sonority constraints are not tested at the boundaries of the word, which are independent of the syllabification choice. We also incorporate another important principle of English phonotactics that asserts that lax vowels do not occur in open syllables (Rogers, 2000).

In our implementation, each candidate syllable is tested with respect to the following sequence of four violable constraints, ordered from the strongest to the weakest: (1) the syllable contains exactly one *vowel* phoneme; (2) the *onset* satisfies the sonority principle; (3) if the nucleus contains a *lax* vowel (except ə), the coda is non-empty; (4) the *coda* satisfies the sonority principle. For a syllabification to be accepted, all its syllables must satisfy the four constraints. However, if this results in rejection of all possible syllabifications, the constraints are gradually relaxed starting from the weakest.

As an example, consider the word *abandonment* [əbændənmənt], which has 18 different syllabifications satisfying the VOWEL constraint (Table 1). 8 of the 18 satisfy the ONSET constraint as well, but only two syllabifications satisfy all four constraints: [əb-æn-dən-mənt] and [ə-bæn-dən-mənt].

5.2 P2L Generator

The respelling problem can be viewed as a string transduction problem, with the transduction occurring between phonemes and letters. As such, it is directly related to the well-studied letter-to-phoneme conversion task. The difference is that the letters may not conform to the standard orthography of English. If we had a sufficiently large training set of pronunciation-respelling pairs, we could train a machine learning algorithm to directly generate respellings for any strings of English phonemes. However, such a training set is not readily available. The respellings in the corpus collected by Ghoshal et al. (2009) are not easily matched to the phonetic transcriptions, and few of them can be found in electronic pronunciation dictionaries. In addition, the quality of Web respellings vary greatly.

In place of a direct pronunciation-to-respelling model, we aim to model the orthographic intuitions of readers by deriving a phoneme-to-letter (P2L) transduction model from an English pronunciation dictionary. A possible criticism of such an approach is that our model may create ambiguous respellings, which abound in English orthography. However, we rely on a separate evaluation module to identify and filter ambiguous respellings at a later stage.

Our systems utilizes the DIRECTL+ program (Jiampojamarn et al., 2008), which was originally designed for L2P conversion. Since our basic unit is the syllable, rather than the word, we train our P2L model on a set of 4215 pairs of monosyllabic words and their pronunciations extracted from the Combilex dictionary. We exclude syllables in multi-syllabic words from training because their pronunciation is often affected by context. This is consistent with our expectation that the reader will pronounce each hyphen-delimited segment of the respelling as if it was an individual word.

Since the P2L training data consists of a relatively small set of syllables, we ensure that the phoneme-letter alignment is highly accurate. As a preprocess-

ing step, we replace the letter *x* with *ks*, and we convert digraphs, such as *ch* and *th*, to single symbols. The alignment is performed by M2M-ALIGNER (Jiampojamarn et al., 2007), under the restriction that each phoneme is matched to either one or two letter symbols.

5.3 Context-Sensitive Respeller

A hand-crafted context-sensitive respeller is intended to complement the trained P2L model described in the previous section. It is similar to the phonemic respelling approach described in Section 4.3 in that it converts each phoneme to a letter sequence. However, the mappings depend on adjacent phonemes, as well as on the CV pattern of the current syllable. In addition, more than one mapping for a phoneme can be proposed. We designed the mappings by analyzing their frequency and consistency in pronunciation dictionaries.

The process of candidate generation involves establishing the pattern of consonants in the input syllable. The consonant mappings are the same as in the baseline, except for [g] and [θ], while the vowels yield up to three different letter sequences. For example, [o] is mapped to *oh* as a default, but also to *o* if both onset and coda are empty, or to *o* followed by a consonant and a silent *e* if the coda is composed of a single consonant. So, given the syllable [tok] as input, the respeller produces two candidates: *tohk* and *toke*.

We make no claims about the completeness or optimality of the mappings, but in our development experiments we observed that the context-sensitive respeller contributes to the robustness of our system, and in some cases produces more attractive respellings than the P2L model.

6 Candidate Selection

We aim at developing a stand-alone method for the assessment of respellings that could be applied regardless of their origin. We consider two criteria: correctness, which is evaluated against the intended pronunciation, and ambiguity, which is a property of the respelling itself. As was the case in the generation stage, the evaluation is performed at the level of syllables.

6.1 L2P Correctness Filter

The principal method of verifying the correctness of a respelling involves the application of a letter-to-phoneme (L2P) model trained on the word-pronunciation pairs extracted from an English dictionary. The generated pronunciation of each syllable is compared against its intended pronunciation; if any of the syllables fail the test, the entire respelling is rejected.

The L2P model is derived using the DIRECTL+ system. The main difference between the L2P model described in this section and the P2L model from Section 5.2 is that the input and output data are reversed. However, the L2P model is not simply a mirror image of the P2L model. Often the phonemic output of the composition of the two models is different from the initial phonemic input; e.g., [ro] → *row* → [raʊ]. This is because the intermediate orthographic string may be ambiguous. Furthermore, the L2P model is also intended to test the correctness of respellings that were generated with other methods.

Other differences between the two models pertain to the preprocessing of the training data, and the letter-to-phoneme alignment. As with the P2L model, the training data consists of a set of monosyllabic words from the Combilex dictionary. However, in order to make our correctness filter more conservative, we also remove all words that contain diacritics (e.g., *crêpe*), non-English phonemes (e.g., *avant*), or silent consonants (e.g., *lmn*). The alignment is restricted to matching each letter symbol to at most one phoneme, and is derived with the ALINE phonetic aligner (Kondrak, 2000), which has been shown to outperform other 1-1 alignment methods (Jiampojamarn and Kondrak, 2010).

6.2 Vowel Counter

Syllables that contain multiple vowel groups may be confusing to readers even if they correctly represent the intended pronunciation. For example, readers might be unsure whether *takess* represents one or two syllables. A simple vowel counter is provided to filter out such syllables. The vowel filter accepts a syllable only if (a) it contains exactly one vowel group (e.g., *moe*), or (b) the second vowel group consists of a single *e* at the end of the syllable (e.g., *zake*).

6.3 SVM Ambiguity Classifier

This module is designed to compute a score that reflects the ambiguity of an orthographic syllable. The ambiguity score of a respelling is defined as the average of scores assigned to each of its syllables. The score can then be used to select the best respelling from a number of candidates generated by our system, or to rate a respelling from another source.

Since we have no explicit ambiguity annotations for respellings, we attempt instead to exploit ambiguity judgments that are implicitly made when respellings are created by human authors. We approach ambiguity as a binary classification task. For any given syllable, we wish to determine whether it is ambiguous (a negative instance), or unambiguous (a positive instance). Our assumption is that a syllable will not be respelled unless it is necessary due to ambiguity. For each observed word-respelling pair, we take all syllables from the respelling as positive instances, and all syllables in the original word that are not preserved in the respelling as negative instances. For example, the pair consisting of the word *cec-il-y* respelled as ‘*sehs-il-ee*’ provides three positive instances: *sehs*, *il* and *ee*; and two negative instances: *cec* and *y*.

We extracted word-respelling pairs from the Web-derived corpora of Ghoshal et al. (2009). The syllable breaks in the respellings were mapped onto the original words using ALINE. In order to improve the quality of the data, we applied a letter-to-phoneme model to both the original words and their respellings, and removed pairs with divergent pronunciations (computed as normalized edit distance ≤ 0.8). After the filtering, we were left a set of 25067 word-respelling pairs containing 78411 training syllables, which yielded 47270 positive and 31141 negative instances.

For the classification task we utilize the SVM-light software package (Joachims, 1999). Each instance is represented by a set of binary indicator features. The features correspond to character n -grams (including syllable boundary markers) with the values of n ranging from 1 to 5. For example, the syllable *-il-* turns on the following features: *i*, *l*, *-i*, *il*, *l-*, *-il*, *il-*, *-il-*. The model learns which n -grams are characteristic of ambiguous or unambiguous syllables. For example, it classifies both *le* and *li* as am-

biguous, and *lee* as unambiguous. Apart from the binary classification, the classifier also provides a real-valued score for each syllable.

6.4 Lexical Reviser

Since the use of familiar English letter sequences makes the respellings easier to interpret (Fraser, 1997), we incorporate dictionary lookup (Section 4.2) into our system. When the pronunciation of a syllable happens to correspond to the pronunciation of an actual dictionary word, the syllable may be respelled using that word. This is done as the final step in the generation process because dictionary words often receive poor scores from the SVM classifier on the account of their n -gram composition. The lexical reviser is restricted to optionally improving the top-ranked word respelling candidate as determined by the SVM classifier without altering its syllabification. For example, the respelling ‘*surr-sin-uSS*’ of *circinus* is modified to ‘*sir-sin-us*’. If more than one word can be used, we let the SVM classifier select the least ambiguous one.

7 System Overview

Our respelling generation system is a multi-stage process. The input is a sequence of phonemes representing the pronunciation of the word. We start by identifying acceptable syllabifications of phonemes as described in Section 5.1. For each syllable, we take up to five respelling candidates produced by the P2L model (Section 5.2), and between one and three candidates proposed by the context-sensitive respeller (Section 5.3). The next stage involves filtering the candidate respellings with the L2P model (Section 6.1), and the vowel counter (Section 6.2). If all candidates happen to be rejected, we retain the first output of the context-sensitive respeller as the default. The candidate respellings are then scored by the SVM model (Section 6.3). At this point the syllables are combined into word respellings, which are ranked according to their syllable score average. Finally, the lexical reviser described in Section 6.4 is applied to the top candidate in an attempt to further improve the result.

8 Evaluation

In this section, after describing our test sets, we present the results of two evaluation experiments: direct human judgment, and indirect validation with an L2P system.

8.1 Test Sets

Our two test sets were defined after the development of our system had been completed. There is no overlap between the test sets and any of our training sets. The first test set consists of 27 out of 30 words compiled by Fraser (1997) — 3 words from the original set were excluded because the corresponding respellings assume a non-rhotic variety of English. We refer to Fraser’s respellings as *expert*, and consider them as the upper bound in terms of quality.

The second test set of 231 words (henceforth referred to as the *Web set*) was extracted from the corpus of Ghoshal et al. (2009) after performing additional data clean-up described in Section 6.3. We identified a subset of words for which we could find phonetic transcriptions composed of English phonemes on Wikipedia. In order to ensure that the respellings and the corresponding transcriptions reflect the same pronunciation, we adapted the Soundex algorithm to apply to phonetic transcriptions, and retained only the respelling/transcription pairs that yielded identical Soundex codes. We removed words that are found in the Combilex dictionary as those could be familiar to human judges. Since longer words are more challenging to respell, and more likely to exhibit variation in respellings from different sources, we retained only words containing at least eight phonemes.

8.2 Human Judgment

We conducted an experiment with human evaluators using a specially developed graphical annotation program with synthesized word pronunciations. The evaluators were students enrolled in an introductory linguistic course, who were not involved in our project. 13 out of 20 evaluators declared themselves as native speakers of English.

The evaluation process involves 40 randomly selected words: 10 from Fraser’s set, and 30 from the Web set. For each word, the program displays in a random sequence three respellings, which are from

Source	Web set		Fraser’s set

the following sources: (1) the Baseline approach described in Section 4.3, (2) our system, and (3) either expert design (for Fraser’s set) or the Web (for the Web set). In order to reduce bias, the original spelling of the word is not shown. Each respelling is judged separately with regards to ambiguity, and those that are judged ambiguous are removed from further consideration. Next, an audio clip synthesized from the phonemic sequence representing the intended pronunciation is played through headphones. For each of the remaining respellings, the evaluators decide whether it is correct with respect to the recorded pronunciation. Finally, if more than one respelling have been judged both unambiguous and correct, the evaluators are asked to identify the one that they prefer.

The results of the experiment are shown in Table 2. Our system significantly outperforms both Web respellings and the Baseline approach in terms of unambiguity and correctness. In addition, the respellings produced by our system are more likely to be preferred over the Web respellings, and more than twice as likely to be preferred over the baseline respellings than vice versa. The results on the small Fraser’s set are less conclusive, but suggest that in terms of overall quality our system is much closer to the upper bound than to the baseline.

8.3 Automated Appraisal

Human evaluation is expensive and limited in terms of the number of variant respellings. Moreover, human judgements may be biased by previously seen respellings or by the familiarity with the standard spelling of a word. An automated evaluation is much less constrained, and facilitates an ablation study to determine the relative importance of various components of our system.

Source	Web set		Fraser’s set

w/o L2P correctness filter	33.8	88.0
w/o syllable breaks	20.8	83.9

Table 5: Accuracy of *eSpeak* on respellings produced by variants of our system.

eSpeak is a publicly available speech synthesizer⁵ that can also convert text into phonemic sequences. The letter-to-phoneme component for English utilizes about five thousand rules, and a dictionary of about three thousand words, names, and abbreviations. In our evaluation, we treat *eSpeak* as a “black box” which translates a respelling into its most likely pronunciation. By determining if there is a match between the output of *eSpeak* and the intended pronunciation, we directly test the correctness of the respelling, and indirectly also its ambiguity.

The results of the automated evaluation are shown in Table 4. The accuracy on the original orthography is low, which is unsurprising since the test sets contain mostly rare, unusually spelled words. Neither the baseline nor the Web respellings are significantly easier for *eSpeak* than the original words. On the other hand, respellings generated by our system make a massive difference, boosting phoneme accuracy to well over 90% on both sets. They are also significantly more effective than the expert respellings.

Table 5 shows the results of our system on the

⁵<http://espeak.sourceforge.net>

Table 3: Examples of respellings.

Web set with various modules disabled, which provides an estimate of their importance. Neither the context-sensitive respeller nor dictionary lookup seem to contribute much to *eSpeak*'s performance. On the other hand, disabling the P2L generator produces a significant drop in word accuracy, while removing the L2P correctness filter almost doubles the phoneme error rate. Interestingly, removing syllable breaks from the output of the full system has an even greater negative impact.

8.4 Analysis

Each of 20 evaluators judged 3 variant respellings of 40 different words. The average number of judgments per word was 7.4 for the 27 words in Fraser's set, and 2.8 for the 212 words in the Web set (due to random selection, 19 words from the Web set were not judged). Table 3 shows examples of respellings that were judged by at least five evaluators. The score columns indicate the proportion of the evaluators that judged a particular respelling as unambiguous and correct. The baseline respellings are not included as their scores were rarely higher than the scores of the other respellings for a given word. An interesting exception is *palimpsest*, for which the baseline respelling is identical to the actual spelling of the word.

Examples 1-5 in Table 3 come from the Web set, while examples 6-10 are from Fraser's set. The low scores of the first three Web respellings can be attributed to specific letter-to-phoneme mappings: [i]→*i*, [ə]→*oh*, and [ɔ]→*a*. Each of the examples 3-5 indicate the evaluators' acceptance of a particular respelling device: silent letters, multi-syllable

units, and dictionary words. In examples 6-8, the syllables immediately after the first hyphen in Helen Fraser's respellings seem to be problematic. The expert respelling of *jongleur* is considered correct even though the initial *j* suggests [dʒ], not [ʒ]. Finally, the last example demonstrates that the hyphenation choice can result in very different judgments.

9 Conclusion

In this paper, we introduced the task of automatically generating respellings from the given pronunciation. We investigated the characteristics of good respellings, and discussed three direct methods of their creation. We proposed a system that combines supervised and unsupervised learning with phonetic and orthographic principles. The evaluation experiment involving human participants indicates that the respellings produced by our system are better on average than those found on the Web. The automated verification demonstrates that they are also much easier to interpret for a rule-based text-to-speech converter. In the future we plan to address the related tasks of improving existing respellings, and assisting writers in creating respellings without direct access to the phonemic representations.

Carnegie Mellon University

Pittsburgh, PA 15213, USA

{cdyer, vchahune, nasmith}@cs.cmu.edu

Abstract

We present a simple log-linear reparameterization of IBM Model 2 that overcomes problems arising from Model 1’s strong assumptions and Model 2’s overparameterization. Efficient inference, likelihood evaluation, and parameter estimation algorithms are provided. Training the model is consistently ten times faster than Model 4. On three large-scale translation tasks, systems built using our alignment model outperform IBM Model 4.

An open-source implementation of the alignment model described in this paper is available from http://github.com/clab/fast_align.

1 Introduction

Word alignment is a fundamental problem in statistical machine translation. While the search for more sophisticated models that provide more nuanced explanations of parallel corpora is a key research activity, simple and effective models that scale well are also important. These play a crucial role in many scenarios such as parallel data mining and rapid large scale experimentation, and as subcomponents of other models or training and inference algorithms. For these reasons, IBM Models 1 and 2, which support exact inference in time $\Theta(|\mathbf{f}| \cdot |\mathbf{e}|)$, continue to be widely used.

This paper argues that both of these models are suboptimal, even in the space of models that permit such computationally cheap inference. Model 1 assumes all alignment structures are uniformly

likely (a problematic assumption, particularly for frequent word types), and Model 2 is vastly overparameterized, making it prone to degenerate behavior on account of overfitting.¹ We present a simple log-linear reparameterization of Model 2 that avoids both problems (§2). While inference in log-linear models is generally computationally more expensive than in their multinomial counterparts, we show how the quantities needed for alignment inference, likelihood evaluation, and parameter estimation using EM and related methods can be computed using two simple algebraic identities (§3), thereby defusing this objection. We provide results showing our model is an order of magnitude faster to train than Model 4, that it requires no staged initialization, and that it produces alignments that lead to significantly better translation quality on downstream translation tasks (§4).

2 Model

Our model is a variation of the lexical translation models proposed by Brown et al. (1993). Lexical translation works as follows. Given a source sentence \mathbf{f} with length n , first generate the length of the target sentence, m . Next, generate an *alignment*, $\mathbf{a} = \langle a_1, a_2, \dots, a_m \rangle$, that indicates which source word (or null token) each target word will be a translation of. Last, generate the m output words, where each e_i depends only on f_{a_i} .

The model of alignment configurations we propose is a log-linear reparameterization of Model 2.

¹Model 2 has independent parameters for every alignment position, conditioned on the source length, target length, and current target index.

Given : \mathbf{f} , $n = |\mathbf{f}|$, $m = |\mathbf{e}|$, p_0 , λ , θ

$$h(i, j, m, n) = - \left| \frac{i}{m} - \frac{j}{n} \right|$$

$$\delta(a_i = j \mid i, m, n) = \begin{cases} p_0 & j = 0 \\ (1 - p_0) \times \frac{e^{\lambda h(i, j, m, n)}}{Z_\lambda(i, m, n)} & 0 < j \leq n \\ 0 & \text{otherwise} \end{cases}$$

$$a_i \mid i, m, n \sim \delta(\cdot \mid i, m, n) \quad 1 \leq i \leq m$$

$$e_i \mid a_i, f_{a_i} \sim \theta(\cdot \mid f_{a_i}) \quad 1 \leq i \leq m$$

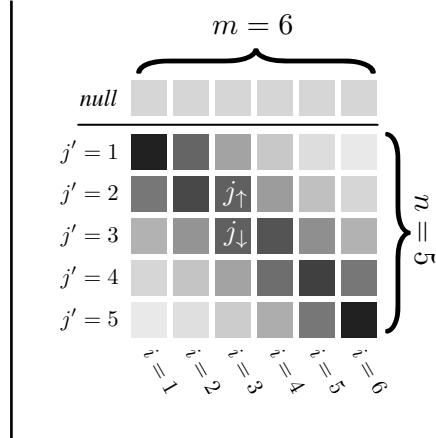

Figure 1: Our proposed generative process yielding a translation \mathbf{e} and its alignment \mathbf{a} to a source sentence \mathbf{f} , given the source sentence \mathbf{f} , alignment parameters p_0 and λ , and lexical translation probabilities θ (left); an example visualization of the distribution of alignment probability mass under this model (right).

Our formulation, which we write as $\delta(a_i = j \mid i, m, n)$, is shown in Fig. 1.² The distribution over alignments is parameterized by a null alignment probability p_0 and a precision $\lambda \geq 0$ which controls how strongly the model favors alignment points close to the diagonal. In the limiting case as $\lambda \rightarrow 0$, the distribution approaches that of Model 1, and, as it gets larger, the model is less and less likely to deviate from a perfectly diagonal alignment. The right side of Fig. 1 shows a graphical illustration of the alignment distribution in which darker squares indicate higher probability.

3 Inference

We now discuss two inference problems and give efficient techniques for solving them. First, given a sentence pair and parameters, compute the marginal likelihood and the marginal alignment probabilities. Second, given a corpus of training data, estimate likelihood maximizing model parameters using EM.

3.1 Marginals

Under our model, the marginal likelihood of a sentence pair $\langle \mathbf{f}, \mathbf{e} \rangle$ can be computed exactly in time

²Vogel et al. (1996) hint at a similar reparameterization of Model 2; however, its likelihood and its gradient are not efficient to evaluate, making it impractical to train and use. Och and Ney (2003) likewise remark on the overparameterization issue, removing a single variable of the original conditioning context, which only slightly improves matters.

$\Theta(|\mathbf{f}| \cdot |\mathbf{e}|)$. This can be seen as follows. For each position in the sentence being generated, $i \in [1, 2, \dots, m]$, the alignment to the source and its translation is independent of all other translation and alignment decisions. Thus, the probability that the i th word of \mathbf{e} is e_i can be computed as:

$$p(e_i, a_i \mid \mathbf{f}, m, n) = \delta(a_i \mid i, m, n) \times \theta(e_i \mid f_{a_i})$$

$$p(e_i \mid \mathbf{f}, m, n) = \sum_{j=0}^n p(e_i, a_i = j \mid \mathbf{f}, m, n).$$

We can also compute the posterior probability over alignments using the above probabilities,

$$p(a_i \mid e_i, \mathbf{f}, m, n) = \frac{p(e_i, a_i \mid \mathbf{f}, m, n)}{p(e_i \mid \mathbf{f}, m, n)}. \quad (1)$$

Finally, since all words in \mathbf{e} (and their alignments) are conditionally independent,³

$$p(\mathbf{e} \mid \mathbf{f}) = \prod_{i=1}^m p(e_i \mid \mathbf{f}, m, n)$$

$$= \prod_{i=1}^m \sum_{j=0}^n \delta(a_i \mid i, m, n) \times \theta(e_i \mid f_{a_i}).$$

³We note here that Brown et al. (1993) derive their variant of this expression by starting with the joint probability of an alignment and translation, marginalizing, and then reorganizing common terms. While identical in implication, we find the direct probabilistic argument far more intuitive.

3.2 Efficient Partition Function Evaluation

Evaluating and maximizing the data likelihood under log-linear models can be computationally expensive since this requires evaluation of normalizing partition functions. In our case,

$$Z_\lambda(i, m, n) = \sum_{j'=1}^n \exp \lambda h(i, j', m, n).$$

While computing this sum is obviously possible in $\Theta(|\mathbf{f}|)$ operations, our formulation permits exact computation in $\Theta(1)$, meaning our model can be applied even in applications where computational efficiency is paramount (e.g., MCMC simulations). The key insight is that the partition function is the (partial) sum of two geometric series of unnormalized probabilities that extend up and down from the probability-maximizing diagonal. The closest point on or above the diagonal j_\uparrow , and the next point down j_\downarrow (see the right side of Fig. 1 for an illustration), is computed as follows:

$$j_\uparrow = \left\lfloor \frac{i \times n}{m} \right\rfloor, \quad j_\downarrow = j_\uparrow + 1.$$

Starting at j_\uparrow and moving up the alignment column, as well as starting at j_\downarrow and moving down, the unnormalized probabilities decrease by a factor of $r = \exp \frac{-\lambda}{n}$ per step.

To compute the value of the partition, we only need to evaluate the unnormalized probabilities at j_\uparrow and j_\downarrow and then use the following identity, which gives the sum of the first ℓ terms of a geometric series (Courant and Robbins, 1996):

$$s_\ell(g_1, r) = \sum_{k=1}^{\ell} g_1 r^{k-1} = g_1 \frac{1 - r^\ell}{1 - r}.$$

Using this identity, $Z_\lambda(i, m, n)$ can be computed as

$$s_{j_\uparrow}(e^{\lambda h(i, j_\uparrow, m, n)}, r) + s_{n-j_\downarrow}(e^{\lambda h(i, j_\downarrow, m, n)}, r).$$

3.3 Parameter Optimization

To optimize the likelihood of a sample of parallel data under our model, one can use EM. In the E-step, the posterior probabilities over alignments are computed using Eq. 1. In the M-step, the lexical translation probabilities are updated by aggregating these

as counts and normalizing (Brown et al., 1993). In the experiments reported in this paper, we make the further assumption that $\theta_f \sim \text{Dirichlet}(\boldsymbol{\mu})$ where $\mu_i = 0.01$ and approximate the posterior distribution over the θ_f 's using a mean-field approximation (Riley and Gildea, 2012).⁴

During the M-step, the λ parameter must also be updated to make the E-step posterior distribution over alignment points maximally probable under $\delta(\cdot | i, m, n)$. This maximizing value cannot be computed analytically, but a gradient-based optimization can be used, where the first derivative (here, for a single target word) is:

$$\begin{aligned} \nabla_\lambda \mathcal{L} &= \mathbb{E}_{p(a_i | e_i, \mathbf{f}, m, n)} [h(i, a_i, m, n)] \\ &\quad - \mathbb{E}_{\delta(j' | i, m, n)} [h(i, j', m, n)] \end{aligned} \quad (2)$$

The first term in this expression (the expected value of h under the E-step posterior) is fixed for the duration of each M-step, but the second term's value (the derivative of the log-partition function) changes many times as λ is optimized.

3.4 Efficient Gradient Evaluation

Fortunately, like the partition function, the derivative of the log-partition function (i.e., the second term in Eq. 2) can be computed in constant time using an algebraic identity. To derive this, we observe that the values of $h(i, j', m, n)$ form an arithmetic sequence about the diagonal, with common difference $d = -1/n$. Thus, the quantity we seek is the sum of a series whose elements are the products of terms from an arithmetic sequence and those of the geometric sequence above, divided by the partition function value. This construction is referred to as an arithmetico-geometric series, and its sum may be computed as follows (Fernandez et al., 2006):

$$\begin{aligned} t_\ell(g_1, a_1, r, d) &= \sum_{k=1}^{\ell} [a_1 + d(k-1)] g_1 r^{k-1} \\ &= \frac{a_\ell g_{\ell+1} - a_1 g_1}{1 - r} + \frac{d(g_{\ell+1} - g_1 r)}{(1 - r)^2}. \end{aligned}$$

In this expression r , the g_1 's and the ℓ 's have the same values as above, $d = -1/n$ and the a_1 's are

⁴The μ_i value was fixed at the beginning of experimentation by minimizing the AER on the 10k sentence French-English corpus discussed below.

equal to the value of h evaluated at the starting indices, j_{\uparrow} and j_{\downarrow} ; thus, the derivative we seek at each optimization iteration inside the M-step is:

$$\begin{aligned}\nabla_{\lambda} \mathcal{L} = & \mathbb{E}_{p(a_i|e_i, \mathbf{f}, m, n)} [h(i, a_i, m, n)] \\ & - \frac{1}{Z_{\lambda}} (t_{j_{\uparrow}}(e^{\lambda h(i, j_{\uparrow}, m, n)}, h(i, j_{\uparrow}, m, n), r, d) \\ & + t_{n-j_{\downarrow}}(e^{\lambda h(i, j_{\downarrow}, m, n)}, h(i, j_{\downarrow}, m, n), r, d)).\end{aligned}$$

4 Experiments

In this section we evaluate the performance of our proposed model empirically. Experiments are conducted on three datasets representing different language typologies and dataset sizes: the FBIS Chinese-English corpus (LDC2003E14); a French-English corpus consisting of version 7 of the Europarl and news-commentary corpora;⁵ and a large Arabic-English corpus consisting of all parallel data made available for the NIST 2012 Open MT evaluation. Table 1 gives token counts.

We begin with several preliminary results. First, we quantify the benefit of using the geometric series trick (§3.2) for computing the partition function relative to naïve summation. Our method requires only 0.62 seconds to compute all partition function values for $0 < i, m, n < 150$, whereas the naïve algorithm requires 6.49 seconds for the same.⁶

Second, using a 10k sample of the French-English data set (only 0.5% of the corpus), we determined 1) whether p_0 should be optimized; 2) what the optimal Dirichlet parameters μ_i are; and 3) whether the commonly used “staged initialization” procedure (in which Model 1 parameters are used to initialize Model 2, etc.) is necessary for our model. First, like Och and Ney (2003) who explored this issue for training Model 3, we found that EM tended to find poor values for p_0 , producing alignments that were overly sparse. By fixing the value at $p_0 = 0.08$, we obtained minimal AER. Second, like Riley and Gildea (2012), we found that small values of α improved the alignment error rate, although the impact was not particularly strong over large ranges of

⁵<http://www.statmt.org/wmt12>

⁶While this computational effort is a small relative to the total cost in EM training, in algorithms where λ changes more rapidly, for example in Bayesian posterior inference with Monte Carlo methods (Chahuneau et al., 2013), this savings can have substantial value.

Table 1: CPU time (hours) required to train alignment models in one direction.

Language Pair	Tokens	Model 4	Log-linear
Chinese-English	17.6M	2.7	0.2
French-English	117M	17.2	1.7
Arabic-English	368M	63.2	6.0

Table 2: Alignment quality (AER) on the WMT 2012 French-English and FBIS Chinese-English. Rows with EM use expectation maximization to estimate the θ_f , and \sim Dir use variational Bayes.

Model	Estimator	FR-EN	ZH-EN
Model 1	EM	29.0	56.2
Model 1	\sim Dir	26.6	53.6
Model 2	EM	21.4	53.3
Log-linear	EM	18.5	46.5
Log-linear	\sim Dir	16.6	44.1
Model 4	EM	10.4	45.8

Table 3: Translation quality (BLEU) as a function of alignment type.

Language Pair	Model 4	Log-linear
Chinese-English	34.1	34.7
French-English	27.4	27.7
Arabic-English	54.5	55.7

α . Finally, we (perhaps surprisingly) found that the standard staged initialization procedure was *less effective* in terms of AER than simply initializing our model with uniform translation probabilities and a small value of λ and running EM. Based on these observations, we fixed $p_0 = 0.08$, $\mu_i = 0.01$, and set the initial value of λ to 4 for the remaining experiments.⁷

We next compare the alignments produced by our model to the Giza++ implementation of the standard IBM models using the default training procedure and parameters reported in Och and Ney (2003). Our model is trained for 5 iterations using the procedure described above (§3.3). The algorithms are

⁷As an anonymous reviewer pointed out, it is a near certainty that tuning of these hyperparameters for each alignment task would improve results; however, optimizing hyperparameters of alignment models is quite expensive. Our intention is to show that it is possible to obtain reasonable (if not optimal) results *without* careful tuning.

compared in terms of (1) time required for training; (2) alignment error rate (AER, lower is better);⁸ and (3) translation quality (BLEU, higher is better) of hierarchical phrase-based translation system that used the alignments (Chiang, 2007). Table 1 shows the CPU time in hours required for training (one direction, English is generated). Our model is at least $10 \times$ faster to train than Model 4. Table 3 reports the differences in BLEU on a held-out test set. Our model’s alignments lead to consistently better scores than Model 4’s do.⁹

5 Conclusion

We have presented a fast and effective reparameterization of IBM Model 2 that is a compelling replacement for the standard Model 4. Although the alignment quality results measured in terms of AER are mixed, the alignments were shown to work exceptionally well in downstream translation systems on a variety of language pairs.

⁸Our Arabic training data was preprocessed using a segmentation scheme optimized for translation (Habash and Sadat, 2006). Unfortunately the existing Arabic manual alignments are preprocessed quite differently, so we did not evaluate AER.

⁹The alignments produced by our model were generally sparser than the corresponding Model 4 alignments; however, the extracted grammar sizes were sometimes smaller and sometimes larger, depending on the language pair.

Phrase Training Based Adaptation for Statistical Machine Translation

Abstract

We present a novel approach for translation model (TM) adaptation using phrase training. The proposed adaptation procedure is initialized with a standard general-domain TM, which is then used to perform phrase training on a smaller in-domain set. This way, we bias the probabilities of the general TM towards the in-domain distribution. Experimental results on two different lectures translation tasks show significant improvements of the adapted systems over the general ones. Additionally, we compare our results to mixture modeling, where we report gains when using the suggested phrase training adaptation method.

1 Introduction

The task of domain-adaptation attempts to exploit data mainly drawn from one domain (e.g. news, parliamentary discussion) to maximize the performance on the test domain (e.g. lectures, web forums). In this work, we focus on translation model (TM) adaptation. A prominent approach in recent work is weighting at different levels of granularity. Foster and Kuhn (2007) perform weighting at the corpus level, where different corpora receive different weights and are then combined using mixture modeling. A finer grained weighting is that of Matsoukas et al. (2009), who weight each sentence in the bitexts using features of meta-information and optimize a mapping from the feature vectors to weights using a translation quality measure.

In this work, we propose to perform TM adaptation using phrase training. We start from a general-domain phrase table and adapt the probabilities by

training on an in-domain data. Thus, we achieve direct phrase probabilities adaptation as opposed to weighting. Foster et al. (2010) perform weighting at the phrase level, assigning each phrase pair a weight according to its relevance to the test domain. They compare phrase weighting to a “flat” model, where the weight directly approximates the phrase probability. In their experiments, the weighting method performs better than the flat model, therefore, they conclude that retaining the original relative frequency probabilities of the TM is important for good performance. The “flat” model of Foster et al. (2010) is similar to our work. We differ in the following points: (*i*) we use the same procedure to perform the phrase training based adaptation and the search thus avoiding inconsistencies between the two; (*ii*) we do not directly interpolate the original statistics with the new ones, but use a training procedure to manipulate the original statistics. We perform experiments on the publicly available IWSLT TED task, on both Arabic-to-English and German-to-English lectures translation tracks. We compare our suggested phrase training adaptation method to a variety of baselines and show its effectiveness. Finally, we experiment with mixture modeling based adaptation. We compare mixture modeling to our adaptation method, and apply our method within a mixture modeling framework.

In Section 2, we present the phrase training method and explain how it is utilized for adaptation. Experimental setup including corpora statistics and the SMT system are described in Section 3. Section 4 summarizes the phrase training adaptation results ending with a comparison to mixture modeling.

2 Phrase Training

The standard phrase extraction procedure in SMT consists of two phases: (*i*) word-alignment training (e.g., IBM alignment models), (*ii*) heuristic phrase extraction and relative frequency based phrase translation probability estimation. In this work, we utilize phrase training for the task of adaptation. We use the forced alignment (FA) method (Wuebker et al., 2010) to perform the phrase alignment training and probability estimation. We perform phrase training by running a normal SMT decoder on the training data and constrain the translation to the given target instance. Using n-best possible phrase segmentation for each training instance, the phrase probabilities are re-estimated over the output. Leaving-one-out is used during the forced alignment procedure phase to avoid over-fitting (Wuebker et al., 2010).

In the standard phrase training procedure, we are given a training set y , from which an initial heuristics-based phrase table p_y^0 is generated. FA training is then done over the training set y using the phrases and probabilities in p_y^0 (possibly updated by the leaving-one-out method). Finally, re-estimation of the phrase probabilities is done over the decoder output, generating the FA phrase table p^1 . We explain next how to utilize FA training for adaptation.

2.1 Adaptation

In this work, we utilize phrase training for the task of adaptation. The main idea is to generate the initial phrase table required for FA using a general-domain training data y' , thus resulting in $p_{y'}^0$, and perform the FA training over y_{IN} , the in-domain training data (instead of y' in the standard procedure). This way, we bias the probabilities of $p_{y'}^0$ towards the in-domain distribution. We denote this new procedure by Y'-FA-IN. This differs from the standard IN-FA-IN by that we have more phrase pairs to use for FA. Thus, we obtain phrase pairs relevant to IN in addition to “general” phrase pairs which were not extracted from IN, perhaps due to faulty word alignments. The probabilities of the general phrase table will be tailored towards IN. In practice, we usually have in-domain IN and other-domain OD data. We denote by ALL the concatenation of IN and OD. To adapt the ALL phrase table, we perform the FA procedure ALL-FA-IN. We also utilize leaving-one-out

to avoid over-fitting.

Another procedure we experimented with is adapting the OD phrase table using FA over IN, without leaving-one-out. We denote it by OD-FA₀-IN. In this FA scenario, we do not use leaving-one-out as IN is not contained in OD, therefore, overfitting will not occur. By this procedure, we train phrases from OD that are relevant for both OD and IN, while the probabilities will be tailored to IN. In this case, we do not expect improvements over the IN based phrase table, but, improvements over OD and reduction in the phrase table size.

We compare our suggested FA based adaptation to the standard FA procedure.

3 Experimental Setup

3.1 Training Corpora

To evaluate the introduced methods experimentally, we use the IWSLT 2011 TED Arabic-to-English and German-to-English translation tasks. The IWSLT 2011 evaluation campaign focuses on the translation of TED talks, a collection of lectures on a variety of topics ranging from science to culture. For Arabic-to-English, the bilingual data consists of roughly 100K sentences of in-domain TED talks data and 8M sentences of “other”-domain United Nations (UN) data. For the German-to-English task, the data consists of 130K TED sentences and 2.1M sentences of “other”-domain data assembled from the news-commentary and the europarl corpora. For language model training purposes, we use an additional 1.4 billion words (supplied as part of the campaign monolingual training data).

The bilingual training and test data for the Arabic-to-English and German-to-English tasks are summarized in Table 1¹. The English data was tokenized and lowercased while the Arabic data was tokenized and segmented using MADA v3.1 (Roth et al., 2008) with the ATB scheme. The German source is decompounded (Koehn and Knight, 2003) and part-of-speech-based long-range verb reordering rules (Popović and Ney, 2006) are applied.

From Table 1, we note that using the general data considerably reduces the number of out-of-

¹For a list of the IWSLT TED 2011 training corpora, see http://www.iwslt2011.org/doku.php?id=06_evaluation

Set	Sen	Tok	OOV/IN	OOV/ALL
German-to-English				
IN	130K	2.5M		
OD	2.1M	55M		
dev	883	20K	398 (2.0%)	215 (1.1%)

dev	934	19K	408 (2.2%)	184 (1.0%)
test	1664	31K	495 (1.6%)	228 (0.8%)
eval	1450	27K	513 (1.9%)	163 (0.6%)

Table 1: IWSLT 2011 TED bilingual corpora statistics: the number of tokens is given for the source side. OOV/X denotes the number of OOV words in relation to corpus X (the percentage is given in parentheses). *IN* is the TED in-domain data, *OD* denotes other-domain data, *ALL* denotes the concatenation of *IN* and *OD*.

vocabulary (OOV) words. This comes with the price of increasing the size of the training data by a factor of more than 20. A simple concatenation of the corpora might mask the phrase probabilities obtained from the in-domain corpus, causing a deterioration in performance. One way to avoid this contamination is by filtering the general corpus, but this discards phrase translations completely from the phrase model. A more principled way is by adapting the phrase probabilities of the full system to the domain being tackled. We perform this by phrase training the full phrase table over the in-domain training set.

3.2 Translation System

The baseline system is built using the open-source SMT toolkit Jane 2.0, which provides a state-of-the-art phrase-based SMT system (Wuebker et al., 2012a). In addition to the phrase based decoder, Jane 2.0 implements the forced alignment procedure used in this work for the purpose of adaptation. We use the standard set of models with phrase translation probabilities for source-to-target and target-to-source directions, smoothing with lexical weights, a word and phrase penalty, distance-based reordering and an n -gram target language model. The SMT systems are tuned on the *dev* (dev2010) development set with minimum error rate training (Och, 2003) us-

ing BLEU (Papineni et al., 2002) accuracy measure as the optimization criterion. We test the performance of our system on the *test* (tst2010) and *eval* (tst2011) sets using the BLEU and translation edit rate (TER) (Snover et al., 2006) measures. We use TER as an additional measure to verify the consistency of our improvements and avoid over-tuning. The Arabic-English results are case sensitive while the German-English results are case insensitive.

4 Results

For TM training, we define three different sets: in-domain (*IN*) which is the TED corpus, other-domain (*OD*) which consists of the UN corpus for Arabic-English and a concatenation of news-commentary and europarl for German-English, and *ALL* which consists of the concatenation of *IN* and *OD*. We experiment with the following extraction methods:

- Heuristics: standard phrase extraction using word-alignment training and heuristic phrase extraction over the word alignment. The extraction is performed for the three different training data, *IN*, *OD* and *ALL*.
- FA standard: standard FA phrase training where the same training set is used for initial phrase table generation as well as the FA procedure. We perform the training on the three different training sets and denote the resulting systems by *IN-FA*, *OD-FA* and *ALL-FA*.
- FA adaptation: FA based adaptation phrase training, where the initial table is generated from some general data and the FA training is performed on the *IN* data to achieve adaptation. We perform two experiments, *OD-FA₀-IN* without leaving-one-out and *ALL-FA-IN* with leaving-one-out.

The results of the various experiments over both Arabic-English and German-English tasks are summarized in Table 2. The usefulness of the *OD* data differs between the Arabic-to-English and the German-to-English translation tasks. For Arabic-to-English, the *OD* system is 2.5%-4.3% BLEU worse than the *IN* system, whereas for the German-to-English task the differences between *IN* and *OD* are smaller and range from 0.9% to 1.6% BLEU. The

	ALL	7.8M	31.2	48.3	29.5	50.5	33.6	46.1
FA standard	IN-FA	0.5M	31.6	48.2	29.7	50.5	33.3	46.4
	OD-FA	3.0M	29.1	51.0	27.6	53.0	30.7	49.6
	ALL-FA	3.2M	31.4	48.3	29.4	50.8	33.6	46.2
FA adaptation	OD-FA ₀ -IN	0.9M	31.2	48.7	29.1	50.9	32.7	46.9
	ALL-FA-IN	0.9M	31.8	47.4	29.7	49.7	33.6	45.5

Table 2: TED 2011 translation results. BLEU and TER are given in percentages. *IN* denotes the TED lectures in-domain corpus, *OD* denotes the other-domain corpus, *ALL* is the concatenation of *IN* and *OD*. *FA₀* denotes forced alignment training without leaving-one-out (otherwise, leaving-one-out is used).

inferior performance of the *OD* system can be related to noisy data or bigger discrepancy between the OD data domain distribution and the IN distribution. The *ALL* system performs according to the usefulness of the OD training set, where for Arabic-to-English we observe deterioration in performance for all test sets and up-to -0.9% BLEU on the *test* set. On the other hand, for German-to-English, the *ALL* system is improving over *IN* where the biggest improvement is observed on the *eval* set with +0.9% BLEU improvement.

The standard FA procedure achieves mixed results, where *IN-FA* deteriorates the results over the *IN* counterpart for Arabic-English, while improving for German-English. *ALL-FA* performs comparably to the *ALL* system on both tasks, while reducing the phrase table size considerably. The *OD-FA* system deteriorates the results in comparison to the *OD* system in most cases, which is expected as training over the OD set fits the phrase model on the OD domain, making it perform worse on IN. (Wuebker et al., 2012b) also report mixed results with FA training.

The FA adaptation results are summarized in the last block of the experiments. The *OD-FA₀-IN* improves over the *OD* system, which means that the training procedure was able to modify the OD probabilities to perform well on the IN data. On the German-to-English task, the *OD-FA₀-IN* performs comparably to the *IN* system, whereas for Arabic-to-English *OD-FA₀-IN* was able to close around half of the gap between OD and IN.

The FA adapted ALL system (*ALL-FA-IN*) performs best in our experiments, improving on both BLEU and TER measures. In comparison to the best heuristics system (*IN* for Arabic-English and *ALL* for German-English), +0.4% BLEU and -0.6% TER improvements are observed on the *eval* set for Arabic-English. For German-English, the biggest improvements are observed on TER with -0.8% on *test* and -0.5% on *eval*. The results suggest that *ALL-FA-IN* is able to learn more useful phrases than the *IN* system and adjust the *ALL* phrase probabilities towards the in-domain distribution.

System	dev		test

Table 3: TED 2011 mixture modeling results. Heuristics_{best} is the best heuristics based system, *IN* for Arabic-English and *ALL* for German-English. *X,Y* denotes linear interpolation between *X* and *Y* phrase tables.

4.1 Mixture Modeling

In this section, we compare our method to mixture modeling based adaptation, in addition to applying mixture modeling on top of our method. We focus on linear interpolation (Foster and Kuhn, 2007) of the in-domain (*IN*) and other-domain phrase tables, where we vary the latter between the heuristically extracted phrase table (*OD*) and the FA adapted one (*OD-FA₀-IN*). The interpolation weight is uniform for the interpolated phrase tables (0.5). The results of mixture modeling are summarized in Table 3. In this table, we include the best heuristics based system (Heuristics_{best}) from Table 2 as a reference system. The results on the *eval* set are omitted as they show similar tendencies to the *test* set results.

Linear interpolation of *IN* and *OD* (*IN,OD*) is performing well in our experiments, with big improvements over the *dev* set, +1.0% BLEU for Arabic-to-English and +0.4% BLEU for German-to-English. On the *test* set, we observe smaller improvements. Interpolating *IN* with the phrase training adapted system *OD-FA₀-IN* (*IN,OD-FA₀-IN*) achieves additional gains over the *IN,OD* system, the biggest are observed on TER for German-to-English, with -0.4% and -0.5% improvements on the *dev* and *test* sets correspondingly.

Comparing heuristics based interpolation (*IN,OD*) to our best phrase training adapted system (*ALL-FA-IN*) shows mixed results. For Arabic-to-English, the systems are comparable, while for the German-to-English *test* set, *IN,OD* is +0.2% BLEU

better and +0.8% TER worse than *ALL-FA-IN*. We hypothesize that for Arabic-to-English interpolation is important due to the larger size of the OD data, where it could reduce the masking of the IN training data by the much larger OD data. Nevertheless, as mentioned previously, using phrase training adapted phrase table in a mixture setup consistently improves over using heuristically extracted tables.

5 Conclusions

In this work, we propose a phrase training procedure for adaptation. The phrase training is implemented using the FA method. First, we extract a standard phrase table using the whole available training data. Using this table, we initialize the FA procedure and perform training on the in-domain set.

Experiments are done on the Arabic-to-English and German-to-English TED lectures translation tasks. We show that the suggested procedure is improving over unadapted baselines. On the Arabic-to-English task, the FA adapted system is +0.9% BLEU better than the full unadapted counterpart on both test sets. Unlike the Arabic-to-English setup, the German-to-English OD data is helpful and produces a strong unadapted baseline in concatenation with *IN*. In this case, the FA adapted system achieves BLEU improvements mainly on the development set with +0.6% BLEU, on the *test* and *eval* sets, improvements of -0.8% and -0.6% TER are observed correspondingly. As a side effect of the FA training process, the size of the adapted phrase table is less than 10% of the size of the full table.

Finally, we experimented with mixture modeling where improvements are observed over the unadapted baselines. The results show that using our phrase training adapted OD table yields better performance than using the heuristically extracted OD in a mixture framework.

Abstract

We propose a new method for translation acquisition which uses a set of synonyms to acquire translations from comparable corpora. The motivation is that, given a certain query term, it is often possible for a user to specify one or more synonyms. Using the resulting set of query terms has the advantage that we can overcome the problem that a single query term’s context vector does not always reliably represent a terms meaning due to the context vector’s sparsity. Our proposed method uses a weighted average of the synonyms’ context vectors, that is derived by inferring the mean vector of the von Mises-Fisher distribution. We evaluate our method, using the synsets from the cross-lingually aligned Japanese and English WordNet. The experiments show that our proposed method significantly improves translation accuracy when compared to a previous method for smoothing context vectors.

1 Introduction

Automatic translation acquisition is an important task for various applications. For example, finding term translations can be used to automatically update existing bilingual dictionaries, which are an indispensable resource for tasks such as cross-lingual information retrieval and text mining.

Various previous research like (Rapp, 1999; Fung, 1998) has shown that it is possible to acquire word translations from comparable corpora.

We suggest here an extension of this approach which uses several query terms instead of a single query term. A user who searches a translation for

a query term that is not listed in an existing bilingual dictionary, might first try to find a synonym of that term. For example, the user might look up a synonym in a thesaurus¹ or might use methods for automatic synonym acquisition like described in (Grefenstette, 1994). If the synonym is listed in the bilingual dictionary, we can consider the synonym’s translations as the translations of the query term. Otherwise, if the synonym is not listed in the dictionary either, we use the synonym together with the original query term to find a translation.

We claim that using a set of synonymous query terms to find a translation is better than using a single query term. The reason is that a single query term’s context vector is, in general, unreliable due to sparsity. For example, a low frequent query term tends to have many zero entries in its context vector. To mitigate this problem it has been proposed to smooth a query’s context vector by its nearest neighbors (Pekar et al., 2006). However, nearest neighbors, which context vectors are close the query’s context vector, can have different meanings and therefore might introduce noise.

The contributions of this paper are two-fold. First, we confirm experimentally that smoothing a query’s context vector with its synonyms leads in deed to higher translation accuracy, compared to smoothing with nearest neighbors. Second, we propose a simple method to combine a set of context vectors that performs in this setting better than a method previously proposed by (Pekar et al., 2006).

Our approach to combine a set of context vec-

¹Monolingual thesauri are, arguably, easier to construct than bilingual dictionaries.

tors is derived by learning the mean vector of a von Mises-Fisher distribution. The combined context vector is a weighted-average of the original context-vectors, where the weights are determined by the word occurrence frequencies.

In the following section we briefly show the relation to other previous work. In Section 3, we explain our method in detail, followed by an empirical evaluation in Section 4. We summarize our results in Section 6.

2 Related Work

There are several previous works on extracting translations from comparable corpora ranging from (Rapp, 1999; Fung, 1998), and more recently (Haghghi et al., 2008; Laroche and Langlais, 2010), among others. Essentially, all these methods calculate the similarity of a query term’s context vector with each translation candidate’s context vector. The context vectors are extracted from the comparable corpora, and mapped to a common vector space with the help of an existing bilingual dictionary.

The work in (Déjean et al., 2002) uses cross-lingually aligned classes in a multilingual thesaurus to improve the translation accuracy. Their method uses the probability that the query term and a translation candidate are assigned to the same class. In contrast, our method does not need cross-lingually aligned classes.

Ismail and Manandhar (2010) proposes a method that tries to improve a query’s context vector by using in-domain terms. In-domain terms are the terms that are highly associated to the query, as well as highly associated to one of the query’s highly associated terms. Their method makes it necessary that the query term has enough highly associated context terms.² However, a low-frequent query term might not have enough highly associated terms.

In general if a query term has a low-frequency in the corpus, then its context vector is sparse. In that case, the chance of finding a correct translation is reduced (Pekar et al., 2006). Therefore, Pekar et al. (2006) suggest to use distance-based averaging to smooth the context vector of a low-frequent query

²In their experiments, they require that a query word has at least 100 associated terms.

term. Their smoothing strategy is dependent on the occurrence frequency of a query term and its close neighbors. Let us denote q the context vector of the query word, and K be the set of its close neighbors. The smoothed context vector q' is then derived by using:

$$q' = \gamma \cdot q + (1 - \gamma) \cdot \sum_{x \in K} w_x \cdot x, \quad (1)$$

where w_x is the weight of neighbor x , and all weights sum to one. The context vectors q and x are interpreted as probability vectors and therefore L1-normalized. The weight w_x is a function of the distance between neighbor x and query q . The parameter γ determines the degree of smoothing, and is a function of the frequency of the query term and its neighbors:

$$\gamma = \frac{\log f(q)}{\log \max_{x \in K \cup \{q\}} f(x)} \quad (2)$$

where $f(x)$ is the frequency of term x . Their method forms the baseline for our proposed method.

3 Proposed Method

Our goal is to combine the context vectors to one context vector which is less sparse and more reliable than the original context vector of query word q . We assume that for each occurrence of a word, its corresponding context vector was generated by a probabilistic model. Furthermore, we assume that synonyms are generated by the same probability distribution. Finally we use the mean vector of that distribution to represent the combined context vector. By using the assumption that *each* occurrence of a word corresponds to one sample of the probability distribution, our model places more weight on synonyms that are highly-frequent than synonyms that occur infrequently. This is motivated by the assumption that context vectors of synonyms that occur with high frequency in the corpus, are more reliable than the ones of low-frequency synonyms.

When comparing context vectors, work like Laroche and Langlais (2010) observed that often the cosine similarity performs superior to other distance-measures, like, for example, the euclidean distance. This suggests that context vectors tend to lie in the spherical vector space,

and therefore the von Mises-Fisher distribution is a natural choice for our probabilistic model. The von Mises-Fisher distribution was also successfully used in the work of (Basu et al., 2004) to cluster text data.

The von Mises-Fisher distribution with location parameter μ , and concentration parameter κ is defined as:

$$p(\mathbf{x}|\mu, \kappa) = c(\kappa) \cdot e^{\kappa \cdot \mathbf{x} \cdot \mu^T},$$

where $c(\kappa)$ is a normalization constant, and $\|\mathbf{x}\| = \|\mu\| = 1$, and $\kappa \geq 0$. $\|\cdot\|$ denotes here the L2-norm. The cosine-similarity measures the angle between two vectors, and the von Mises distribution defines a probability distribution over the possible angles. The parameter μ of the von Mises distribution is estimated as follows (Jammalamadaka and Sengupta, 2001): Given the words x_1, \dots, x_n , we denote the corresponding context vectors as $\mathbf{x}_1, \dots, \mathbf{x}_n$, and assume that each context vector is L2-normalized. Then, the mean vector μ is calculated as:

$$\mu = \frac{1}{Z} \sum_{i=1}^n \frac{\mathbf{x}_i}{n}$$

where Z ensures that the resulting context vector is L2-normalized, i.e. Z is $\|\sum_{i=1}^n \frac{\mathbf{x}_i}{n}\|$. For our purpose, κ is irrelevant and is assumed to be any fixed positive constant.

Since we assume that each occurrence of a word x in the corpus corresponds to one observation of the corresponding word's context vector \mathbf{x} , we get the following formula:

$$\mu = \frac{1}{Z'} \cdot \sum_{i=1}^n \frac{f(x_i)}{\sum_{j=1}^n f(x_j)} \cdot \mathbf{x}_i$$

where Z' is now $\|\sum_{i=1}^n \frac{f(x_i)}{\sum_{j=1}^n f(x_j)} \cdot \mathbf{x}_i\|$. We then use the vector μ as the combined vector of the words' context vectors \mathbf{x}_i .

Our proposed procedure to combine the context vector of query word q and its synonyms can be summarized as follows:

- Denote the context vectors of q and its synonyms as $\mathbf{x}_1, \dots, \mathbf{x}_n$, and L2-normalize each context vector.

- Calculate the weighted average of the vectors $\mathbf{x}_1, \dots, \mathbf{x}_n$, whereas the weights correspond to the frequencies of each word x_i .

- L2-normalize the weighted average.

4 Experiments

As source and target language corpora we use a corpus extracted from a collection of complaints concerning automobiles compiled by the Japanese Ministry of Land, Infrastructure, Transport and Tourism (MLIT)³ and the USA National Highway Traffic Safety Administration (NHTSA)⁴, respectively. The Japanese corpus contains 24090 sentences that were POS tagged using MeCab (Kudo et al., 2004). The English corpus contains 47613 sentences, that were POS tagged using Stepp Tagger (Tsuruoka et al., 2005), and use the Lemmatizer (Okazaki et al., 2008) to extract and stem content words (nouns, verbs, adjectives, adverbs).

For creating the context vectors, we calculate the association between two content words occurring in the same sentence, using the log-odds-ratio (Evert, 2004). It was shown in (Laroche and Langlais, 2010) that the log-odds-ratio in combination with the cosine-similarity performs superior to several other methods like PMI⁵ and LLR⁶. For comparing two context vectors we use the cosine similarity.

To transform the Japanese and English context vectors into the same vector space, we use a bilingual dictionary with around 1.6 million entries.⁷ To express all context vectors in the same vector space, we map the context vectors in English to context vectors in Japanese.⁸ First, for all the words which are listed in the bilingual dictionary we calculate word translation probabilities. These translation probabilities are calculated using the EM-algorithm described in (Koehn and Knight, 2000). We then create a translation matrix T which contains in each

³<http://www.mlit.go.jp/jidosha/carinf/rcl/defects.html>

⁴<http://www-odi.nhtsa.dot.gov/downloads/index.cfm>

⁵point-wise mutual information

⁶log-likelihood ratio

⁷The bilingual dictionary was developed in the course of our Japanese language processing efforts described in (Sato et al., 2003).

⁸Alternatively, we could, for example, use canonical correlation analysis to match the vectors to a common latent vector space, like described in (Haghghi et al., 2008).

column the translation probabilities for a word in English into any word in Japanese. Each context vector in English is then mapped into Japanese using the linear transformation described by the translation matrix T . For word x with context vector \mathbf{x} in English, let \mathbf{x}' be its context vector after transformation into Japanese, i.e. $\mathbf{x}' = T \cdot \mathbf{x}$.

The gold-standard was created by considering all nouns in the Japanese and English WordNet where synsets are aligned cross-lingually. This way we were able to create a gold-standard with 215 Japanese nouns, and their respective English translations that occur in our comparable corpora.⁹ Note that the cross-lingual alignment is needed only for evaluation. For evaluation, we consider only the translations that occur in the corresponding English synset as correct.

Because all methods return a ranked list of translation candidates, the accuracy is measured using the rank of the translation listed in the gold-standard. The inverse rank is the sum of the inverse ranks of each translation in the gold-standard.

In Table 1, the first row shows the results when using no smoothing. Next, we smooth the query’s context vector by using Equation (1) and (2). The set of neighbors K is defined as the k -terms in the source language that are closest to the query word, with respect to the cosine similarity (sim). The weight w_x for a neighbor x is set to $w_x = 10^{0.13 \cdot \text{sim}(x,q)}$ in accordance to (Pekar et al., 2006). For k we tried values between 1 and 100, and got the best inverse rank when using $k=19$. The resulting method (Top- k Smoothing) performs consistently better than the method using no smoothing, see Table 1, second row. Next, instead of smoothing the query word with its nearest neighbors, we use as the set K the set of synonyms of the query word (Syn Smoothing). Table 1 shows a clear improvement over the method that uses nearest neighbor-smoothing. This confirms our claim that using synonyms for smoothing can lead to better translation accuracy than using nearest neighbors. In the last row of Table 1, we compare our proposed method to combine context vectors of synonyms (Syn Mises-Combination), with the pre-

⁹The resulting synsets in Japanese and English, contain in average 2.2 and 2.8 words, respectively. The ambiguity of a query term in our gold-standard is low, since, in average, a query term belongs to only 1.2 different synsets.

vious method (Syn Smoothing). A pair-wise comparison of our proposed method with Syn Smoothing shows a statistically significant improvement ($p < 0.01$).¹⁰

Finally, we also show the result when simply adding each synonym vector to the query’s context vector to form a new combined context vector (Syn Sum).¹¹ Even though, this approach does not use the frequency information of a word, it performs better than Syn Smoothing. We suppose that this is due to the fact that it actually indirectly uses frequency information, since the log-odds-ratio tends to be higher for words which occur with high frequency in the corpus.

Method	Top1	Top5	Top10	MIR
No Smoothing	0.14	0.30	0.36	0.23
Top- k Smoothing	0.16	0.33	0.43	0.26
Syn Smoothing	0.18	0.35	0.46	0.28
Syn Sum	0.23	0.46	0.57	0.35
Syn Mises-Combination	0.31	0.46	0.55	0.40

Table 1: Shows Top-n accuracy and mean inverse rank (MIR) for baseline methods which use no synonyms (No Smoothing, Top- k Smoothing), the proposed method (Syn Mises-Combination) which uses synonyms, and alternative methods that also use synonyms (Syn Smoothing, Syn Sum).

5 Discussion

We first discuss an example where the query terms are クルーズ (cruise) and 巡航 (cruise). Both words can have the same meaning. The resulting translation candidates suggested by the baseline methods and the proposed method is shown in Table 2. Using no smoothing, the baseline method outputs the correct translation for クルーズ (cruise) and 巡航 (cruise) at rank 10 and 15, respectively. When combining both queries to form one context vector our proposed method (Syn Mises-Combination) retrieves the correct translation at rank 2. Note that we considered all nouns that occur three or more times as possible translation candidates. As can be seen in Table 2, this also includes spelling mistakes like "sevice" and "infromation".

¹⁰We use the sign-test (Wilcox, 2009) to test the hypothesis that the proposed method ranks higher than the baseline.

¹¹No normalization is performed before adding the context vectors.

Method	Query	Output	Rank
No Smoothing	クルーズ	..., affinity, delco, cruise , sevice, sentrum,...	10
No Smoothing	巡航	..., denali, attendant, cruise , abs, tactic,...	15
Top-k Smoothing	クルーズ	pillar, multi, cruise , star, affinity,...	3
Top-k Smoothing	巡航	..., burnout, dipstick, cruise , infromation, speed, ...	8
Syn Smoothing	クルーズ smoothed with 巡航	..., affinity, delco, cruise , sevice, sentrum,...	10
Syn Smoothing	巡航 smoothed with クルーズ	..., alldata, mode, cruise , expectancy, mph,...	8
Syn Sum	クルーズ, 巡航	assumption, level, cruise , reimbursment, infromation,...	3
Syn Mises-Combination	クルーズ, 巡航	pillar, cruise , assumption, level, speed,...	2

Table 2: Shows the results for クルーズ and 巡航 which both have the same meaning "cruise". The third column shows part of the ranked translation candidates separated by comma. The last column shows the rank of the correct translation "cruise". Syn Smoothing uses Equation (1) with \mathbf{q} corresponding to the context vector of the query word, and K contains only the context vector of the term that is used for smoothing.

Finally, we note that some terms in our test set are ambiguous, and the ambiguity is not resolved by using the synonyms of only one synset. For example, the term 操舵 (steering, guidance) belongs to the synset "steering, guidance" which includes the terms 舵取り (steering, guidance) and ガイド (guidance), 案内 (guidance). Despite this conflation of senses in one synset, our proposed method can improve the finding of (one) correct translation. The baseline system using only 操舵 (steering, guidance) outputs the correct translation "steering" at rank 4, whereas our method using all four terms outputs it at rank 2.

6 Conclusions

We proposed a new method for translation acquisition which uses a set of synonyms to acquire translations. Our approach combines the query term's context vector with all the context vectors of its synonyms. In order to combine the vectors we use a weighted average of each context vector, where the weights are determined by a term's occurrence frequency.

Our experiments, using the Japanese and English WordNet (Bond et al., 2009; Fellbaum, 1998), show that our proposed method can increase the translation accuracy, when compared to using only a single query term, or smoothing with nearest neighbours. Our results suggest that instead of directly searching for a translation, it is worth first looking for synonyms, for example by considering spelling variations or monolingual resources.

Abstract

We consider the task of tagging Arabic nouns with WordNet supersenses. Three approaches are evaluated. The first uses an expert-crafted but limited-coverage lexicon, Arabic WordNet, and heuristics. The second uses unsupervised sequence modeling. The third and most successful approach uses machine translation to translate the Arabic into English, which is automatically tagged with English supersenses, the results of which are then projected back into Arabic. Analysis shows gains and remaining obstacles in four Wikipedia topical domains.

1 Introduction

A taxonomic view of lexical semantics groups word senses/usages into categories of varying granularities. WordNet *supersense tags* denote coarse semantic classes, including and (for nouns) and and (for verbs); these categories can be taken as the top level of a taxonomy. Nominal *supersense tagging* (Ciaramita and Johnson, 2003) is the task of identifying lexical chunks in the sentence for common as well as proper nouns, and labeling each with one of the 25 nominal supersense categories. Figure 1 illustrates two such labelings of an Arabic sentence. Like the narrower problem of named entity recognition, supersense tagging of text holds attraction as a way of inferring representations that move toward language independence. Here we consider the problem of nominal supersense tagging for Arabic, a language with ca. 300 million speakers and moderate linguistic resources, including a WordNet (Elkateb et al., 2006), annotated datasets (Maamouri et al., 2004; Hovy et al., 2006), monolingual corpora, and large amounts of Arabic-English parallel data.

The supervised learning approach that is used in state-of-the-art English supersense taggers (Cia-

ramita and Altun, 2006) is problematic for Arabic, since there are supersense annotations for only a small amount of Arabic text (65,000 words by Schneider et al., 2012, versus the 360,000 words that are annotated for English). Here, we reserve that corpus for development and evaluation, not training.

We explore several approaches in this paper, the most effective of which is to (1) translate the Arabic sentence into English, returning the alignment structure between the source and target, (2) apply English supersense tagging to the target sentence, and (3) heuristically project the tags back to the Arabic sentence across these alignments. This “**MT-in-the-middle**” approach has also been successfully used for mention detection (Zitouni and Florian, 2008) and coreference resolution (Rahman and Ng, 2012).

We first discuss the task and relevant resources (§2), then the approaches we explored (§3), and finally present experimental results and analysis in §4.

2 Task and Resources

A gold standard corpus of sentences annotated with nominal supersenses (as in figure 1) facilitates automatic evaluation of supersense taggers. For development and evaluation we use

the AQMAR Arabic Wikipedia Supersense Corpus¹ (Schneider et al., 2012), which augmented a named entity corpus (Mohit et al., 2012) with nominal supersense tags. The corpus consists of 28 articles selected from four topical areas: **history** (e.g., “Islamic Golden Age”), **science** (“Atom”), **sports** (“Real Madrid”), and **technology** (“Linux”). Schneider et al. (2012) found the distributions of supersense categories in these four topical domains to be markedly different; e.g., most instances of (which includes kinds of software) occurred in the technology domain, whereas most s were found in the science domain.

The 18 test articles have 1,393 sentences (39,916 tokens) annotated at least once.² As the corpus was released with two annotators’ (partially overlapping) taggings, rather than a single gold standard, we treat the output of each annotator as a separate test set. Both annotated some of every article; the first (**Ann-A**) annotated 759 sentences, the second (**Ann-B**) 811 sentences.

Lexicon. What became known as “supersense tags” arose from a high-level partitioning of synsets in the original English WordNet (Fellbaum, 1998) into *lexicographer files*. Arabic WordNet (AWN) (Elkateb et al., 2006) allows us to recover supersense categories for some 10,500 Arabic nominal types, since many of the synsets in AWN are cross-referenced to English WordNet, and can therefore be associated with supersense categories. Further, OntoNotes contains named entity annotations for Arabic (Hovy et al., 2006).

From these, we construct an Arabic supersense lexicon, mapping Arabic noun lemmas to supersense tags. This lexicon contains 23,000 types, of which 11,000 are multiword units. Token coverage of the test set is 18% (see table 1). Lexical units encountered in the test data were up to 9-ways supersense-ambiguous; the average ambiguity of in-vocabulary tokens was 2.0 supersenses.

Unlabeled Arabic text. For unsupervised learning we collected 100,000 words of Arabic Wikipedia text, not constrained by topic. The articles in this sample were subject to a minimum length threshold

¹<http://www.ark.cs.cmu.edu/ArabicSST>

²Our development/test split of the data follows Mohit et al. (2012), but we exclude two test set documents—“Light” and “Ibn Tolun Mosque”—due to preprocessing issues.

and are all cross-linked to corresponding articles in English, Chinese, and German.

Arabic→English machine translation. We used two independently developed Arabic-English MT systems. One (**QCRI**) is a phrase-based system (Koehn et al., 2003), similar to Moses (Koehn et al., 2007); the other (**cdec**) is a hierarchical phrase-based system (Chiang, 2007), as implemented in cdec (Dyer et al., 2010). Both were trained on about 370M tokens of parallel data provided by the LDC (by volume, mostly newswire and UN data). Each system includes preprocessing for Arabic morphological segmentation and orthographic normalization.³ The **QCRI** system used a 5-gram modified Kneser-Ney language model that generated full-cased forms (Chen and Goodman, 1999). **cdec** used a 4-gram KN language model over lowercase forms and was recased in a post-processing step. Both language models were trained using the Gigaword v. 4 corpus. Both systems were tuned to optimize BLEU on a held-out development set (Papineni et al., 2002).

English supersense tagger. For English supersense tagging, an open-source reimplementation of the approach of Ciaramita and Altun (2006) was released by Michael Heilman.⁴ This tagger was trained on the SemCor corpus (Miller et al., 1993) and achieves 77% F_1 in-domain.

3 Methods

We explored 3 approaches to the supersense tagging of Arabic: heuristic tagging with a lexicon, unsupervised sequence tagging, and MT-in-the-middle.

3.1 Heuristic Tagging with a Lexicon

Using the lexicon built from AWN and OntoNotes (see §2), our heuristic approach works as follows:

1. Stem and vocalize; we used MADA (Habash and Rambow, 2005; Roth et al., 2008).
2. Greedily detect word sequences matching lexicon entries from left to right.
3. If a lexicon entry has more than one associated supersense, Arabic WordNet synsets are

³**QCRI** accomplishes this using MADA (Habash and Rambow, 2005; Roth et al., 2008). **cdec** includes a custom CRF-based segmenter and standard normalization rules.

$\hat{\mathbf{E}}$	1	2	3	4	5	6	7	8	9	Automatic English supersense tagging
$\hat{\mathbf{e}}$	1	2	3	4	5	6	7	8	9	English sentence
\mathbf{a}	1	2	3	4	A	5	N	6	N	Arabic sentence (e.g., token 6 aligns to English tokens 7–9)
$\hat{\mathbf{A}}$	P	N								Arabic POS tagging
										Projected supersense tagging

Figure 2: A hypothetical aligned sentence pair of 9 English words (with their supersense tags) and 6 Arabic words (with their POS tags). Step 4 of the projection procedure constructs the Arabic-to-English mapping $\{1 \rightarrow 1, 4 \rightarrow 3, 5, 6 \rightarrow 7\}$, resulting in the tagging shown in the bottom row.

weighted to favor earlier senses (presumed by lexicographers to be more frequent) and then the supersense with the greatest aggregate weight is selected. Formally: Let $senses(w)$ be the ordered list of AWN senses of lemma w . Let $senses(w, s) \subseteq senses(w)$ be those senses that map to a given supersense s . We choose $\arg \max_s (|senses(w, s)| / \min_{i: senses(w)_i \in senses(w, s)} i)$.

3.2 Unsupervised Sequence Models

Unsupervised sequence labeling is our second approach (Merialdo, 1994). Although it was largely developed for part-of-speech tagging, the hope is to use in-domain Arabic data (the unannotated Wikipedia corpus discussed in §2) to infer clusters that correlate well with supersense groupings. We applied the generative, feature-based model of Berg-Kirkpatrick et al. (2010), replicating a feature-set used previously for NER (Mohit et al., 2012)—including context tokens, character n -grams, and POS—and adding the vocalized stem and several stem shape features: 1) **ContainsDigit?**; 2) digits replaced by #; 3) digit sequences replaced by # (for stems mixing digits with other characters); 4) **YearLike?**—true for 4-digit numerals starting with 19 or 20; 5) **LatinWord?**, per the morphological analysis; 6) the shape feature of Ciaramita and Altun (2006) (Latin words only). We used 50 iterations of learning (tuned on dev data). For evaluation, a many-to-one mapping from unsupervised clusters to supersense tags is greedily induced to maximize their correspondence on evaluation data.

3.3 MT-in-the-Middle

A standard approach to using supervised linguistic resources in a second language is **cross-lingual projection** (Yarowsky and Ngai, 2001; Yarowsky et al., 2001; Smith and Smith, 2004; Hwa et al., 2005; Mihalcea et al., 2007; Burkett and Klein, 2008; Burkett et al., 2010; Das and Petrov, 2011; Kim et al., 2012,

who use parallel sentences extracted from Wikipedia for NER). The simplest such approach starts with an aligned parallel corpus, applies supersense tagging to the English side, and projects the labels through the word alignments. A supervised monolingual tagger is then trained on the projected labels. Preliminary experiments, however, showed that this underperformed even the simple heuristic baseline above (likely due to domain mismatch), so it was abandoned in favor of a technique that we call **MT-in-the-middle** projection.

This approach does not depend on having parallel data in the training domain, but rather on an Arabic→English machine translation system that can be applied to the sentences we wish to tag. The approach is inspired by token-level pseudo-parallel data methods of previous work (Zitouni and Florian, 2008; Rahman and Ng, 2012). MT output for this language pair is far from perfect—especially for Wikipedia text, which is distant from the domain of the translation system’s training data—but, in the spirit of Church and Hovy (1993), we conjecture that it may still be useful. The method is as follows:

1. Preprocess the input Arabic sentence \mathbf{a} to match the decoder’s model of Arabic.
2. Translate the sentence, recovering not just the English output $\hat{\mathbf{e}}$ but also the derivation/alignment structure \mathbf{z} relating words and/or phrases of the English output to words and/or phrases of the Arabic input.
3. Apply the English supersense tagger to the English translation, discarding any verbal supersense tags. Call the tagger output $\hat{\mathbf{E}}$.
4. Project the supersense tags back to the Arabic sentence, yielding $\hat{\mathbf{A}}$: Each Arabic token $a \in \mathbf{a}$ that is (a) a noun, or (b) an adjective following 0 or more adjectives following a noun is mapped to the first English supersense mention in $\hat{\mathbf{E}}$ containing some word aligned to a . Then, for each English supersense men-

	Coverage			Ann-A			Ann-B		
	Nouns	All Tokens	Mentions	P	R	F_1	P	R	F_1
Lexicon heuristics (§3.1)	8,058	33%	8,465	18%	8,407	32 55 16 29 21.6 37.9	29 53 15 27 19.4 35.6		
Unsupervised (§3.2)				20 59 16 48 17.5 52.6			14 56 10 39 11.6 45.9		
MT-in-the-middle (§3.3)	QCRI	14,401 59%	16,461 35%	12,861	34 65 27 50 29.9 56.4		36 64 28 51 31.6 56.6		
	cdec	14,270 58%	15,542 33%	13,704	37 69 31 57 33.8 62.4		38 67 32 56 34.6 61.0		
MTitM + Lex.	cdec	16,798 68%	18,461 40%	16,623		35 64 36 65 35.5 64.6	36 63 36 63 36.0 63.2		

Table 1: Supersense tagging results on the test set: coverage measures⁵ and gold-standard evaluation—exact labeled/unlabeled⁶ mention precision, recall, and F-score against each annotator. The last row is a hybrid: MT-in-the-middle followed by lexicon heuristics to improve recall. Best single-technique and best hybrid results are bolded.

tion, all its mapped Arabic words are grouped into a single mention and the supersense category for that mention is projected. Figure 2 illustrates this procedure. The **cdec** system provides word alignments for its translations derived from the training data; whereas **QCRI** only produces phrase-level alignments, so for every aligned phrase pair $\langle \bar{a}, \bar{e} \rangle \in z$, we consider every word in \bar{a} as aligned to every word in \bar{e} (introducing noise when English supersense mention boundaries do not line up with phrase boundaries).

4 Experiments and Analysis

Table 1 compares the techniques (§3) for full Arabic supersense tagging.⁷ The number of nouns, tokens, and mentions covered by the automatic tagging is reported, as is the mention-level evaluation against human annotations. The evaluation is reported separately for the two annotators in the dataset.

With heuristic lexicon lookup, 18% of the tokens are marked as part of a nominal supersense mention. Both labeled and unlabeled mention recall with this method are below 30%; labeled precision is about 30%, and unlabeled mention precision is above 50%. From this we conclude that the biggest problems are (a) out-of-vocabulary items and (b) poor semantic disambiguation of in-vocabulary items.

The unsupervised sequence tagger does even worse on the labeled evaluation. It has some success at *detecting* supersense mentions—unlabeled recall is substantially improved, and unlabeled precision is

⁵The unsupervised evaluation greedily maps clusters to tags, separately for each version of the test set; coverage numbers thus differ and are not shown here.

⁶Unlabeled tagging refers to noun chunk *detection* only.

⁷It was produced in part using the `chunkeval.py` script: see <https://github.com/nschneid/pyutil>

slightly improved. But it seems to be much worse at assigning semantic categories; the number of labeled true positive mentions is actually *lower* than with the lexicon-based approach.

MT-in-the-middle is by far the most successful single approach: both systems outperform the lexicon-only baseline by about 10 F_1 points, despite many errors in the automatic translation, English tagging, and projection, as well as underlying linguistic differences between English and Arabic. The baseline’s unlabeled recall is doubled, indicating substantially more nominal expressions are detected, in addition to the improved labeled scores.

We further tested simple **hybrids** combining the lexicon-based and MT-based approaches. Applying MT-in-the-middle first, then expanding token coverage with the lexicon improves recall at a small cost to precision (table 1, last row). Combining the techniques in the reverse order is slightly worse than MT-based projection without consulting the lexicon.

MT-in-the middle improves upon the lexicon-only baseline, yet performance is still dwarfed by the supervised English tagger (at least in the SemCor evaluation; see §2), and also well below the 70% inter-annotator F_1 reported by Schneider et al. (2012). We therefore examine the weaknesses of our approach for Arabic.

4.1 MT for Projection

In analyzing our projection framework, we performed a small-scale MT evaluation with the Wikipedia data. Reference English translations for 140 Arabic Wikipedia sentences—5 per article in the corpus—were elicited from a bilingual linguist. Table 2 compares the two systems under three standard metrics of overall sentence translation quality.⁸

⁸BLEU (Papineni et al., 2002); METEOR (Banerjee and Lavie, 2005; Lavie and Denkowski, 2009), with default options;

ت تكون الذرة من سحابة من الشحنات السالبة (الإلكترونات) تحوم حول نواة موجة الشحنة صغيرة جداً في الوسط .

QCRI: *corn* consists of a negative *shipments* (*electron*) hovering around the *nucleus* of the *shipment*) are very small in the *center* . (3/6)

cdec: The *corn* is composed of negative *shipments* (*electronics*) cloud hovering over the *nucleus* of a very small positive *shipment* in the *center* . (2/6)

تأهلت البرتغال للنهائيات بعتيبي السهولة ، فالبرتغال لم تهزم طوال مشوار التصفيات .

QCRI: *Portugal* qualified for the *finals* very easily , *Portugal* defeated throughout the *mission liquidations* . (3/5)

cdec: *Portugal* qualified easily for the *finals* , *Portugal* unbeaten throughout the *journey* . (3/4)

Figure 3: Example Arabic inputs and the outputs of the two MT systems, with lexical projection precision ratios.

While the resulting number of sentences with references is far from ideal and there is only one reference translation for each, all three measures favor **QCRI**.

For a targeted measure of *lexical* translation quality of noun expressions, we elicited acceptability judgments from a bilingual annotator for translated and supersense-projected phrases. Given each MT system output (for the same 140 sentences) in which mentions predicted by the English supervised tagger were highlighted, along with the Arabic source sentence, the judge was asked for each English mention whether it was a valid translation.⁹ We call this **lexical projection precision**. Figure 3 shows examples, and the last column of table 2 gives overall statistics. Upwards of 90% of the lexical translations were accepted; as with the automatic MT measures, **QCRI** slightly outperforms **cdec** (especially in the technology and sports domains¹⁰). Of the problematic lexical translations, some are almost certainly domain effects: e.g., *corn* or *maize* instead of *atom*. Others are more nuanced, e.g., *shipments* for *charges* and *electronics* for *electrons*. Transliteration errors included *IMAX* in place of *EMACS* and *genoa lynx* for *GNU Linux*. However, lexical projection precision seems to be a relatively small part of the problem, especially considering that not all translation errors lead to supersense tagging errors.

Lexical projection *recall* was not measured, but noun token coverage (see table 1) is instructive. Most noun tokens ought to be tagged; 77% is the noun coverage rate in the gold standard. In table 1,

and translation edit rate (TER) (Snover et al., 2006)

⁹The judge did not see alignments or supersense categories.

¹⁰For technology articles, the differences in F_1 scores between the two systems were 6.1 and 4.2 for **Ann-A** and **Ann-B**, respectively. For sports the respective differences were 4.3 and 4.4. In the other domains the differences never exceeded 3.3. Interestingly, this is the only generalization about topical domain performance we were able to find that holds across annotators and systems, in contrast with the stark topical effects observed by Mohit et al. (2012) for NER.

	BLEU	METEOR	TER	Lex. Prec.
QCRI	32.86	32.10	0.46	91.9%
cdec	28.84	31.38	0.49	90.0%

Table 2: MT quality measures comparing the two systems over 140 sentences. The first three are automatic measures with 1 reference translation. For the fourth, a bilingual judged the translation acceptability of phrases that were identified as supersense mentions by the English tagger (**lexical projection precision**). noun coverage gains track overall improvements.

If **QCRI** produces better translations, why is **cdec** more useful for supersense tagging? As noted in §3.3, **cdec** gives word-level alignments (even when the decoder uses large phrasal units for translation), allowing for more precise projections.¹¹ We suspect this is especially important in light of findings that larger phrase sizes are indicative of better translations (Gamon et al., 2005), so these are exactly the cases where we expect the translations to be valuable.

5 Conclusion

To our knowledge, this is the first study of automatic Arabic supersense tagging. We have shown empirically that an MT-in-the-middle technique is most effective of several approaches that do not require labeled training data. Analysis sheds light on several challenges that would need to be overcome for better Arabic lexical semantic tagging.

Acknowledgments

We thank Wajdi Zaghouani for the translation of the Arabic Wikipedia MT set, Francisco Guzman and Preslav Nakov for the output of QCRI’s MT system, and Waleed Ammar and anonymous reviewers for their comments. This publication was made possible by grant NPPR-08-485-1-083 from the Qatar National Research Fund (a member of the Qatar Foundation). The statements made herein are solely the responsibility of the authors.

¹¹Our experiments use **QCRI** as an off-the-shelf system. As a reviewer notes, it could be retrained to produce word-level alignments, which would likely improve the accuracy of supersense tag projection.

Zipfian corruptions for robust POS tagging

Anders Søgaard

Center for Language Technology
University of Copenhagen
soegaard@hum.ku.dk

Abstract

Inspired by robust generalization and adversarial learning we describe a novel approach to learning structured perceptrons for part-of-speech (POS) tagging that is less sensitive to domain shifts. The objective of our method is to minimize average loss under random distribution shifts. We restrict the possible target distributions to mixtures of the source distribution and random Zipfian distributions. Our algorithm is used for POS tagging and evaluated on the English Web Treebank and the Danish Dependency Treebank with an average 4.4% error reduction in tagging accuracy.

1 Introduction

Supervised learning approaches have advanced the state of the art on a variety of tasks in natural language processing, often resulting in systems approaching the level of inter-annotator agreement on in-domain data, e.g. in POS tagging, where Shen et al. (2007) report a tagging accuracy of 97.3%. However, performance of state-of-the-art supervised systems is known to drop considerably on out-of-domain data. State-of-the-art POS taggers trained on the Penn Treebank (Marcus et al., 1993) mapped to Google’s universal tag set (Petrov et al., 2011) achieve tagging accuracies in the range of 89–91% on Web 2.0 data (Petrov and McDonald, 2012).

To bridge this gap we may consider using semi-supervised or transfer learning methods to adjust to new target domains (Blitzer et al., 2006; Daume III, 2007), pooling unlabeled data from those domains. However, in many applications this is not possible.

If we want to provide an online service or design a piece of software with many potential users covering a wide range of use cases, we do not know the target domain in advance. This is the usual problem of *robust* learning, but in this paper we describe a novel learning algorithm that goes beyond robust learning by making various assumptions about the difference between the source domain and the (unknown) target domain. Under these assumptions we can minimize average loss under (all possible or a representative sample of) domain shifts. We evaluate our approach on two recently introduced cross-domain POS tagging datasets.

Our approach is inspired by work in robust generalization (Ben-Tal and Nemirovski, 1998; Trafalis and Gilbert, 2007) and adversarial learning (Globerson and Roweis, 2006; Dekel and Shamir, 2008; Søgaard and Johannsen, 2012). Our approach also bears similarities to feature bagging (Sutton et al., 2006). Sutton et al. (2006) noted that in learning of linear models useful features are often swamped by correlating, but more indicative features. If the more indicative features are absent in the target domain due to out-of-vocabulary (OOV) effects, we are left with the swamped features which were not updated properly. This is, indirectly, the problem solved in adversarial learning with corrupted data points. Adversarial learning can also be seen as a way of averaging exponentially many models (Hinton et al., 2012).

Adversarial learning techniques have been developed for security-related learning tasks, e.g. where systems need to be robust to failing sensors. We also show how we can do better than straight-forward ap-

plication of adversarial learning techniques by making a second assumption about our data, namely that domains are mixtures of Zipfian distributions over our features. Similar assumptions have been made before in computational linguistics, e.g. by Goldberg and Elhadad (2008).

2 Approach overview

In this paper we consider the structured perceptron (Collins, 2002) – with POS tagging as our practical application. The structured perceptron is prone to feature swamping (Sutton et al., 2006), and we want to prevent that using a technique inspired by adversarial learning (Globerson and Roweis, 2006; Dekel and Shamir, 2008). The modification presented here to the structured perceptron only affects a single line of code in a publicly available implementation (see below), but the consequences are significant.

Online adversarial learning (Søgaard and Johannsen, 2012), briefly, works by sampling random corruptions of our data, or random feature deletions, in the learning phase. A discriminative learner seeing corrupted data points with missing features will not update part of the model and will thus try to find a decision boundary classifying the training data correctly relying on the remaining features. This decision boundary may be very different from the decision boundary found otherwise by the discriminative learner. If we sample enough corruptions, the model learned from the corrupted data will converge on the model minimizing average loss over all corruptions (Dekel and Shamir, 2008).

Example Consider the plot in Figure 1. The solid line with no stars (2d-fit) is the SVM fit in two dimensions, while the dashed line is what that fit amounts to if the feature x is missing in the target. The solid line with stars (1d-fit) is our fit if we could predict the missing feature, training an SVM only with the y feature. The 1d-fit decision boundary only misclassifies a single data point compared to the original fit which misclassifies more than 15 negatives with the x feature missing.

The plot thus shows that the best fit in m dimensions is often not the best in $< m$ dimensions. Consequently, if we think there is a risk that features will be missing in the target, finding the best fit in m dimensions is not necessarily the best we can do. Of

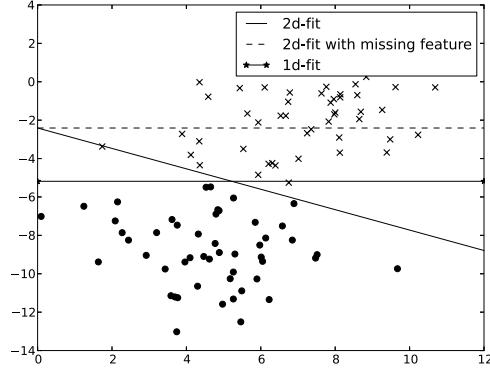

Figure 1: The best fit in m dimensions is often not the best in $< m$ dimensions.

course we do not know what features will be missing in advance. The intuition in adversarial learning is that we may obtain more robust decision boundaries by minimizing loss over a set of possible feature deletions. We extend this idea below, modeling not only OOV effects, but a broader class of distributional shifts.

3 Structured perceptron

The structured perceptron (Collins, 2002) models sequences as Markov chains of unobserved variables (POS), each emitting an observed variable (a word form). The structured perceptron is similar to the averaged perceptron (Freund and Schapire, 1999), except data points are sequences of vectors rather than just vectors. Consequently, the structured perceptron does not predict a class label but a sequence of labels (using Viterbi decoding). In learning we update the features at the positions where the predicted labels are different from the true labels. We do this by adding weight to features present in the correct solution and subtracting weight from features only present in the predicted solution. The generic averaged perceptron learning algorithm is presented in Figure 2. A publicly available and easy-to-modify Python reimplementation of the structured perceptron can be found in the LXMLS toolkit.¹ We use the LXMLS toolkit as our baseline with the default feature model, but use the PTB tagset rather than the Google tagset (Petrov et al., 2011) used by default in the LXMLS toolkit.

4 Minimizing loss under OOV effects

We will think of domain shifts as data point corruptions. Søgaard and Johannsen (2012) model domain shifts using binary vectors of length m where m is the size of our feature representation. Each vector then represents an expected OOV effect by encoding what features are (predicted to be) missing in the target data, i.e. the i th feature will be missing if the i th element of the binary vector is 0. However, since we are minimizing average loss under OOV effects it makes sense to restrict the class of vectors to encode OOV effects that we are likely to observe. This could, for example, involve fixing an expected rate of missing features or bounding it by some interval, or it could involve distinguishing between features that are likely to be missing in the target and features that are not. Here is what we do in this paper:

Rather than thinking of domain shifts as something that deletes features, we propose to see domain shifts as something making certain features less likely to occur in our data. We will in other words simulate *soft* OOV effects, rather than hard OOV effects. One way to think of this is as an importance weighting of our features. This section provides some intuition for using inverse Zipfian distributions as weight functions.

Say we are interested in making a model $\theta_{\mathcal{D}_1}$ learned from a known distribution \mathcal{D}_1 robust against the distributional differences between \mathcal{D}_1 and an unknown distribution \mathcal{D}_2 . These two distributions are somehow related to a distribution \mathcal{D}_0 (the underlying language distribution from which the domain distributions are sampled).

It is common to assume that linguistic distribu-

Figure 3: Z₃SP

tions follow power laws (Zipf, 1935; Goldberg and Elhadad, 2008). We will assume that $\mathcal{D}_1 = \mathcal{D}_0 \times \mathcal{Z}_1$ where \mathcal{Z}_1 is some Zipfian distribution. Say $\mathcal{D}_0 \sim \mathcal{Z}_0$ is the master Zipfian distribution of language \mathcal{L}_0 . If we assume that (otherwise independent) domains \mathcal{L}_1 and \mathcal{L}_2 follow products of Zipfians $\mathcal{Z}_0 \times \mathcal{Z}_1$ and $\mathcal{Z}_0 \times \mathcal{Z}_2$, we derive the following:

Say $\mathbf{w} = \theta_{\mathcal{Z}_0 \times \mathcal{Z}_1}$ is the model learned from the source data. The ideal model is $\mathbf{w}' = \theta_{\mathcal{Z}_0 \times \mathcal{Z}_2}$, but both Zipfians \mathcal{Z}_1 and \mathcal{Z}_2 are unknown. Since \mathcal{Z}_2 is unknown (and in many applications, we want to model several \mathcal{Z}_i), the overall best model we can hope for is $\mathbf{w}' = \theta_{\mathcal{Z}_0}$. \mathcal{Z}_0 is also unknown, but we can observe a finite sample $\mathcal{Z}_0 \times \mathcal{Z}_1$. Since the density of \mathcal{Z}_1 is directly related to the weights in \mathbf{w} , a crude estimate of $\theta_{\mathcal{Z}_0}$ would be $\mathbf{w}' \sim \mathbf{w} \frac{1}{\mathcal{Z}_1}$. Since we cannot observe \mathcal{Z}_1 , we instead try to minimize average loss under all hypotheses about \mathcal{Z}_1 .

In practice, we implement the idea of reweighting by random inverse Zipfian distributions (instead of binary vectors) in the following way: Passing through the data in averaged perceptron learning (Figure 2), we consider one data point at a time. In order to minimize loss in all possible domains, we need to consider all possible inverse Zipfian reweightings. This would be possible if we provided a convex formulation of the minimization problem along the lines of Dekel and Shamir (2008), but instead we randomly sample from a Zipfian and factor its inverse into our dataset. The parameter of the Zipfians is set (to 3) on development data (the EWT-email development data). The modified learning algorithm, Z₃SP, is presented in Figure 3.

5 POS tagging

POS tagging is the problem of assigning syntactic categories or POS to tokenized word forms in running text. Most approaches to POS tagging use supervised learning to learn sequence labeling models from annotated resources. The major resource for English is the Wall Street Journal (WSJ) sections of the English Treebank (Marcus et al., 1993). POS taggers are usually trained on Sect. 0–18 and evaluated on Sect. 22–24. In this paper we are not interested in in-domain performance on WSJ data, but rather in developing a robust POS tagger that is less sensitive to domain shifts than current state-of-the-art POS taggers and use the splits from a recent parsing shared task rather than the standard POS tagging ones.

6 Experiments

We train our tagger on Sections 2–21 of the WSJ sections of the English Treebank, in the OntoNotes 4.0 release. This was also the training data used in the experiments in the Parsing the Web (PTW) shared task at NAACL 2012.² In the shared task they used the coarse-grained Google tagset (Petrov et al., 2011). We believe this tagset is too coarse-grained for most purposes (Manning, 2011) and do experiments with the original PTB tagset instead.

Our evaluation data comes from the English Web Treebank (EWT),³ which was also used in the PTW shared task. The EWT contains development and evaluation data for five domains: answers (from Yahoo!), emails (from the Enron corpus), BBC newsgroups, Amazon reviews, and weblogs. In order not to optimize on in-domain data, we tune on the Email development data and evaluate on the remaining domains (the test sections).

The Web 2.0 data used for evaluation contains a lot of non-canonical language use. An example is the sentence *you r retarded.* from the Email section. The POS tagger finds no support for *r* as a verb in the training data, but needs to infer this from the context.

We also include experiments on the Danish Dependency Treebank (DDT) (Buch-Kromann, 2003), which comes with meta-data enabling us to single out four domains: newspaper, law, literature and

	SP	BSP	Z ₃ SP
EWT-answers	85.22	85.45	85.59
EWT-newsgroups	86.82	86.94	87.42
EWT-reviews	84.92	85.14	85.67
EWT-weblogs	87.00	87.06	87.39
DDT-law	92.38	92.80	93.35
DDT-lit	93.61	93.80	93.85
DDT-mag	94.71	94.44	94.68

Table 1: Results. BSP samples binary vectors with probabilities {0 : 0.1, 1 : 0.9}

magazines. We train our tagger on the newspaper data and evaluate on the remaining three sections.

6.1 Results

The results are presented in Table 1. We first note that improvements over the structured perceptron are statistically significant with $p < 0.01$ across all domains, except DDT-mag. We also note that using inverse Zipfian reweightings is better than using binary vectors in almost all cases. We believe that these are strong results given that we are assuming *no* knowledge of the target domain, and our modification of the learning algorithm does not affect computational efficiency at training or test time. The average error reduction of Z₃SP over the structured perceptron (SP) is 8%. Since using inverse Zipfian reweightings seems more motivated for node potentials than for edge potentials, we also tried using BSP for edge potentials and Z₃SP for node potentials. This mixed model achieved 93.70, 93.91 and 94.35 on the DDT data, which on average is slightly better than Z₃SP.

7 Conclusions

Inspired by robust generalization and adversarial learning we introduced a novel approach to learning structured perceptrons for sequential labeling, which is less sensitive to OOV effects. We evaluated our approach on POS tagging data from the EWT and the DDT with an average 4.4% error reduction over the structured perceptron.

A Multi-Dimensional Bayesian Approach to Lexical Style

Abstract

We adapt the popular LDA topic model (Blei et al., 2003) to the representation of stylistic lexical information, evaluating our model on the basis of human-interpretability at the word and text level. We show, in particular, that this model can be applied to the task of inducing stylistic lexicons, and that a multi-dimensional approach is warranted given the correlations among stylistic dimensions.

1 Introduction

In language, stylistic variation is a reflection of various contextual factors, including the backgrounds of and relationship between the parties involved. Although in the context of prescriptive linguistics (Strunk and White, 1979), style is often assumed to be a matter of aesthetics, the stylistic intuitions of language users are inextricably linked to the conventions of register and genre (Biber and Conrad, 2009). Intentional or not, stylistic differences play a role in numerous NLP tasks. Examples include genre classification (Kessler et al., 1997), author profiling (Garera and Yarowsky, 2009; Rosenthal and McKeown, 2011), social relationship classification (Peterson et al., 2011), sentiment analysis (Wilson et al., 2005), readability classification (Collins-Thompson and Callan, 2005), and text generation (Hovy, 1990; Inkpen and Hirst, 2006). Following the classic work of Biber (1988), computational modeling of style has often focused on textual statistics and the frequency of function words and syntactic categories. When content words are considered, they are often limited to manually-constructed lists (Argamon

et al., 2007), or used as individual features for supervised classification, which can be confounded by topic (Petrenz and Webber, 2011) or fail in the face of lexical variety. Our interest is models that offer broad lexical coverage of human-identifiable stylistic variation.

Research most similar to ours has focused on classifying the lexicon in terms of individual aspects relevant to style (e.g. formality, specificity, readability) (Brooke et al., 2010; Pan and Yang, 2010; Kidwell et al., 2009) and a large body of research on the induction of polarity lexicons, in particular from large corpora (Turney, 2002; Kaji and Kitsuregawa, 2007; Velikovich et al., 2010). Our work is the first to represent multiple dimensions of style in a single statistical model, adapting latent Dirichlet allocation (Blei et al., 2003), a Bayesian ‘topic’ model, to our stylistic purposes; as such, our approach also follows on recent interest in the interpretability of topic-model topics (Chang et al., 2009; Newman et al., 2011). We show that our model can be used for acquisition of stylistic lexicons, and we also evaluate the model relative to theories of register variation and the expected stylistic character of particular genres.

2 Model

2.1 Linguistic foundations

In English manuals of style and other prescriptivist texts (Fowler and Fowler, 1906; Gunning, 1952; Follett, 1966; Strunk and White, 1979; Kane, 1983; Hayakawa, 1994), writers are urged to pay attention to various aspects of lexical style, including elements such as clarity, familiarity, readability, for-

mality, fanciness, colloquialness, specificity, concreteness, objectivity, and naturalness; these stylistic categories reflect common aesthetic judgments about language. In descriptive studies of register, some researchers have posited a few fixed styles (Joos, 1961) or a small, discrete set of situational constraints which determine style and register (Crystal and Davy, 1969; Halliday and Hasan, 1976); by contrast, the applied approach of Biber (1988) and theoretical framework of Leckie-Tarry (1995) offer a more continuous interpretation of register variation.

In Biber's approach, functional dimensions such as *Involved vs. Informational*, *Argumentative vs. Non-argumentative*, and *Abstract vs. non-Abstract* are derived in an unsupervised manner from a mixed-genre corpus, with the labels assigned depending on where features (a small set of known indicators of register) and genres fall on each spectrum. The theory of Leckie-Tarry posits a single main cline of register with one pole (the oral pole) reflecting a full reliance on the context of the linguistic situation, and the other (the literate pole) reflecting a reliance on cultural knowledge. The more specific elements of register are represented as subclines which are strongly influenced by this main cline, creating probabilistic relationships between related dimensions (Birch, 1995).

For the present study, we have chosen 3 dimensions (6 styles) which are clearly represented in the lexicon, which are discussed often in the relevant literature, and which fit well into the Leckie-Tarry conception of related subclines: colloquial vs. literary, concrete vs. abstract, and subjective vs. objective. In addition to a negative correlation between opposing styles, we also expect a positive correlation between stylistic aspects that tend toward the same main pole, situational (i.e. colloquial, concrete, subjective) or cultural (i.e. literary, abstract, objective). These correlations can potentially interfere with accurate lexical acquisition.

2.2 Implementation

Our main model is an adaption of the popular latent Dirichlet allocation topic model (Blei et al., 2003), with each of the 6 styles corresponding to a topic. Briefly, latent Dirichlet allocation (LDA) is a generative Bayesian model: for each document d , a distribution of topics θ_d is drawn from a Dirichlet prior

(with parameter α). For each topic z , there is a probability distribution β_z^1 corresponding to the probability of that topic generating any given word in the vocabulary. Words in document d are generated by first selecting a topic z randomly according to θ_d , and then randomly selecting a word w according to β_z . An extension of LDA, the correlated topic model (CTM) (Blei and Lafferty, 2007), supposes a more complex representation of topics: given a matrix Σ representing the covariance between topics and μ representing the means, for each document a topic distribution η (analogous to θ) is drawn from the logistic normal distribution. Given a corpus, good estimates for the relevant parameters can be derived using Bayesian inference.

For both LDA and CTM we use the original variational Bayes implementation of Blei. Variational Bayes (VB) works by approximating the true posterior with a simpler distribution, minimizing the Kullback-Leibler divergence between the two through iterative updates of specially-introduced free variables. The mathematical and algorithmic details are omitted here; see Blei et al. (2003; 2007). Our early investigations used an online, batch version of LDA (Hoffman et al., 2010), which is more appropriate for large corpora because it requires only a single iteration over the dataset. We discovered, however, that batch models were markedly inferior to more traditional models for our purposes because the influence of the initial model diminishes too quickly; here, we need particular topics in the model to correspond to particular styles, and we accomplish this by seeding the model with known instances of each style (see Section 3). Specifically, our initial β consists of distributions where the entire probability mass is divided amongst the seeds for each corresponding topic, and a full iteration over the corpus occurs before β is updated. Typically, LDA iterates over the corpus until a convergence requirement is met, but in this case this is neither practical (due to the size of our corpus) nor necessarily desirable; the diminishing effects of the initial seeding means that the model may not stabilize, in terms of its likelihood, until after it has shifted away from our desired stylistic dimensions towards some other

¹Some versions of LDA smooth this distribution using a Dirichlet prior; here, though, we use the original formulation from Blei (2003), which does not.

variation in the data. Therefore, we treat the optimal number of iterations as a variable to investigate.

The model is trained on a 1 million text portion of the 2009 version of the ICWSM Spinn3r dataset (Burton et al., 2009), a corpus of blogs we have previously used for formality lexicon induction (Brooke et al., 2010). Since our method relies on co-occurrence, we followed our earlier work in using only texts with at least 100 different word types. All words were tokenized and converted to lower-case, with no further lemmatization. Following Hoffman et al. (2010), we initialized the α of our models to $1/k$ where k is the number of topics. Otherwise we used the default settings; when they overlap they were identical for the LDA and CTM models.

3 Lexicon Induction

Our primary evaluation is based on the stylistic induction of held-out seed words. The words were collected from various sources by the first author and further reviewed by the second; we are both native speakers of English with significant experience in English linguistics. Included words had to be clear, extreme members of their stylistic category, with little or no ambiguity with respect to their style. The colloquial seeds consist of English slang terms and acronyms, e.g. *cuz*, *gig*, *asshole*, *lol*. The literary seeds were primarily drawn from web sites which explain difficult language in texts such as the Bible and *Lord of the Rings*; examples include *behold*, *resplendent*, *amiss*, and *thine*. The concrete seeds all denote objects and actions strongly rooted in the physical world, e.g. *shove* and *lamppost*, while the abstract seeds all involve concepts which require significant human psychological or cultural knowledge to grasp, for instance *patriotism* and *nonchalant*. For our subjective seeds, we used an edited list of strongly positive and negative terms from a manually-constructed sentiment lexicon (Taboada et al., 2011), e.g. *gorgeous* and *depraved*, and for our objective set we selected words from sets of near-synonyms where one was clearly an emotionally-distant alternative, e.g. *residence* (for *home*), *jocular* (for *funny*) and *communicable* (for *contagious*). We filtered initial lists to 150 of each type, removing words which did not appear in the corpus or which occurred in multiple lists. For evaluation we

used stratified 3-fold crossvalidation, averaged over 5 different (3-way) splits of the seeds, with the same splits used for all evaluated conditions.

Given two sets of opposing seeds, we follow our earlier work in evaluating our performance in terms of the number of pairings of seeds from each set which have the expected stylistic relationship relative to each other (the guessing baseline is 0.5). Given a word w and two opposing styles (topics) p and n , we place w on the PN dimension according to the β of our trained model as follows:

$$PN_w = \frac{\beta_{pw} - \beta_{nw}}{\beta_{pw} + \beta_{nw}}$$

The normalization is important because otherwise more-common words would tend to have higher PN 's, when in fact the opposite is true (rare words tend to be more stylistically prominent). We then calculate pairwise accuracy as the percentage of pairs $\langle w_p, w_n \rangle$ ($w_p \in P_{seeds}$ and $w_n \in N_{seeds}$) where $PN_{w_p} > PN_{w_n}$. However, this metric does not address the case where the degree of a word in one stylistic dimension is overestimated because of its status on a parallel dimension. Two more-holistic alternatives are total accuracy, the percentage of seeds for which the highest β_{tw} is the topic t for which w is a seed (guessing baseline is 0.17), and the average rank of the correct t as ordered by β_{tw} (in the range 1–6, guessing baseline is 3.5); the latter is more forgiving of near misses.

We tested a few options which involved straightforward modifications to model training. Standard LDA produces all tokens in the document, but when dealing with style rather than topic, the number of times a word appears is much less relevant (Brooke et al., 2010). Our binary model assumes an LDA that generates types, not tokens.² A key comparison

²At the theoretical level, this move is admittedly problematic, since our LDA model is thus being trained under the assumption that texts with multiple instances of the same type can be generated, when of course such texts cannot by definition exist. We might address this by moving to Bayesian models with very different generative assumptions, e.g. the spherical topic model (Reisinger et al., 2010), but these methods involve a significant increase of computational complexity and we believe that on a practical level there are no real negatives associated with directly using a binary representation as input to LDA; in fact, we are avoiding what appears to be a much more serious problem, burstiness (Doyle and Elkan, 2009), i.e. the fact that

Model	Pairwise Accuracy (%)				Total Acc. (%)	Avg. Rank
	Lit/Col	Abs/Con	Obj/Sub	All		
guessing baseline	50.0	50.0	50.0	50.0	16.6.	3.50
basic LDA (iter 2)	94.3	98.8	93.0	95.4	55.0	1.79
binary LDA (iter 2)	96.2	98.9	93.5	96.2	57.7	1.74
combo binary LDA (iter 1)	95.4	99.2	93.3	96.0	53.1	1.86
binary CTM (iter 1)	96.3	99.0	89.6	95.0	53.0	1.87

Table 1: Model performance in lexical induction of seeds. Bold indicates best in column.

here is with a combined LDA model (*combo*), an amalgamation of three independently trained 2-topic models, one for each dimension; this tests our key hypothesis that training dimensions of style together is beneficial. Finally, we test against the correlated topic model (CTM), which offers an explicit representation of style correlation, but which has done poorly with respect to interpretability, despite offering better perplexity (Chang et al., 2009).

The results of the lexicon induction evaluation are in Table 1. Since the number of optimal iterations varies, we report the result from the best of the first five iterations, as measured by total accuracy; the best iteration is shown in parenthesis. In general, all the results are high enough—we are reliably above 90% for the pairwise task, and above 50% for the 6-way task—for us to conclude with some confidence that our model is capturing a significant amount of stylistic variation. As predicted, using words as boolean features had a net positive gain, consistent across all of our metrics, though this effect was not as marked as we have seen previously. The model with independent training of each dimension (*combo*) did noticeably worse, supporting our conclusion that a multidimensional approach is warranted here. Particularly striking is the much larger drop in overall accuracy as compared to pairwise accuracy, which suggests that the *combo* model is capturing the general trends but not distinguishing correlated styles as well. However, the most complex model, the CTM, actually does slightly worse than the *combo*, which was contrary to our expectations but nonetheless consistent with previous work on the interpretability of topic models. The performance of the full LDA models benefited from a second iteration,

traditional LDA is influenced too much by multiple instances of the same word.

but this was not true of *combo* LDA or CTM, and the performance of all models dropped after the second iteration.

An analysis of individual errors reveals, unsurprisingly, that most of the errors occur across styles on the same pole; by far the largest single common misclassification is objective words to abstract. Of the words that consistently show this misclassification across the runs, many of them, e.g. *animate*, *aperture*, *encircle*, and *constrain* are clearly errors (if anything, these words tend towards concreteness), but in other cases the word in question is arguably also fairly abstract, e.g. *categorize* and *predominant*, and might not be labeled an error at all. Other signs that our model might be doing better than our total accuracy metric gives it credit for: many of the subjective words that are consistently mislabeled as literary have an exaggerated, literary feel, e.g. *jubilant*, *grievous*, and *malevolent*.

4 Text-level Analysis

Our secondary analysis involved evaluating the θ 's of our best configuration (based on average pairwise and total accuracy) on other texts. After training, we carried out inference on the BNC corpus, averaging the resulting θ 's to see which styles are associated with which genres. Appearances of the seed terms for each model were disregarded during this process; only the induced part of the lexicon was used. The average differences relative to the mean across the various stylistic dimensions (as measured by the probabilities in θ) are given for a selection of genres in Table 2.

The most obvious pattern in table 2 is the dominance of the medium: all written genres are positive for our styles on the ‘cultural’ pole and negative for styles on the ‘situational’ pole and the opposite is

Genre	Styles					
	Literary	Abstract	Objective	Colloquial	Concrete	Subjective
News	+0.67	+0.50	+0.43	-0.31	-0.72	-0.57
Religious texts	+0.38	+0.38	+0.28	-0.27	-0.44	-0.32
Academic	+0.18	+0.29	+0.26	-0.20	-0.36	-0.18
Fiction	+0.31	+0.09	+0.02	-0.05	-0.12	-0.25
Meeting	-0.61	-0.54	-0.42	+0.35	+0.69	+0.55
Courtroom	-0.63	-0.53	-0.41	+0.32	+0.69	+0.57
Conversation	-0.56	-0.63	-0.54	+0.43	+0.80	+0.50

Table 2: Average differences from corpus mean of LDA-derived stylistic dimension probabilities for various genres in the BNC, in hundredths.

true for spoken genres. The magnitude of this effect is more difficult to interpret: though it is clear why fiction should sit on the boundary (since it contains spoken dialogue), the appearance of news at the written extreme is odd, though it might be due to the fact that news blogs are the most prevalent formal genre in the training corpus.

However, if we ignore magnitude and focus on the relative ratios of the stylistic differences for styles on the same pole, we can identify some individual stylistic effects among genres within the same medium. Relative to the other written genres, for instance, fiction is, sensibly, more literary and much less objective, while academic texts are much more abstract and objective; for the other two written genres, the spread is more even, though relative to religious texts, news is more objective. At the situational pole, fiction also stands out, being much more colloquial and concrete than other written genres. Predictably, if we consider again the ratios across styles, conversation is the most colloquial genre here, though the difference is subtle.

We carried out a correlation analysis of the LDA-reduced styles of all texts in the BNC and, consistent with the genre results in Table 2, found a strong positive correlation for all styles on the same main pole, averaging 0.83. The average negative correlation between opposing poles is even higher, -0.88. This supports the Leckie-Tarry formulation. The independence assumptions of the LDA model did not prevent strong correlations from forming between these distinct yet clearly interrelated dimensions; if anything, the correlations are stronger than we would have predicted.

5 Conclusion

We have introduced a Bayesian model of stylistic variation. Topic models like LDA are often evaluated using information-theoretic measures, but our emphasis has been on interpretability: at the word level we can use the model to induce stylistic lexicons which correspond to human judgement, and at the text level we can use it distinguish genres in expected ways. Another theme has been to offer evidence that indeed a multi-dimensional approach is strongly warranted: importantly, our results indicate that separate unidimensional models of style are inferior for identifying the core stylistic character of each word, and in our secondary analysis we found strong correlations among styles attributable to the situational/cultural dichotomy. However, an off-the-shelf model that integrates correlation among topics did not outperform basic LDA.

One advantage of a Bayesian approach is in the flexibility of the model: there are any number of other interesting possible extensions at both the θ and β levels of the model, including alternative approaches to correlation (Li and McCallum, 2006). Beyond Bayesian models, vector space and graphical approaches should be compared. More work is clearly needed to improve evaluation: some of our seeds could fall into multiple stylistic categories, so a more detailed annotation would be useful.

Abstract

The topic of a document can prove to be useful information for Word Sense Disambiguation (WSD) since certain meanings tend to be associated with particular topics. This paper presents an LDA-based approach for WSD, which is trained using any available WSD system to establish a sense per (Latent Dirichlet allocation based) topic. The technique is tested using three unsupervised and one supervised WSD algorithms within the SPORT and FINANCE domains giving a performance increase each time, suggesting that the technique may be useful to improve the performance of any available WSD system.

1 Introduction

Assigning each word its most frequent sense (MFS) is commonly used as a baseline in Word Sense Disambiguation (WSD). This baseline can be difficult to beat, particularly for unsupervised systems which do not have access to the annotated training data used to determine the MFS. However, it has also been shown that unsupervised methods can be used to identify the most likely sense for each ambiguous word type and this approach can be effective for disambiguation (McCarthy et al., 2004).

Knowledge of the domain of a document has been shown to be useful information for WSD. For example, Khapra et al. (2010) improve the performance of a graph-based WSD system using a small number of hand-tagged examples, but further examples would be required for each new domain. Agirre et al. (2009) automatically construct a thesaurus from texts in a domain which they use for

WSD. Unfortunately, performance drops when the thesaurus is combined with information from local context. Stevenson et al. (2011) showed that performance of an unsupervised WSD algorithm can be improved by supplementing the context with domain information. Cai et al. (2007) use LDA to create an additional feature for a supervised WSD algorithm, by inferring topics for labeled training data. Boyd-Graber et al. (2007) integrate a topic model with WordNet and use it to carry out disambiguation and learn topics simultaneously. Li et al. (2010) use sense paraphrases to estimate probabilities of senses and carry out WSD. Koeling et al. (2005) showed that automatically acquiring the predominant sense of a word from a corpus from the same domain increases performance (over using a predominant sense acquired from a balanced corpus), but their work requires a separate thesaurus to be built for each domain under investigation. Navigli et al. (2011) extracted relevant terms from texts in a domain and used them to initialize a random walk over the WordNet graph.

Our approaches rely on a one sense per topic hypothesis (Gale et al., 1992), making use of topics induced using LDA – we present three novel techniques for exploiting domain information that are employable with any WSD algorithm (unsupervised or supervised). Using any WSD algorithm, we create a sense per topic distribution for each LDA topic, and the classification of a new document into a topic determines the sense distribution of the words within. Once a sense per topic distribution is obtained, no further WSD annotation of new texts is required. Instead of fixing domains, our technique

allows these to be dynamically created (using LDA) and we use four existing publicly available WSD algorithms (three unsupervised and one supervised) to show that our technique increases their performance with no changes to the original algorithm.

Section 2 briefly introduces LDA, while Section 3 describes our three techniques for adding domain information to a WSD algorithm. The WSD algorithms employed in the evaluation of our techniques are described in Section 4 with experiments and results in Section 5. Section 6 draws our conclusions and presents avenues for future work.

2 Latent Dirichlet allocation

LDA (Blei et al., 2003) is a widely used topic model, which views the underlying document distribution as having a Dirichlet prior. We employ a publicly available implementation of LDA¹ which has two main execution methods: parameter estimation (model building) and inference for new data (classification of a new document). Both invocation methods produce θ distributions (the topic-document distributions, i.e., $p(t_i|d)$ for t_i topics and d document), and ϕ distributions (word-topic distributions, i.e., $p(w_j|t_i)$ for words w_j). The parameter estimation phase also creates a list of n words most likely to be associated with each topic.

3 Using LDA for WSD

The underlying idea of our approach lies in deriving a document invariant sense distribution for each topic, $p(w, s|t)$. Once this word sense distribution is obtained, the underlying WSD algorithm is never needed again. We make the assumption that while the WSD algorithm may not be able to select the correct sense within an individual text due to insufficient domain information, the topic specific sense will be selected with a greater frequency over all documents pertaining to a topic, and thus the probability distributions over senses generated in this fashion should be more accurate.

Only the distribution $p(w, s|t)$ is dependent on an underlying WSD algorithm – once this distribution is obtained, it can be combined with the LDA derived θ distribution, $p(t|d_{new})$, to compute the de-

sired word sense distribution within the new document d_{new} :

$$p(w, s|d_{new}) = \sum_t p(w, s|t)p(t|d_{new})$$

Sections 3.1, 3.2 and 3.3 describe three different methods for deriving $p(w, s|t)$, and we investigate the performance changes with different WSD algorithms: two versions of Personalized PageRank, described in Section 4.1, a similarity based WSD system outlined in Section 4.2, and a supervised graph based algorithm (Section 4.3).

3.1 Sense-based topic model (SBTM)

In its usual form, the ϕ distribution generated by LDA merely provides a word-topic distribution ($p(w|t)$). However, we modify the approach to directly output $p(w, s|t)$, but we remain able to classify (non WSD annotated) new text. The topic model is built from documents annotated with word senses using the chosen WSD algorithm.² The topic model created from this data is based on word-sense combinations and thus ϕ represents $p(w, s|t)$.

To classify new (non sense disambiguated) documents, the model is transformed to a word (rather than word-sense) based for: i.e., the $p(w, s|t)$ probabilities are summed over all senses of w to give resulting probabilities for the wordform. A new document, d_{new} , classified using this system gives rise to a number of distributions, including the probability of a topic given a document distribution ($p(t|d_{new})$).

3.2 Linear equations (LinEq)

If the topic model is created directly from wordforms, we can use the known probabilities $p(s|w, d)$ (obtained from the WSD algorithm), and $p(t|d)$ (from the LDA classifier) to yield an overdetermined system of linear equations of the form

$$p(s|w, d) = \sum_t p(s|w, t)p(t|d)$$

We use an existing implementation of linear least squares to find a solution (i.e. $p(s|w, t)$ for each t)

²It is not crucial to word sense disambiguate all words in the text – a word can be passed to LDA in either its word-sense, disambiguated, form or in its raw form. While we do not attempt this in our work, it would be possible to build a model specifically for noun senses of a word, by including noun senses of the word and leaving the raw form for any non-noun occurrences.

¹<http://jgibllda.sourceforge.net/>.

by minimizing the sum of squared differences between the data values and their corresponding modeled values, i.e., minimizing:

$$\sum_d \left(p(s|w, d) - \sum_t p(s|w, t)p(t|d) \right)^2$$

3.3 Topic words (TopicWord)

The techniques presented in Sections 3.1 and 3.2 both require the WSD algorithm to annotate a reasonably high proportion of the data used to build the topic model. For systems which do not rely on word order, an alternative based on the most likely words per topic is possible: the LDA algorithm generates ϕ , a word-topic distribution. It is therefore possible to extract the most likely words per topic.

To acquire a sense-topic distribution for a topic t , each target word w is included in a bag of words which includes the most likely words for t and the unsupervised WSD algorithm is executed (w is added to the list if t does not already contain it). This technique is not applicable to non bag-of-words WSD algorithms, as structure is absent.

4 Word Sense Disambiguation

Only the topic model documents need to be automatically annotated with the chosen WSD system, after this, the WSD system is never applied again (an LDA classification determines the sense distribution) – this is particularly useful for supervised system which frequently have a long execution time. We explore three different types of WSD system: two versions of a knowledge base based system (Section 4.1), an unsupervised system (Section 4.2) and a supervised system (Section 4.3).

4.1 Personalized PageRank (ppr and w2w)

We use the freely available³ Personalized PageRank algorithm (Agirre and Soroa, 2009) with WordNet 3.0. In Section 5 we present results from two options of the Personalized PageRank algorithm: *ppr*, which performs one PageRank calculation for a whole content, and *w2w*, which performs one PageRank calculation for every word in the context to be disambiguated.

³Available from <http://ixa2.si.ehu.es/ukb/>

4.2 WordNet similarity (sim)

We also evaluated another unsupervised approach, the Perl package WordNet::SenseRelate::AllWords (Pedersen and Kolhatkar, 2009), which finds senses of each word in a text based on senses of the surrounding words. The algorithm is invoked with Lesk similarity (Banerjee and Pedersen, 2002).

4.3 Vector space model (vsm)

An existing vector space model (VSM) based state-of-the-art supervised WSD system with features derived from the text surrounding the ambiguous word (Stevenson et al., 2008) is trained on Semcor (Miller et al., 1993).⁴

5 Experiments

5.1 Data

The approach is evaluated using a domain-specific WSD corpus (Koeling et al., 2005) which includes articles from the FINANCE and SPORTS domains taken from the Reuters corpus (Rose et al., 2002). This corpus contains 100 manually annotated instances (from each domain) for 41 words.⁵

The word-sense LDA topic models are created from 80,128 documents randomly selected from the Reuters corpus (this corresponds to a tenth of the entire Reuters corpus). LDA can abstract a model from a relatively small corpus and a tenth of the Reuters corpus is much more manageable in terms of memory and time requirements, particularly given the need to word sense disambiguate (some part of) each document in this dataset.⁶

⁴A version of Semcor automatically transformed to WordNet 3.0 available from <http://www.cse.unt.edu/~rada/downloads.html#semcor> was used in this work.

⁵Unfortunately, the entire domain-specific sense disambiguated corpus could not be used in the evaluation of our system, as the released corpus does not link each annotated sentence to its source document, and it is not always possible to recover these; approximately 87% of the data could be used. This dataset is available at http://staffwww.dcs.shef.ac.uk/people/J.Preiss/downloads/source_texts.tgz

⁶In this work, all 80,128 documents were word sense disambiguated. However, it would be possible to restrict this set to a smaller number, as long as a reliable distribution of word senses per topic could be obtained.

	ppr	w2w	sim	vsm
Baseline	36	41	23	27
SBTM model	39	43	30	31
LinEq	41	44	—	33
TopicWord	38	41	—	—

Table 1: Summary of results based on 150 topics

5.2 Results

Table 1 presents the performance results for the four WSD algorithms based on 150 topics. A range of topic values was explored, and 150 topics yielded highest performance, though the variance between the performance based on different topics (ranging from 50 to 250) was very small (0.4% difference to the average performance with 250 topics, and 3% with 50). The performance shown indicates the precision (number correct / number attempted). Recall is 100% in all cases.

The similarity algorithm (sim) fails on certain documents and therefore the linear equations technique could not be applied. The topic word technique (TopicWord) could not be evaluated using the similarity algorithm, due to the high sensitivity to word order within the test paragraph. In addition, the topic words technique is not applicable to supervised systems, due to its reliance on structured sentences. The best results with this technique were obtained with including all likely words with probabilities exceeding 0.001 and smoothing of 0.1 of the topic document distribution.

Using a Wilcoxon signed-rank test, the results were found to be significantly better over the original algorithms in every case (apart from TopicWords). Both the WordNet similarity (sim) and the VSM approach (vsm) have a lower performance than the two PPR based WSD algorithms (ppt and w2w). For example, sim assigns the same (usually incorrect) sense to all occurrences of the word *tie*, while both PPR based algorithms detect an obvious domain change. The vsm approach suffers from a lack of training data (only a small number of examples of each word appear in Semcor), while sim does not get enough information from the context.

As an interesting aside, the topic models based on word-sense combinations, as opposed to wordforms only, are more informative with less overlap. Exam-

ining the word *stake* annotated with the *w2w* WSD algorithm: only topic 1 contains *stake* among the top 12 terms associated with a topic in the word-sense model, while 10 topics are found in the wordform topic model. Table 2 shows the top 12 terms associated with topics containing the word *stake*.

Topic	Word-based model
39	say, will, company, share, deal, european, buy, agreement, stake , new, hungary, oil
63	say, share, united, market, offer, stock, union, percent, stake , will, point, new
90	say, will, fund, price, london, sell, stake , indonesia, court, investment, share, buy
91	say, market, bond, russia, press, party, stake , russian, country, indonesia, new, election
97	say, million, bank, uk, percent, share, stake , world, will, year, central, british
113	say, will, percent, week, billion, last, italy, plan, stake , year, budget, czech
134	say, china, percent, hong, kong, official, stake , billion, report, buy, group, year

Table 2: The presence of *stake* within the word- and sense-based topic models

6 Conclusion

We present three unsupervised techniques based on acquiring LDA topics which can be used to improve the performance of a number of WSD algorithms. All approaches make use of topic information obtained using LDA and do not require any modification of the underlying WSD system. While the technique is dependent on the accuracy of the WSD algorithm, it consistently outperforms the baselines for all four different algorithms.

Abstract

Multi-Domain learning assumes that a single metadata attribute is used in order to divide the data into so-called domains. However, real-world datasets often have multiple metadata attributes that can divide the data into domains. It is not always apparent which single attribute will lead to the best domains, and more than one attribute might impact classification. We propose extensions to two multi-domain learning techniques for our *multi-attribute* setting, enabling them to simultaneously learn from several metadata attributes. Experimentally, they outperform the multi-domain learning baseline, even when it selects the single “best” attribute.

1 Introduction

Multi-Domain Learning (Evgeniou and Pontil, 2004; Daumé III, 2007; Dredze and Crammer, 2008; Finkel and Manning, 2009; Zhang and Yeung, 2010; Saha et al., 2011) algorithms learn when training instances are spread across many domains, which impact model parameters. These algorithms use examples from each domain to learn a general model that is also sensitive to individual domain differences.

However, many data sets include a host of metadata attributes, many of which can potentially define the domains to use. Consider the case of restaurant reviews, which can be categorized into domains corresponding to the cuisine, location, price range, or several other factors. For multi-domain learning, we should use the metadata attribute most likely to characterize a domain: a change in vocabulary (i.e. features) that most impacts the classification decision

(Ben-David et al., 2009). This choice is not easy. First, we may not know which metadata attribute is most likely to fit this role. Perhaps the location most impacts the review language, but it could easily be the price of the meal. Second, multiple metadata attributes could impact the classification decision, and picking a single one might reduce classification accuracy. Therefore, we seek multi-domain learning algorithms which can simultaneously learn from many types of domains (metadata attributes).

We introduce the *multi-attribute multi-domain* (MAMD) learning problem, in which each learning instance is associated with multiple metadata attributes, each of which may impact feature behavior. We present extensions to two popular multi-domain learning algorithms, FEDA (Daumé III, 2007) and MDR (Dredze et al., 2009). Rather than selecting a single domain division, our algorithms consider all attributes as possible distinctions and discover changes in features across attributes. We evaluate our algorithms using two different data sets – a data set of restaurant reviews (Chahuneau et al., 2012), and a dataset of transcribed speech segments from floor debates in the United States Congress (Thomas et al., 2006). We demonstrate that multi-attribute algorithms improve over their multi-domain counterparts, which can learn distinctions from only a single attribute.

2 MAMD Learning

In multi-domain learning, each instance \mathbf{x} is drawn from a domain d with distribution $\mathbf{x} \sim \mathcal{D}_d$ over a vectors space \mathbb{R}^D and labeled with a domain specific function f_d with label $y \in \{-1, +1\}$ (for binary classification). In multi-attribute multi-domain

(MAMD) learning, we have M metadata attributes in a data set, where the m th metadata attribute has K_m possible unique values which represent the domains induced by that metadata attribute. Each instance \mathbf{x}_i is drawn from a distribution $\mathbf{x}_i \sim \mathcal{D}_a$ specific to a set of attribute values \mathcal{A}_i associated with each instance. Additionally, each unique set of attributes indexes a function $f_{\mathcal{A}}$.¹ \mathcal{A}_i could contain a value for each attribute, or no values for any attribute (which would index a domain-agnostic “background” distribution and labeling function). Just as a domain can change a feature’s probability and behavior, so can each metadata attribute.

Examples of data for MAMD learning abound. The commonly used Amazon product reviews data set (Blitzer et al., 2007) only includes product types, but the original reviews can be attributed with author, product price, brand, and so on. Additional examples include congressional floor debate records (e.g. political party, speaker, bill) (Joshi et al., 2012). In this paper, we use restaurant reviews (Chahuneau et al., 2012), which have upto 20 metadata attributes that define domains, and congressional floor debates, with two attributes that define domains.

It is difficult to apply multi-domain learning algorithms when it is unclear which metadata attribute to choose for defining the “domains”. It is possible that there is a single “best” attribute to use for defining domains, one that when used in multi-domain learning will yield the best classifier. To find this attribute, one must rely on one’s intuition about the problem,² or perform an exhaustive empirical search over all attributes using some validation set. Both these strategies can be brittle, because as the nature of data changes over time so may the “best” domain distinction. Additionally, multi-domain learning was not designed to benefit from multiple helpful attributes.

We note here that Eisenstein et al. (2011), as well as Wang et al. (2012), worked with a “multifaceted topic model” using the framework of sparse additive generative models (SAGE). Both those models capture interactions between topics and multiple as-

pects, and can be adapted to the case of MAMD. While our problem formulation has significant conceptual overlap with the SAGE-like multifaceted topic models framework, our proposed methods are motivated from a fast online learning perspective.

A naive approach for MAMD would be to treat every unique set of attributes as a domain, including unique proper subsets of different attributes to account for the case of missing attributes in some instances.³ However, introducing an exponential number of domains requires a similar increase in training data, clearly an infeasible requirement. Instead, we develop multi-attribute extensions for two multi-domain learning algorithms, such that the increase in parameters is linear in the number of metadata attributes, and no special handling is required for the case where some metadata attributes might be missing from an instance.

Multi-Attribute FEDA The key idea behind FEDA (Daumé III, 2007) is to encode each domain using its own parameters, one per feature. FEDA maps a feature vector \mathbf{x} in \mathbb{R}^D to $\mathbb{R}^{D(K+1)}$. This provides a separate parameter sub-space for every domain $k \in 1 \dots K$, and also maintains a domain-agnostic shared sub-space. Essentially, each feature is duplicated for every instance in the appropriate sub-space of $\mathbb{R}^{D(K+1)}$ that corresponds to the instance’s domain. We extend this idea to the MAMD setting by using one parameter per attribute value. The original instance $\mathbf{x} \in \mathbb{R}^D$ is now mapped into $\mathbb{R}^{D(1+\sum_m K_m)}$; a separate parameter for each attribute value and a shared set of parameters. In effect, for every metadata attribute $a \in \mathcal{A}_i$, the original features are copied into the appropriate sub-space. This grows linearly with the number of metadata attribute values, as opposed to exponentially in our naive solution. While this is still substantial growth, each instance retains the same feature sparsity as in the original input space. In this new setup, FEDA allows an instance to contribute towards learning the shared parameters, and the attribute-specific parameters for all the attributes present on an instance. Just like multi-domain FEDA, any supervised learning algorithm can be applied to the transformed representation.

¹Distributions and functions that share attributes could share parameters.

²Intuition is often critical for learning and in some cases can help, such as in the Amazon product reviews data set, where product type clearly corresponds to domain. However, for other data sets the choice may be less clear.

³While we used a similar setup for formulating our problem, we did not rule out the potential for factoring the distributions.

Multi-Attribute MDR We make a similar change to MDR (Dredze et al., 2009) to extend it for the MAMD setting. In the original formulation, Dredze et al. used confidence-weighted (CW) learning (Dredze et al., 2008) for learning shared and domain-specific classifiers, which are combined based on the confidence scores associated with the feature weights. For training the MDR approaches in a multi-domain learning setup, they found that computing updates for the combined classifier and then equally distributing them to the shared and domain-specific classifiers was the best strategy, although it approximated the true objective that they aimed to optimize. In our multi-attribute setup confidence-weighted (CW) classifiers are learned for each of the $\sum_m K_m$ attribute values in addition to a shared CW classifier. At classification time, a combined classifier is computed for every instance. However, instead of combining the shared classifier and a *single* domain-specific classifier, we combine the shared CW classifier and $|\mathcal{A}_i|$ different attribute value-specific CW classifiers associated with \mathbf{x}_i . The combined classifier is found by minimizing the KL-divergence of the combined classifier with respect to each of the underlying classifiers.⁴

When learning the shared and domain-specific classifiers, we follow the best result in Dredze et al. and use the “averaged update” strategy (§7.3 in Dredze et al.), where updates are computed for the combined classifier, and are then distributed to the shared and domain-specific classifiers. MDR-U will indicate that the updates to the combined classifiers are *uniformly* distributed to the underlying shared and domain-specific classifiers.

Dredze et al. also used another scheme called “variance” to distribute the combined update to the underlying classifiers (§4, last paragraph in Dredze et al.) Their idea was to give a lower portion of the update to the underlying classifier that has higher variance (or in their terminology, “less confidence”) since it contributed less to the combined classifier. We refer to this as MDR-V. However, this conflicts with the original CW intuition that features with higher variance (lower confidence) should receive higher updates; since they are more in need of change. Therefore, we implemented a modified “variance” scheme, where the updates are dis-

tributed to the underlying classifiers such that higher variance features receive the larger updates. We refer to this as MDR-NV. We observed significant improvements with this modified scheme.

3 Experiments

To evaluate our multi-attribute algorithms we consider two datasets. First, we use two subsets of the restaurant reviews dataset (1,180,308 reviews) introduced by Chahuneau et al. (2012) with the goal of labeling reviews as positive or negative. The first subset (50K-RND) randomly selects 50,000 reviews while the second (50K-BAL) is a class-balanced sample. Following the approach of Blitzer et al. (2007), scores above and below 3-stars indicated positive and negative reviews, while 3-star reviews were discarded. Second, we use the transcribed segments of speech from the United States Congress floor debates (Convote), introduced by Thomas et al. (2006). The binary classification task on this dataset is that of predicting whether a given speech segment supports or opposes a bill under discussion in the floor debate.

In the WordSalad datasets, each restaurant review can have many metadata attributes, including a unique identifier, name (which may not be unique), address (we extract the zipcode), and type (Italian, Chinese, etc.). We select the 20 most common metadata attributes (excluding latitude, longitude, and the average rating).⁵ In the Convote dataset, each speech segment is associated with the political party affiliation of the speaker (democrat, independent, or republican) and the speaker identifier (we use bill identifiers for creating folds in our 10-fold cross-validation setup).

In addition to our new algorithms, we evaluate several baselines. All methods use confidence-weighted (CW) learning (Crammer et al., 2012).

BASE A single classifier trained on all the data, and which ignores metadata attributes and uses unigram features. For CW, we use the best-performing setting from Dredze et al. (2008) — the “variance” algorithm, which computes approximate but closed-form updates, which also lead to faster learning. Parameters are tuned over a validation set within each training fold.

⁴We also tried the l_2 distance method of Dredze et al. (2009) but it gave consistently worse results.

⁵Our method requires categorical metadata attributes, although real-valued attributes can be discretized.

	metadata	1-META	FEDA	MDR-U	MDR-V	MDR-NV

	1-TUNE	† 90.33 (± 0.10)	†‡ 90.70 (± 0.14)	89.13 (± 0.16)	†‡ 91.26 (± 0.08)
	1-MEAN	† 90.30 (± 0.06)	89.92 (± 0.07)	88.25 (± 0.07)	90.06 (± 0.08)

Table 2: Average accuracy (\pm standard error) using 10-fold cross-validation for methods that use all attributes, either directly (our proposed methods) or for selecting the “best” single attribute using one of the strategies described earlier. Formatting and significance symbols are the same as in Table 1.

META Identical to BASE with a unique bias feature added for each attribute value (Joshi et al., 2012).

1-META A special case of META where a unique bias feature is added *only for a single attribute*.

To use multi-domain learning directly, we could select a single attribute as the domain. We consider several strategies for picking this attribute and evaluate both FEDA and MDR in this setting.

1-MEAN Choose an attribute randomly, equivalent to the expected (mean) error over all attributes.

1-TUNE Select the best performing attribute on a validation set.

1-ORCL Select the best performing attribute on the *test* set. Though impossible in practice, this gives the oracle upper bound on multi-domain learning.

All experiments use ten-fold cross-validation. We report the mean accuracy, along with standard error.

4 Results

Table 1 shows the results of single-attribute multi-domain learning methods for the WordSalad datasets. The table shows the three best-performing metadata attributes (as decided by the highest accuracy among all the methods across all 20 metadata attributes). Clearly, several of the attributes can pro-

vide meaningful domains, which demonstrates that methods that can select multiple attributes at once are desirable. We also see that our modification to MDR (MDR-NV) works the best.

Table 3 shows the results of single-attribute multi-domain learning methods for the Convote dataset. The first observation to be made on this dataset is that neither the PARTY, nor the SPEAKER attribute individually achieve significant improvement over the META baseline, which uses both these attributes as features. This is in contrast with the results on the WordSalad dataset, where some attributes by themselves showed an improvement over the META baseline. Thus, this dataset represents a more challenging setup for our multi-attribute multi-domain learning methods — they need to exploit the two weak attributes simultaneously.

We next demonstrate multi-attribute improvements over the multi-domain baselines (Tables 2 and 4). For WordSalad datasets, our extensions that can use all metadata attributes simultaneously are consistently better than both the 1-MEAN and the 1-TUNE strategies (except for the case of the old variance scheme used by (Dredze et al., 2009)). For the skewed subset

metadata	1-META	FEDA	MDR-U	MDR-V	MDR-NV
NONE (BASE)			67.08 (± 1.74)		
ALL (META)			† 82.60 (± 1.95)		
PARTY	† 78.81 (± 1.47)	† 84.19 (± 2.44)	† 83.23 (± 2.48)	† 81.38 (± 2.22)	† 83.92 (± 2.31)
SPEAKER	† 77.49 (± 1.75)	† 82.88 (± 2.43)	† 78.32 (± 1.91)	62.43 (± 2.20)	† 72.26 (± 1.37)

Table 3: Convote: Average accuracy (\pm standard error) when using a single attribute at a time. Results that are *numerically the best* within a row are in **bold**. Results significantly better than BASE are marked with †, and better than META are marked with ‡. Significance is measured using a two-tailed paired t -test with $\alpha = 0.05$.

#attributes	FEDA	MDR-U	MDR-V	MDR-NV
MAMD	†‡ 85.71 (± 2.74)	† 84.12 (± 2.56)	50.44 (± 1.78)	†‡ 86.19 (± 2.49)
1-ORCL	† 84.77 (± 2.47)	† 83.88 (± 2.27)	† 81.38 (± 2.22)	† 83.92 (± 2.31)
1-TUNE	† 84.19 (± 2.44)	† 83.23 (± 2.48)	† 81.38 (± 2.22)	† 83.92 (± 2.31)
1-MEAN	† 83.53 (± 2.40)	† 80.77 (± 1.92)	† 71.91 (± 1.82)	† 78.09 (± 1.69)

Table 4: Convote: Average accuracy (\pm standard error) using 10-fold cross-validation for methods that use all attributes, either directly (our proposed methods) or for selecting the “best” single attribute using one of the strategies described earlier. Formatting and significance symbols are the same as in Table 3.

50K-RND, MAMD+FEDA is significantly better than 1-TUNE+FEDA; MAMD+MDR-U is significantly better than 1-TUNE+MDR-U; MAMD+MDR-NV is not significantly different from 1-TUNE+MDR-U. For the balanced subset 50K-BAL, a similar pattern holds, except that MAMD+MDR-NV is significantly better than 1-TUNE+MDR-NV. Clearly, our multi-attribute algorithms provide a benefit over existing approaches. Even with oracle knowledge of the test performance using multi-domain learning, we can still obtain improvements (FEDA and MDR-U in the 50K-BAL set, and all the Convote results, except MDR-V).

Although MAMD+MDR-NV is not significantly better than 1-TUNE+MDR-NV on the 50K-RND set, we found that in every single fold in our ten-fold cross-validation experiments, the “best” single metadata attribute decided using a validation set did not match the best-performing single metadata attribute on the corresponding test set. This shows the potential instability of choosing a single best attribute. Also, note that MDR-NV is a variant that we have proposed in the current work, and in fact for the earlier variant of MDR (MDR-U), as well as for FEDA, we do see significant improvements when using all metadata attributes. Furthermore, the computational cost of evaluating every metadata attribute independently to tune the single best metadata attribute can be high and often impractical. Our approach requires no such tuning. Finally, observe that for FEDA, the 1-TUNE strategy is not significantly different from 1-MEAN, which just randomly picks a single best metadata attribute. For MDR-U,

1-TUNE is significantly better than 1-MEAN on the balanced subset 50K-BAL, but not on the skewed subset 50K-RND.

As mentioned earlier, the Convote dataset is a challenging setting for our methods due to the fact that no single attribute is strong enough to yield improvements over the META baseline. In this setting, both MAMD+FEDA and MAMD+MDR-NV achieve a significant improvement over the META baseline, with MDR-NV being the best (though not significantly better than FEDA). Additionally, both of them are significantly better than their corresponding 1-TUNE strategies. This result further supports our claim that using multiple attributes in combination for defining domains (even when any single one of them is not particularly beneficial for multi-domain learning) is important.

5 Conclusions

We propose multi-attribute multi-domain learning methods that can utilize multiple metadata attributes simultaneously for defining domains. Using these methods, the definition of “domains” does not have to be restricted to a single metadata attribute. Our methods achieve a better performance on two multi-attribute datasets as compared to traditional multi-domain learning methods that are tuned to use a single “best” attribute.

Abstract

This opinion piece proposes that recent advances in opinion detection are limited in the extent to which they can detect important categories of opinion because they are not designed to capture some of the pragmatic aspects of opinion. A component of these is the perspective of the user of an opinion-mining system as to what an opinion really is, which is in itself a matter of opinion (metasubjectivity). We propose a way to define this component of opinion and describe the challenges it poses for corpus development and sentence-level detection technologies. Finally, we suggest that investment in techniques to handle metasubjectivity will likely bear costs but bring benefits in the longer term.

1 Introduction

Opinion mining, also known as sentiment analysis (Pang and Lee, 2008), is a relatively recent area of research in natural language processing. It has grown very quickly as a research area, developing around a small number of basic approaches. However, these approaches are based on particular definitions of opinion, assumptions about opinion expressions, and evaluation practices that we believe need to be expanded in order for sentiment analysis to reach new domains and applications.

We are not the first to express concern over the direction of sentiment analysis as a field. This paper seeks to further expand upon the views expressed in Alm (2011) that prevailing evaluation concepts in sentiment analysis limit the kinds of models we can build, particularly through the encouragement of a focus on “high-performing” systems.

The central thread that connects our view of the field is the idea that the basis of standard techniques and evaluation in information retrieval and extraction that underlie existing approaches needs to be rethought for applications that are inherently subjective and that the field needs to return to more theoretical groundwork. This will entail sacrificing some of the performance gains made in recent times, as well as potentially reducing the capacity for easily comparable research that has been gained by the rapid adoption of corpora that are very easily produced, shared, and used.

This problem is particularly relevant in the expansion of sentiment analysis techniques to areas such as market prediction (Bollen et al., 2010) and social science. In these areas, it is not enough to detect opinions in predefined areas of text or even to mine for the locations of opinions in large corpora, but it is necessary to be able to connect opinions across documents and to reconstruct the social networks that underlie social trends. Furthermore, it must be possible to do this in text that can have an arbitrary number of opinions intertwined in ways that go beyond the base case of product review text. This requires both additional consideration of the perspective of the user and attention to the finer-grained details of sentiment expression.

Do existing resources and techniques really reflect the ultimate goals and end-uses of fine-grained opinion-mining, particularly focusing on the sentential and sub-sentential levels? Consider an “ideal case” of a marketing director or a political campaign manager requesting a forecast of how a product or concept will unfold in the media and market. How do the present conceptions of opinion mining relate to this among other real-world problems of affect?

In the remainder of this position paper, we briefly describe three closely related issues in sentiment analysis that pertain to expanding beyond the current limits of the field.

2 Challenges

2.1 Metasubjectivity and pragmatic opinion

Recent efforts in opinion mining (Ruppenhofer et al., 2008) technology have often tended to take the position that opinion is an internal characteristic of the speaker, a “private state”, and that the overall aim of the opinion mining field is to discover techniques that allow us to infer the that latent state from the evidence presented in text. But this may not always be appropriate to all circumstances.

A very simple boundary example comes from Somasundaran and Wiebe (2009): *The blackberry is something like \$150 and the iPhone is \$500.* This comes from a corpus of opinions on cell phone preference, and this sentence is intended to be a negative opinion about the iPhone. According to Somasundaran and Wiebe, this kind of opinion-expression requires a model of world-knowledge that is either not practical under current technologies, or it requires the development of techniques that can recruit a larger context in the text in order to make the correct inference. They refer to this phenomenon as “pragmatic opinion”.

One crucial piece of world-knowledge that provides an opinion its polarity is that of the perspective of the reader or listener to the opinion; we can minimally represent this as the “application” to which the opinion will be put. We refer to variation in the application-specific interpretation of the concept of opinion as “metasubjectivity.” Metasubjectivity is a serious problem in extending sentiment analysis work to other domains, particularly for reasons that we describe in the next section.

Metasubjectivity is closely related to the underlying relative nature of veridicality assessment. The veridicality of an utterance is the level to which the listener may judge it as a factual statement about the world. de Marneffe et al. (2012) note that this requires, in some cases, extensive pragmatic knowledge. They present this sentence as an example: *FBI agents alleged in court documents today that Zazi had admitted receiving weapons and explosives*

training from al-Qaeda operatives in Pakistan last year. There is an interplay between the trustworthiness of the source of the sentence, the mentioned entities, and the veridicality of words *alleged* and *admitted*, all of which are mediated by the perspective of the reader. For example, if the reader is strongly inclined to trust the FBI, then there may be a high level of veridicality in “alleged” than otherwise. But it could also be the case that the reader believes that Zazi is misleading the FBI.

These distinctions operate directly in the context of determining polarity in opinion mining. Consider the following example sentence from a major information technology (IT) business journal: *Lloyd Hession, chief security officer at BT Radianz in New York, said that virtualization also opens up a slew of potential network access control issues.*

This sentence can be taken to represent an opinion or merely a factual statement. A casual reader without experience in the domain of IT might be convinced that this sentence is simply a neutral statement of fact. But from the perspective of an interested reader such as an investor, this may actually represent a mildly negative statement about virtualization, or it may represent a negative statement about network access control. From the perspective of the manager of an IT support department, it may well be very negative. But from the perspective of Lloyd Hession, we have no idea outside of the pragmatic context. Mr. Hession could be a developer of IT solutions, in which case he would view this as a positive development for the market in new network access control technologies, or, for that matter, he may be invested in a set of technological approaches that compete with virtualization.

This extends to the vocabulary used to express opinions. The use of the word “slew”, in this case, has negative connotations, but only if the whole statement is construed by the perspective of the reader to represent an opinion. However, if Lloyd Hession is a provider of new network access control solutions, then the use of “open” may convert this negative context into a positive context.

This is not merely a matter of the perspectives of individual users and participants. It is a matter of how providers of sentiment analysis applications choose to represent these choices to the user, which is in turn reflected in the way in which they create

resources, models, and algorithms. If, for example, our goal is to provide sentiment analysis for domain-specific market prediction or social science, then we need to model the reactions not of the private state of Mr. Hession or of the writer of the article, but of an “aggregate reader” with a presumed interest in the text. Here is a definition of this external state aggregate reader model that might apply to the IT business domain:

Opinion source *A* expresses opinion about opinion target *B* if an interested third party *C*’s actions towards *B* may be affected by *A*’s textually recorded actions, in a context where actions have positive or negative weight.

This accounts for the cases in which the opinion of interest in the IT example happens to be held by an investor or a IT support manager or other interested readers, and it can be generalized to apply to other domains in which the world’s opinion matters.

It is once again within the area of veridicality assessment that we suggest that a possible form of solution exists. de Marneffe et al. (2012) present a model in which the uncertainty in veridicality is represented as a distribution rather than a discrete labelling problem.

In the case of veridicality, there is generally an ultimate ground truth in verifiable facts about the world, apart from the relative veridical nature of a statement. For sentiment, however, there is no such foundation: opinion presence and opinion polarity exist entirely relative to the perspective of the aggregate reader. This requires a different process of annotation, the challenges of which we describe in the next section.

2.2 Corpus development and evaluation

Considering the prevalence of machine learning techniques in opinion mining research, addressing the issue of metasubjectivity must mean addressing the matter of the corpus development.

Existing evaluation techniques depend on a notion of “gold standard data” that are produced by expert judges or crowdsourced annotators (Wilson, 2007; Kessler et al., 2010; Hsueh et al., 2009). There are NLP areas in which popular notions of objectivity may partly apply, such as query relevance; due, among other things, to metasubjectivity, opinion mining is not entirely one of these. However,

gold standard data for opinion mining is typically produced using procedures that are standard for information retrieval research, and the quality measures that are generally used happen to assume the presence of an underlying objective truth.

This assumption can be coerced to fit particular cases. For example, a large proportion of opinion mining research is invested in predicting the ratings of product reviews and then aggregating results into a single ratings summary, sometimes based on a lower-level breakdown of product features (de Albornoz et al., 2011). Implicit in this type of work is the assumption of the existence of an ideal rater who uses language in a roughly predictable way to express his or her feelings about the text.

The users of these types of systems can be assumed, to some degree of safety, to share some of the expectations of the builders of these systems, particularly since groups of users as product raters are often the source of the information itself.

But in environments where the users of the system may have various different perspectives on the nature of sentiment, it does not make sense to assume that there would ever be significant agreement among annotators, particularly for market-relevant applications where prediction of reader reaction is central to the task. We attempted to annotate IT business press articles for sentence-level reader-perspective opinion occurrences and found that multiple trained annotators had very low inter-rater agreement by Cohen’s κ . Multiple attempts at further annotator training and error analysis revealed that the annotators simply found it very difficult to agree on what the definition of an opinion was. Originally, we had two trained student annotators for this task, with repeated training and joint practice annotations in order to achieve consensus as to what counts as an opinion mention instance and what does not. Other groups of annotators and annotation designs had no better success.

However, we observed that this appears to be primarily a problem of conservativeness where annotators differed in the quantity of sentences that they considered to be opinionated, and had a large amount of overlap in those that they did consider to be opinionated. Further discussion with the annotators found that some simply had a much lower threshold at which they would consider a sentence to contain an

opinion. In other words, this form of annotation is more affected by metasubjectivity than opinion annotation focused on opinion source perspective. It should be noted that this is a different task from finding opinion sources and labelling the textual evidence of their private states; we were attempting to model the “ideal case” we identified in section 1.

We suggest that the answer to this problem is to deploy the concept of the aggregate reader mentioned in the previous section and to pose the annotation question indirectly. The former requires the collection of data from a larger number of people and can be provided by existing crowdsourcing techniques (Snow et al., 2008). The latter, however, requires designing the annotation in such a way that it avoids letting the annotator consider the question: “What is an opinion?” This is most likely done by a user interface that simulates the behaviour of the intended aggregate reader (Sayeed et al., 2011).

2.3 Grammatical expression

There are a number of types of features with which one can construct and train supervised sentence-level sentiment detection models. Most recent techniques (Kim and Hovy, 2006; Choi et al., 2006; Jakob and Gurevych, 2010) take into account the syntactic context of the sentence but limit the amount of syntactic context thus used. These restrictions reduce the presence or absence of particular structures to binary features in the model. We argue that we need techniques that take into account more syntactic context, particularly without making use of predefined structures.

The latest techniques make use of larger syntactic contexts with potentially unlimited scope. One example is Nakagawa et al. (2010), who use factor graphs (McCallum et al., 2009) to learn a model that traces paths through the dependency trees of opinion-relevant sentences (de Marneffe and Manning, 2008). However, this is in the service of polarity classification, as it assumes that the appropriate sentences have already been identified; then it is a matter of correctly processing negations and other polarity-changing items. The challenge of metasubjectivity is a barrier to opinion sentence detection itself, well before polarity classification.

Another example is Qiu et al. (2011). They are more directly focused on detecting opinion-relevant

language. However, they make use of a system of hard-coded heuristics to find opinion words in dependency parses. While these types of heuristics support longer-distance syntactic relations, they tend to focus on cases where some form of semantic compositionality holds. However, consider this sentence from the IT business press: *The contract is consistent with the desktop computing Outsourcing deals Citibank awarded EDS and Digital Equipment in 1996...* In this case, an interested aggregate reader might note that “awarded” is a word that puts “outsourcing” in a positive light. However, the syntactic relationship between these two words does not directly imply or permit any semantic compositionality. In order to find these relationships, we would need to invest in techniques that can learn from arbitrary non-compositional structure, thereby potentially capturing patterns in grammar that actually reflect some aspects of external pragmatic knowledge.

3 Conclusions

This paper has proposed a challenge for opinion mining, the challenge of metasubjectivity: where the answer to the question “What is an opinion?” is in itself an opinion and an intrinsic part of the task. We first established the context of metasubjectivity relative to existing characterizations of the opinion mining task, establishing the notion of an external aggregate reader as a way to extend from existing notions of sentiment as an internal state. Then we described how this affects the annotation process, given the as-yet-continuing dependence on supervised corpus-based detection techniques. Finally, we described how this affects sentence-level fine-grained opinion detection at the level of syntactic analysis.

One of the risks for the field in proceeding to investigations of how to deal with the question of metasubjectivity is one familiar in natural language processing as a whole: there is a strong risk that these techniques will—initially and for a non-trivial quantity of time—cause the incremental performance gains in existing research to be lost or damaged. It will also require the creation of new training corpora and related resources, temporarily threatening comparability. Nevertheless, we believe that these risks need to be accepted in order to make progress in sentiment analysis.

Abstract

Social media users who post bullying related tweets may later experience regret, potentially causing them to delete their posts. In this paper, we construct a corpus of bullying tweets and periodically check the existence of each tweet in order to infer if and when it becomes deleted. We then conduct exploratory analysis in order to isolate factors associated with deleted posts. Finally, we propose the construction of a regrettable posts predictor to warn users if a tweet might cause regret.

1 Introduction

A large body of literature suggests that participants in bullying events, including victims, bullies, and witnesses, are likely to report psychological adjustment problems (Jimerson, Swearer, and Espelage, 2010). One potential source of therapy for these issues can be self-disclosure of the experience to an adult or friend (Mishna and Alaggia, 2005); existing research suggests that victims who seek advice and help from others report less maladjustment than victims who do not (Shelley and Craig, 2010).

Disclosure of bullying experiences through social media may be a particularly effective mechanism for participants seeking support because social media has the potential to reach large audiences and because participants may feel less inhibition when sharing private information in an online setting (Walther, 1996). Furthermore, there is evidence that online communication stimulates self-disclosure, which leads to higher quality social rela-

tionships and increased well-being (Valkenburg and Peter, 2009).

Online disclosure may also present risks for those involved in bullying however, such as re-victimization, embarrassment, and social ostracization. Evidence exists that some individuals may react to these risks retroactively, by deleting their social media posts (Child et al., 2011; Christofides, Muise, and Desmarais, 2009). Several relevant motives have been found to be associated with deleting posted information, including conflict management, safety, fear of retribution, impression management, and emotional regulation (Child, Haridakis, and Petronio, 2012).

Our previous work (Xu et al., 2012) demonstrates that social media can be a valuable data source when studying bullying, and proposes a text categorization method to recognize social media posts describing bullying episodes, *bullying traces*. To better understand, and possibly prevent, user regret after posting bullying related tweets, we collect bullying traces using the same method and perform regular status checks to determine if and when tweets become inaccessible. While a tweet becoming inaccessible does not guarantee it has been deleted, we attempt to leverage http response codes to rule out other common causes of inaccessibility. Speculating that regret may be a major cause of deletion, we first conduct exploratory analysis on this corpus and then report the results of an off-the-shelf regret predictor.

2 Data Collection

We adopt the procedure used in (Xu et al., 2012) to obtain bullying traces; each identified trace contains

at least one bullying related keyword and passes a bullying-or-not text classifier.

Our data was collected in realtime using the Twitter streaming API; once a tweet is collected, we query its url (<https://twitter.com/USERID/status/TWEETID>) at regular intervals and infer its status from the resulting http response code. We interpret an HTTP 200 response as an indication a tweet still exists and an HTTP 404 response, which indicates the tweet is unavailable, as indicating deletion. A user changing their privacy settings can also result in an HTTP 403 response; we do not consider this to be a deletion. Other response codes, which appear quite rarely, are treated as anomalies and ignored. All non HTTP 200 responses are retried twice to ensure they are not transient oddities.

To determine when a tweet is deleted, we attempted to access each tweet at time points $T_i = 5 \times 4^i$ minutes for $i = 0, 1, \dots, 7$ after the creation time. These roughly correspond to periods of 5 minutes, 20 minutes, 1.5 hours, 6 hours, 1 day, 4 days, 2 weeks, and 2 months. While we assume that user deletion is the main cause of a tweet becoming unavailable, other causes are possible such as the censorship of illegal contents by Twitter (Twitter, 2012).

Our sample data was collected from July 31 through October 31, 2012 and contains 522,984 bullying traces. Because of intermittent network and computer issues, several multiple day data gaps exist in the data. To combat this, we filter our data to include only tweets of unambiguous status. If any check within the 20480 minutes (about two weeks) interval returns an HTTP 404 code, the tweet is no longer accessible and we consider it *deleted*. If the 20480 minute or 81920 minute check returns an HTTP 200 response, that tweet is still accessible and we consider it *surviving*. The union of the surviving and deleted groups formed our cleaned dataset, containing 311,237 tweets in total.

3 Exploratory Data Analysis

A user’s decision to delete a bullying trace may be the result of many factors which we would like to isolate and understand. In this section we will examine several such possible factors.

3.1 Word Usage

Our dataset contains 331,070 distinct words and we are interested in isolating those with a significantly higher presence among either deleted or surviving tweets. We define the odds ratio of a word w

$$r(w) = \frac{P(w \mid \text{deleted})}{P(w \mid \text{surviving})},$$

where $P(w \mid \text{deleted})$ is the probability of word w occurring in a deleted tweet, and $P(w \mid \text{surviving})$ is the probability of w appearing in a surviving tweet. In order to ensure stability in the probability estimation, we only considered words appearing at least 50 times in either the surviving or deleted corpora.

Following (Bamman, OConnor, and Smith, 2012), we qualitatively analyzed words with extreme values of $r(w)$, and found some interesting trends. There was a significant tendency for “joking” words to occur with $r(w) < 0.5$; examples include “xd,” “haha,” and “hahaha.” Joking words occur less frequently in deleted tweets than surviving ones. On the other end of the spectrum, there were no joking words with $r(w) > 2$. What we found instead were words such as “rip,” “fat,” “kill,” and “suicide.” While it is relatively clear that joking is less likely to occur in deleted tweets, there was less of a trend among words appearing more frequently in deleted tweets.

3.2 Surviving Time

Let N be the total number of tweets in our corpus, and $D(T_i)$ be the number of tweets that were first detected as deleted at minute T_i after creation. Note that $D(T_i)$ is not cumulative over time: it includes only deletions that occurred in the time interval $(T_{i-1}, T_i]$. Then we may define the deletion rate at time T_i as

$$R_T(T_i) = \frac{D(T_i)}{N(T_i - T_{i-1})}.$$

In other words, $R_T(t)$ is the fraction of tweets that are deleted during the one minute period $(t, t+1)$.

We plot R_T vs. t using logarithmic scales on both axes in Figure 1 and the result is a quite strong linear trend. Fitting the plot with a linear regression, we derive an inverse relationship between R_T and t of the form

$$R_T(t) \propto 1/t.$$

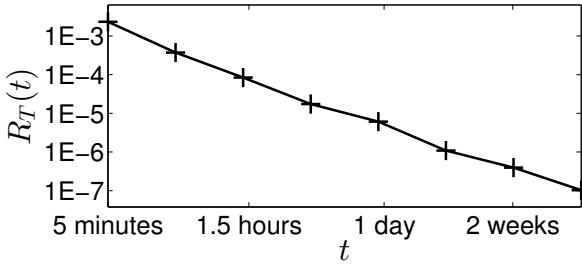

Figure 1: Deletion rate decays over time.

This result makes sense; the social effects of a particular bullying tweet may decay over time, making regret less of a factor. Furthermore, the author may assume an older tweet has already been seen, rendering deletion ineffective. Additionally, because the drop off in deletion rate is so extreme, we are able to safely exclude deletions occurring after two weeks from our filtered dataset without introducing a significant amount of noise. Finally, $\sum_{t=0}^{\infty} R_T(t)$ gives the overall fraction of deletion, which in our case is around 4%.

3.3 Location and Hour of Creations

Some bullying traces contain location meta-data in the form of GPS coordinates or a user-created profile string. We employed a reverse geocoding database (<http://www.datasciencetoolkit.org>) and a rule-based string matching method to map these tweets to their origins (at the state level; only for tweets within the USA). This also allowed us to convert creation timestamps from UTC to local time by mapping user location to timezone. Because many users don't share their location, we were only able to successfully map 85,465 bullying traces to a US state s , and local hour of day h . Among these traces, 3,484 were deleted which translates to an overall deletion rate of about 4%.

Let $N(s, h)$ be the count of bullying traces created in state s and hour h . Aggregating these counts temporally yields $N_S(s) = \sum_h N(s, h)$, while aggregating spatially produces $N_H(h) = \sum_s N(s, h)$. Similarly, we can define $D(s, h)$, $D_S(s)$ and $D_H(h)$ as the corresponding counts of deleted traces. We can now compute the deletion rate

$$R_H(h) = \frac{D_H(h)}{N_H(h)}, \text{ and } R_S(s) = \frac{D_S(s)}{N_S(s)}.$$

The top row of Figure 2 shows $N_H(h)$, $D_H(h)$, and $R_H(h)$. We find that $N_H(h)$ and $D_H(h)$ peak in the evening, indicating social media users are generally more active at that time. The peak of $R_H(h)$ appears at late night and, while there are multiple potential causes for this, we hypothesize that users may fail to fully evaluate the consequences of their posts when tired. The bottom row of Figure 2 shows $N_S(s)$, $D_S(s)$, and $R_S(s)$. The plot of $N_S(s)$ shows that bullying traces are more likely to originate in California, Texas or New York which is the result of a population effect. Importantly however, the deletion rate $R_S(s)$ is not affected by population bias and we see, as expected, that spatial differences in $R_S(s)$ are small. We performed χ^2 -test to see if a state's deletion rate is significantly different from the national average. We chose the significance level at 0.05 and used Bonferroni correction for multiple testing. Only four states have significantly different deletion rates from the average: Arizona (6.3%, $p = 5.9 \times 10^{-5}$), California (5.2%, $p = 2.7 \times 10^{-7}$), Maryland (1.9%, $p = 2.3 \times 10^{-5}$), and Oklahoma (7.1%, $p = 3.5 \times 10^{-5}$).

3.4 Author's Role

Participants in a bullying episode assume well-defined roles which dramatically affect the viewpoint of the author describing the event. We trained a text classifier to determine author role (Xu et al., 2012), and used it to label each bullying trace in the cleaned corpus by author role: *Accuser*, *Bully*, *Reporter*, *Victim* or *Other*.

Table 1 shows that compared to tweets produced by bullies, victims create more bullying traces, possibly due to an increased need for social support on the part of the victim. More importantly, $P(\text{deleted} | \text{victim})$ is higher than $P(\text{deleted} | \text{bully})$, a statistically significant difference in a two-proportion z -test. Possibly, victims are more sensitive to their audience's reaction than bullies.

3.5 Teasing

Many bullying traces are written jokingly. We built a text classifier to identify teasing bullying traces (Xu et al., 2012) and applied it to the cleaned corpus.

Table 2 shows that $P(\text{deletion} | \text{Teasing})$ is much lower than $P(\text{deletion} | \text{Not Teasing})$ and the difference is statistically significant in a two-proportion z -

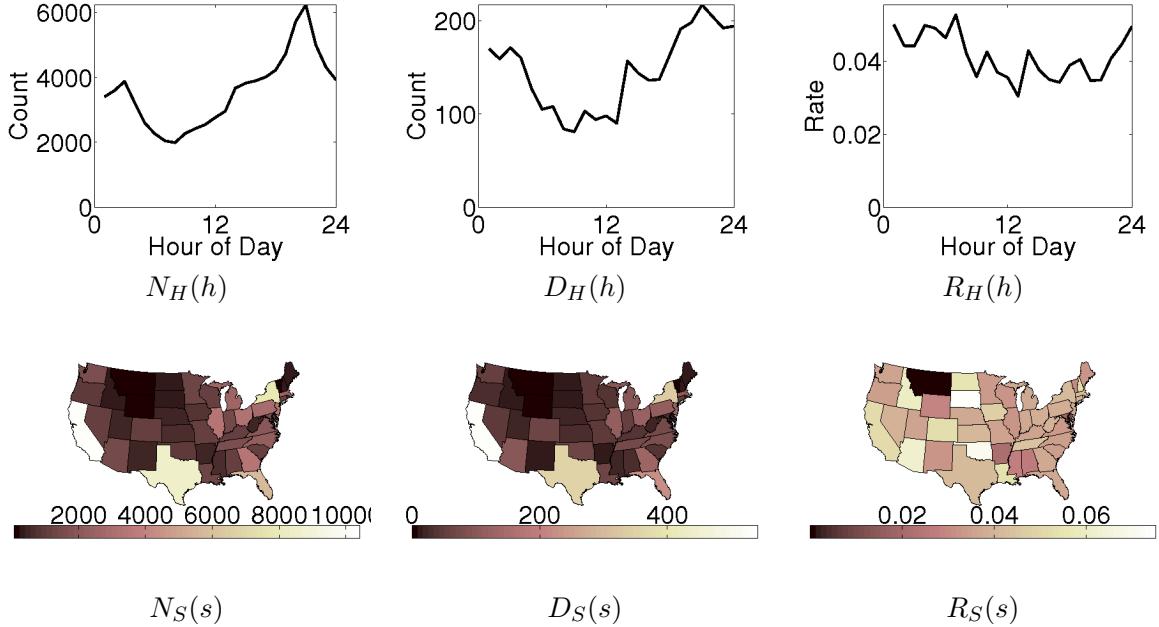

Figure 2: Counts and deletion rates of geo-tagged bullying traces.

	Deleted	Total	$P(\text{deleted} \mid \text{Role})$
Accuser	2541	50088	5.07%
Bully	1792	30123	5.95%
Reporter	11370	147164	7.73%
Victim	6497	83412	7.79%
Other	41	450	9.11%

Table 1: Counts and deletion rate for different roles.

	Deleted	Total	$P(\text{deleted} \mid \text{Teasing?})$
Yes	858	22876	3.75%
Not	21383	288361	7.42%

Table 2: Counts and deletion rate for teasing or not.

test. It seems plausible that authors are less likely to regret teasing posts because they are less controversial and have less potential to generate negative audience reactions. This also corroborates our findings in word usage that joking words are less frequent in deleted tweets.

4 Predicting Regrettable Tweets

Once a bullying tweet is published and seen by others, the ensuing effects are often impossible to undo. Since ill-thought-out posts may cause unexpectedly negative consequences to an author’s reputation, re-

lationship, and career (Wang et al., 2011), it would be helpful if a system could warn users before a potentially regrettable tweet is posted. One straightforward approach is to formulate the task as a binary text categorization problem.

We use the cleaned dataset, in which each tweet is known to be surviving or deleted after 20480 minutes (about two weeks). Since this dataset contains 22,241 deleted tweets, we randomly sub-sampled the surviving tweets down to 22,241 to force our deleted and surviving datasets to be of equal size. Consequentially, the baseline accuracy of the classifier is 0.5. While this does make the problem artificially easier, our initial goal was to test for the presence of a signal in the data.

We then followed the preprocessing procedure in (Xu et al., 2012), performing case-folding, anonymization, and tokenization, treating URLs, emoticons and hashtags specially. We also chose the unigrams+bigrams feature representation, only keeping tokens appearing at least 15 times in the corpus.

We chose to employ a linear SVM implemented in LIBLINEAR (Fan et al., 2008) due to its efficiency on this large sparse text categorization task and a 10-fold cross validation was conducted to eval-

uate its performance. Within the first fold, we use an inner 5-fold cross validation on the training portion to tune the regularization parameter on the grid $\{2^{-10}, 2^{-9}, \dots, 1\}$; the selected parameter is then fixed for all the remaining folds.

The resulting cross validation accuracy was 0.607 with a standard deviation of 0.012. While it is statistically significantly better than the random-guessing baseline accuracy of 0.5 with a *p*-value of 5.15×10^{-10} , this accuracy is nevertheless too low to be useful in a practical system. One possibility is that the tweet text contains very limited information for predicting inaccessibility; a user’s decision to delete a tweet potentially depends on many other factors, such as the conversation context and the characteristics of the author and audience.

In the spirit of exploring additional informative features for deletion prediction, we also used the teasing and author role classifiers in (Xu et al., 2012), and appended the predicted teasing, and author role labels to our feature vector. This augmented feature representation achieved a cross validation accuracy of 0.606, with standard deviation 0.007; not statistically significantly different from the text-only feature representation. While it seems that a signal does exist, leveraging it usefully in real world scenarios may prove challenging due to the highly-skewed nature of the data.

5 Discussion

There have been several recent works examining causes of deletion in social media. Wang *et al.* (2011) qualitatively investigated regret associated with users’ posts on social networking sites and identified several possible causes of regret. Bamman *et al.* (2012) focused on censorship-related deletion of social media posts, identifying a set of sensitive terms related to message deletion through a statistical analysis and spatial variation of deletion rate.

Assuming that deletion in social media is indicative of regret, we studied regret in a bullying context by analyzing deletion trends in bullying related tweets. Through our analysis, we were able to isolate several factors related to deletion, including word usage, surviving time, and author role. We used these factors to build a regret predictor which achieved statistically significant results on this very

noisy data. In the future, we plan to explore more factors to better understand deletion behavior and regret, including users’ recent posts, historical behavior, and other statistics related to their specific social network.

Abstract

We investigate two systems for automatic disfluency detection on English and Mandarin conversational speech data. The first system combines various lexical and prosodic features in a Conditional Random Field model for detecting edit disfluencies. The second system combines acoustic and language model scores for detecting filled pauses through constrained speech recognition. We compare the contributions of different knowledge sources to detection performance between these two languages.

1 Introduction

Speech disfluencies are common phenomena in spontaneous speech. They consist of spoken words and phrases that represent self-correction, hesitation, and floor-grabbing behaviors, but do not add semantic information; removing them yields the intended, fluent utterance. The presence of disfluencies in conversational speech data can cause problems for both downstream processing (parsing and other natural language processing tasks) and human readability of speech transcripts. There has been much research effort on automatic disfluency detection in recent years (Shriberg and Stolcke, 1997; Snover et al., 2004; Liu et al., 2006; Lin and Lee, 2009; Schuler et al., 2010; Georgila et al., 2010; Zwarts and Johnson, 2011), particularly from the DARPA EARS (Effective, Affordable, Reusable Speech-to-Text) MDE (MetaData Extraction) (DARPA Information Processing Technology Office, 2003) program, which focused on the automatic transcription

of sizable amounts of speech data and rendering such transcripts in readable form, for both conversational telephone speech (CTS) and broadcast news (BN).

However, the EARS MDE effort was focused on English only, and there hasn't been much research on the effectiveness of similar automatic disfluency detection approaches for multiple languages. This paper presents three main innovations. First, we extend the EARS MDE-style disfluency detection approach combining lexical and prosodic features using a Conditional Random Field (CRF) model, which was employed for detecting disfluency on English conversational speech data (Liu et al., 2005), to Mandarin conversational speech, as presented in Section 2. Second, we implement an automatic filled pause detection approach through constrained speech recognition, as presented in Section 3. Third, for both disfluency detection systems, we compare side-by-side contributions of different knowledge sources to detection performance for two languages, English and Mandarin, as presented in Section 4. Conclusions appear in Section 5.

2 EARS MDE Style Automatic Disfluency Detection

We focus on two types of disfluencies, *Fillers* and *Edit disfluencies*, following the EARS MDE disfluency types modeled in (Liu et al., 2006). Fillers include filled pauses (FP), discourse markers (DM), and explicit editing terms (ET). FPs are words used by the speakers as floor holders to maintain control of a conversation. They can also indicate hesitations of the speaker. In this work, English FPs

comprise *uh* and *um*, based on English CTS corpora. For Mandarin, Zhao and Jurafsky found that Mandarin speakers intensively used both demonstratives *zhege* (*literally ‘this’*) and *nage* (*literally ‘that’*) and *uh/mm* as FPs based on a large speech corpus of Mandarin telephone conversation (Zhao and Jurafsky, 2005). We study the same set of Chinese FPs in this study. DMs are words or phrases related to the structure of the discourse and help taking or keeping a turn, or serving as acknowledgment, for example, *I mean, you know*. An explicit ET is an editing term in an edit disfluency that is not an FP or a DM. For example, *we have two action items * sorry three action items from the meeting*, where *sorry* is an explicit ET.

Edit disfluencies involve syntactically relevant content that is either repeated, revised, or abandoned. The basic pattern for edit disfluencies has the form **(reparandum) * <editing term> correction**. The reparandum is the portion of the utterance that is corrected or abandoned entirely (in the case of restarts). An interruption point (IP), marked with ‘*’ in the pattern, is the point at which the speaker breaks off the original utterance and then repeats, revises, or restarts the utterance. The editing term is optional and consists of one or more filler words. The correction is the portion of the utterance that corrects the original reparandum. Revisions denote the cases when a speaker modifies the original utterance with a similar syntactic structure, e.g., *we have two action items * sorry three action items from the meeting*. Restarts denote the cases when a speaker abandons an utterance or a constituent and restarts all over again, e.g., *He * I like this idea*.

We used a CRF model to combine lexical features, shallow syntactic features, and prosodic features for joint detection of edit words and IP words. A CRF defines a global log-linear distribution of the state (or label) sequence E conditioned on an observation sequence, in our case including the word sequence W and the features F , and optimized globally over the entire sequence considering the context event information for making decisions at each point. We used the Mallet package (McCallum, 2002) to implement the CRF model. We used a first-order model that includes only two sequential events in the feature set. The CRF model is trained to maximize the conditional log-likelihood of a given training

set $P(E|W, F)$. During testing, the most likely sequence E is found using the Viterbi algorithm. To avoid over-fitting, a zero-mean Gaussian prior (McCallum and Li, 2003) was applied to the parameters, where the variance of the prior was optimized on the development test set. Each word is associated with a class label, representing whether it is an edit word or not. We included IP in the target classes and used five states, as *outside edit* (O), *begin edit with an IP* (B-E+IP), *begin edit* (B-E), *inside edit with an IP* (I-E+IP), and *inside edit* (I-E) (Liu et al., 2006). State transitions are also the same as in (Liu et al., 2006). We built a Hidden Markov Model (HMM) based part-of-speech (POS) taggers for English conversational speech and Mandarin broadcast conversation data. After employing the co-training approach described in (Wang et al., 2007), we achieved 94% POS tagging accuracy for both data sets. The features for CRF modeling include: n-grams from words and automatically generated POS tags, speaker turns, whether there is a repeated word sequence ending at a word boundary, whether a word is a fragment, whether there is a predefined filler phrase after the word boundary, and the prosody model posterior probabilities from a decision tree model (Shriberg and Stolcke, 1997) and discretized by cumulative binning (Liu et al., 2006). The prosodic features were computed for each interword boundary from words and phonetic alignments of the manual transcriptions. We extracted the same set of prosodic features for English and Mandarin data, based on duration, fundamental frequency (f0), energy, and pause information, and nonprosodic information such as speaker gender and speaker change, for training and applying the decision-tree-based prosody model (Liu et al., 2006).

We implemented a rule-based system for filler word detection. We defined a list of possible Chinese and English filler words, including filled pauses and discourse markers. The rules also explore POS tags assigned by our Chinese and English POS taggers.

3 Constrained Speech Recognition for Filled Pause Detection

We also propose an alternative approach for automatic detection of FPs given speech transcripts that omit FPs but are otherwise accurate. This approach is motivated by situations where only an edited, “cleaned-up” transcript is available, but where an accurate verbatim transcript is to be recovered automatically. We treat this task as a constrained speech recognition problem, and investigate how effectively it is solved by a state-of-the-art large vocabulary continuous speech recognition (LVCSR) system. Hence, this approach can be considered as combining LVCSR acoustic model (AM) and language model (LM) knowledge sources in a search framework for FP detection. Compared to the FP detection component in the disfluency detection systems described in Section 2, this alternative approach explores different knowledge sources. In particular, the AMs explore different front-end features compared to the lexical and prosodic features explored in those disfluency detection systems presented in Section 2. Details of the front-end features are illustrated below.

We evaluated this approach on both English and Mandarin conversational speech. For detecting FPs in English conversational speech, we used a modified and simplified form of the recognition system developed for the 2004 NIST Rich Transcription Conversational Telephone Speech (CTS) evaluations, described in (Stolcke et al., 2006). The first pass of the recognizer uses a within-word MFCC+MLP model (i.e, trained on Mel-frequency cepstral coefficient (MFCC) features augmented with Multi-Layer Perceptron (MLP) based phone-posterior features), while the second pass uses a cross-word model trained on Perceptual Linear Prediction (PLP) features adapted (by speaker) to the output of the first pass. For purposes of FP detection, the recognition is constrained to a word lattice formed by the manually transcribed non-FP reference words, with optional FP words inserted between any two words and at the beginning and end of each utterance. Both first and second pass decoding was constrained by the optional-FP lattices. In the second pass, HTK lattices were generated with bigram LM probabilities and rescored with a

4-gram LM. The consensus decoding output from the rescored lattices was used for scoring FP detection. The system thus evaluates the posterior probability of an FP at every word boundary using both acoustic model (AM) and language model (LM) evidence. The acoustic model for the English recognition system was trained on about 2300 hours of CTS data. The language models (which models FP like any other word) are bigram and 4-gram statistical word n-gram LMs estimated from the same data plus additional non-CTS data and web data.

For detecting FPs in Mandarin broadcast conversation speech, we used a modified form of the recognition system developed for the 2008 DARPA GALE (Global Autonomous Language Exploitation) Speech-to-Text evaluation, described in (Lei et al., 2009). The system conducted a constrained decoding on the optional-FP lattices, using a speaker-independent within-word triphone MPE-trained MFCC+pitch+MLP model and a pruned trigram LM. For the Mandarin ASR system, the MFCC+MLP front-end features were augmented with 3-dimension smoothed pitch features (Lei et al., 2006). HTK lattices were generated with probabilities from the pruned trigram LM and rescored by the full trigram LM. The consensus decoding output from the rescored lattices was used for scoring FP detection. The AMs for this system were trained on 1642 hours of Mandarin broadcast news and conversation speech data and the LMs were trained on 1.4 billion words comprising a variety of resources. Details of training data and system development were illustrated in (Lei et al., 2009).

This procedure is similar to forced aligning the word lattices to the audio data (Finke and Waibel, 1997). Both Finke et al.’s approach (Finke and Waibel, 1997) and our approach built a lattice from each transcription sentence (in our approach, optional filled pauses are inserted between any two words and at the beginning and end of each utterance). Then Finke et al. force-aligned the lattice with utterance; whereas, we used multi-pass constrained decoding with within-word and cross-word models, MLLR adaptation of the acoustic models, and resoring with a higher-order n-gram LM, so the performance will be better than just flexible alignment to the lattices. Note that when constructing the word lattices with optional FP words, for En-

glish, the optional FP words are a choice between *uh* and *um*. For Mandarin, the optional FP words are a choice between *uh*, *mm*, *zhege*, and *nage*. We assigned equal weights to FP words.

4 Experimental Results

Scoring of EARS MDE-style automatic disfluency detection output is done using the NIST tools¹, computing the error rate as the average number of misclassified words per reference event word. For English, the training and evaluation data were from the 40 hours CTS data in the NIST RT-04F MDE training data including speech, their transcriptions and disfluency annotations by LDC. We randomly held out two 3-hour subsets from this training data set for evaluation and parameter tuning respectively, and used the remaining data for training. Note that for Mandarin, there is no LDC released Mandarin MDE training data. We adapted the English MDE annotation guidelines for Mandarin and manually annotated the manual transcripts of 92 Mandarin broadcast conversation (BC) shows released by LDC under the DARPA GALE program, for edit disfluencies and filler words. We randomly held out two 3-hour subsets from the 92 shows for evaluation and parameter tuning respectively, and manually corrected disfluency annotation errors on the evaluation set.

Table 1 shows the results in NIST error rate (%) for edit word, IP, and filler word detection. We observe that adding POS features improves edit word, edit IP, and filler word detection for both languages, and adding a prosody model produced further improvement (note that filler word detection systems did not employ prosodic features). The gains from combining the word, POS, and prosody model over the word n-gram baseline are statistically significant for both languages (confidence level $p < 0.05$ using matched pair test). Also, adding the prosody model over word+POS yielded a larger relative gain in edit word+IP detection performance for Mandarin than for English data. A preliminary study of these results has shown that the prosody model contributes differently for different types of disfluencies for English and Mandarin conversational speech and we will continue this study in future work. We also plan

to investigate the prosodic features considering the special characteristics of edited disfluencies in Mandarin studied in (Lin and Lee, 2009).

Table 1: NIST error rate (%) for edit word, IP, and filler word detection on the English and Mandarin test set, using word n-gram features, POS n-gram features, and prosody model.

Feature	NIST Error Rate (%)		
	Edit Word	Edit IP	Filler Word
English			
Word	53.0	38.7	31.2
+POS	52.6	38.2	29.8
++Prosody	52.3	38.0	29.8
Mandarin			
Word	58.5	42.8	33.4
+POS	57.7	42.1	32.9
++Prosody	56.9	41.5	32.9

For evaluating constrained speech recognition for FP detection, the English test set of conversational speech data and word transcripts is derived from the CTS subset of the NIST 2002 Rich Transcription evaluation. The waveforms were segmented according to utterance boundaries given by the human-generated transcripts, resulting in 6554 utterance segments with a total duration of 6.8 hours. We then excluded turns that have fewer than five tokens or have two or more FPs in a row (such as ‘uh um’ and ‘uh, uh’), resulting in 3359 segments. This yields the test set from which we computed English FP detection scores. The transcripts of this test set contain 54511 non-FP words and 1394 FPs, transcribed as either *uh* or *um*. When evaluating FP detection performance, these two orthographical forms were mapped to a single token type, so recognizing one form as the other is not penalized. The Mandarin test set is the DARPA GALE 2008 Mandarin speech-to-text development test set of 1 hour duration. The transcripts of this test set contain 9820 non-FP words and 370 FP words, transcribed as *uh*, *mm*, *zhege*, and *nage*. We collapsed them to a single token type for FP scoring. We evaluated FP detection performance in terms of both false alarm (incorrect detection) and miss (failed detection) rates, shown in Table 2. We observed that adding pronunciation scores didn’t change the P_{fa} and P_{miss} . On the English

¹www.itl.nist.gov/iad/mig/tests/rt/2004-fall/index.html

test set, adding LM scores degraded P_{miss} but improved P_{fa} . However, on the Mandarin test set, increasing LM weight improved both P_{miss} and P_{fa} , suggesting that for the Mandarin LVCSR system in this study, the LM could provide complementary information to the AM to discriminate FP and non-FP words.

Table 2: Probabilities of false alarms (FAs) and misses in FP detection on the English and Mandarin test set w.r.t. acoustic model weight w_a , language model weight w_g , and pronunciation score weight w_p .

$\{w_a, w_g, w_p\}$	FAs (%)	Misses (%)
English		
{1,0,8}	1.76	3.23
{1,8,8}	1.18	4.73
Mandarin		
{1,0,8}	1.19	19.68
{1,8,8}	0.76	16.76

5 Conclusion

In conclusion, we have presented two automatic disfluency detection systems, one combining various lexical and prosodic features, and the other combining LVCSR acoustic and language model knowledge sources. We observed significant improvements in combining lexical and prosodic features over just employing word n-gram features, for both languages. When combining AM and LM knowledge sources for FP detection in constrained speech recognition, we found increasing LM weight improved both false alarm and miss rates for Mandarin but degraded the miss rate for English.

Abstract

Atypical semantic and pragmatic expression is frequently reported in the language of children with autism. Although this atypicality often manifests itself in the use of unusual or unexpected words and phrases, the rate of use of such unexpected words is rarely directly measured or quantified. In this paper, we use distributional semantic models to automatically identify unexpected words in narrative retellings by children with autism. The classification of unexpected words is sufficiently accurate to distinguish the retellings of children with autism from those with typical development. These techniques demonstrate the potential of applying automated language analysis techniques to clinically elicited language data for diagnostic purposes.

1 Introduction

Autism spectrum disorder (ASD) is a neurodevelopmental disorder characterized by impaired communication and social behavior. Although the symptoms of ASD are numerous and varied, atypical and idiosyncratic language has been one of the core symptoms observed in verbal individuals with autism since Kanner first assigned a name to the disorder (Kanner, 1943). Atypical language currently serves as a diagnostic criterion in many of the most widely used diagnostic instruments for ASD (Lord et al., 2002; Rutter et al., 2003), and the phenomenon is especially marked in the areas of semantics and pragmatics (Tager-Flusberg, 2001; Volden and Lord, 1991).

Because structured language assessment tools are not always sensitive to the particular atypical semantic and pragmatic expression associated with ASD, measures of atypical language are often drawn from spontaneous language samples. Expert manual annotation and analysis of spontaneous language in young people with ASD has revealed that children and young adults with autism include significantly more bizarre and irrelevant content (Loveland et al., 1990; Losh and Capps, 2003) in their narratives and more abrupt topic changes (Lam et al., 2012) in their conversations than their language-matched typically developing peers. Most normed clinical instruments for analyzing children’s spontaneous language, however, focus on syntactic measures and developmental milestones related to the acquisition of vocabulary and syntactic structures. Measures of semantic and pragmatic atypicality in spontaneous language are rarely directly measured. Instead, the degree of language atypicality is often determined via subjective parental reports (e.g., asking a parent whether their child has ever used odd phrases (Rutter et al., 2003)) or general impressions during clinical examination (e.g., rating the child’s degree of “stereotyped or idiosyncratic use of words or phrases” on a four-point scale (Lord et al., 2002)). This has led to a lack of reliable and objective information about the frequency of atypical language use and its precise nature in ASD.

In this study, we attempt to automatically detect instances of contextually atypical language in spontaneous speech at the lexical level in order to quantify its prevalence in the ASD population. We first determine manually the off-topic, surprising, or in-

appropriate words in a set of narrative retellings elicited in a clinical setting from children with ASD and typical development. We then apply word ranking methods and distributional semantic modeling to these narrative retellings in order to automatically identify these unexpected words. The results indicate not only that children with ASD do in fact produce more semantically unexpected and inappropriate words in their narratives than typically developing children but also that our automated methods for identifying these words are accurate enough to serve as an adequate substitute for manual annotation. Although unexpected off-topic word use is just one example of the atypical language observed in ASD, the work presented here highlights the potential of computational language evaluation and analysis methods for improving our understanding of the linguistic deficits associated with ASD.

2 Data

Participants in this study included 37 children with typical development (TD) and 21 children with autism spectrum disorder (ASD). ASD was diagnosed via clinical consensus according to the DSM-IV-TR criteria (American Psychiatric Association, 2000) and the established threshold scores on two diagnostic instruments: the Autism Diagnostic Observation Schedule (ADOS) (Lord et al., 2002), a semi-structured series of activities designed to allow an examiner to observe behaviors associated with autism; and the Social Communication Questionnaire (SCQ) (Rutter et al., 2003), a parental questionnaire. None of the children in this study met the criteria for a language impairment, and there were no significant between-group differences in age (mean=6.4) or full-scale IQ (mean=114).

The narrative retelling task analyzed here is the

Narrative Memory subtest of the NEPSY (Korkman et al., 1998), a large and comprehensive battery of tasks that test neurocognitive functioning in children. The NEPSY Narrative Memory (NNM) subtest is a narrative retelling test in which the subject listens to a brief narrative, excerpts of which are shown in Figure 1, and then must retell the narrative to the examiner. The NNM was administered to each participant in the study, and each participant's retelling was recorded and transcribed. Using Amazon's Mechanical Turk, we also collected a large corpus of retellings from neurotypical adults, who listened to a recording of the story and provided written retellings. We describe how this corpus was used in Section 3, below.

Two annotators, blind to the diagnosis of the experimental subjects, identified every word in each retelling transcript that was unexpected or inappropriate given the larger context of the story. For instance, in the sentence *T-rex could smell things*, both *T-rex* and *smell* were marked as unexpected, since there is no mention of either concept in the story. In a seemingly more appropriate sentence, *the boy sat up off the bridge*, the word *bridge* is considered unexpected since the boy is trapped up in a tree rather than on a bridge.

3 Methods

We start with the expectation that different retellings of the same source narrative will share a common vocabulary and semantic space. The presence of words outside of this vocabulary or semantic space in a retelling may indicate that the speaker has strayed from the topic of the story. Our approach for automatically identifying these unexpected words relies on the ranking of words according to the strength of their association with the target topic of the corpus. The word association scores used in the

Figure 1: Excerpts from the NNM narrative.

Jim was a boy whose best friend was Pepper. Pepper was a big black dog. [...] Near Jim's house was a very tall oak tree with branches so high that he couldn't reach them. Jim always wanted to climb that tree, so one day he took a ladder from home and carried it to the oak tree. He climbed up [...] When he started to get down, his foot slipped, his shoe fell off, and the ladder fell to the ground. [...] Pepper sat below the tree and barked. Suddenly Pepper took Jim's shoe in his mouth and ran away. [...] Pepper took the shoe to Anna, Jim's sister. He barked and barked. Finally, Anna understood that Jim was in trouble. She followed Pepper to the tree where Jim was stuck. Anna put the ladder up and rescued Jim.

ranking are informed by the frequency of a word in the child’s retelling relative to the frequency of that word in other retellings in the larger corpus of retellings. These association measures are similar to those developed for the information retrieval task of topic modeling, in which the goal is to identify topic-specific words – i.e., words that appear frequently in only a subset of documents – in order to cluster together documents about a similar topic. Details about how these scores are calculated and interpreted are provided in the following sections.

The pipeline for determining the set of unusual words in each retelling begins by calculating word association scores, described below, for each word in each retelling and ranking the words according to these scores. A threshold over these scores is determined for each child using leave-one-out cross validation in order to select a set of potentially unexpected words. This set of potential unexpected words is then filtered using two external resources that allow us to eliminate words that were not used in other retellings but are likely to be semantically related to topic of the narrative. This final set of words is evaluated against the set of manually identified words in order determine the accuracy of our unexpected word classification.

3.1 Word association measures

Before calculating the word association measures, we tokenize, downcase, and stem (Porter, 1980) the transcripts and remove all punctuation. We then use two association measures to score each word in each child’s retelling: *tf-idf*, the term frequency-inverse document frequency measure (Salton and Buckley, 1988), and the log odds ratio (van Rijsbergen et al., 1981). We use the following formulation to calculate *tf-idf* for each child’s retelling i and each word in that retelling j , where c_{ij} is the count of word j in retelling i ; f_j is the number of retellings from the full corpus of child and adult retellings containing that word j ; and D is the total number of retellings in the full corpus (Manning et al., 2008):

$$tf\text{-}idf_{ij} = \begin{cases} (1 + \log c_{ij}) \log \frac{D}{f_j} & \text{if } c_{ij} \geq 1 \\ 0 & \text{otherwise} \end{cases}$$

The log odds ratio, another association measure used in information retrieval and extraction tasks, is

the ratio between the odds of a particular word, j , appearing in a child’s retelling, i , as estimated using its relative frequency in that retelling, and the odds of that word appearing in all other retellings, again estimated using its relative frequency in all other retellings. Letting the probability of a word appearing in a retelling be p_1 and the probability of that word appearing in all other retellings be p_2 , we can express the odds ratio as follows:

$$\text{odds ratio} = \frac{\text{odds}(p_1)}{\text{odds}(p_2)} = \frac{p_1/(1-p_1)}{p_2/(1-p_2)}$$

A large *tf-idf* or log odds score indicates that the word j is very specific to the retelling i , which in turn suggests that the word might be unexpected or inappropriate in the larger context of the NNM narrative. Thus we expect that the words with higher association measure scores are likely to be the words that were manually identified as unexpected in the context of the NNM narrative.

3.2 Application of word association measures

As previously mentioned, both of these word association measures are used in information retrieval (IR) to cluster together documents about a similar target topic. In IR, words that appear only in a subset of documents from a large and varied corpus of documents will have high word association scores, and the documents containing those words will likely be focused on the same topic. In our task, however, we have a single cluster of documents focused on a single topic: the NNM narrative. Topic-specific words ought to occur much more frequently than other words. As a result, words with high *tf-idf* and log odds scores are likely to be those *unrelated* to the topic of the NNM story. If a child veers away from the topic of the NNM story and uses words that do not occur frequently in the retellings produced by neurotypical speakers, his retellings will contain more words with high word association scores. We predict that this set of high-scoring words is likely to overlap significantly with the set of words identified by the manual annotators as unexpected or off-topic.

Applying these word association scoring approaches to each word in each child’s retelling yields a list of words from each retelling ranked in order of decreasing *tf-idf* or log odds score. We use cross-validation to determine, for each measure, the op-

erating point that maximizes the unexpected word identification accuracy in terms of F-measure. For each child, the threshold is found using the data from all of the other children. This threshold is then applied to the ranked word list of the held-out child. All words above this threshold are potential unexpected words, while all words below this threshold are considered to be expected and appropriate in the context of the NNM narrative. Table 1 shows the recall, precision, and F-measure using the two word association measures discussed here. We see that these two techniques result in high recall at the expense of precision. The next stage in the pipeline is therefore to use external resources to eliminate any semantically appropriate words from the set of potentially unexpected or inappropriate words generated via thresholding on the *tf-idf* or log odds score.

3.3 Filtering with external resources

Recall that the corpus of retellings used to generate the word association measures described above, is very small. It is therefore quite possible that a child may have used an entirely appropriate word that by chance was never used by another child or one of the neurotypical adults. One way of increasing the lexical coverage of the corpus of retellings is through semantic expansion using an external resource. For each word in the set of potential unexpected words, we located the WordNet synset for that word (Fellbaum, 1998). If any of the WordNet synonyms of the potentially unexpected word was present in the source narrative or in one of the adult retellings, that word was removed from the set of unexpected words.

In the final step, we used the CHILDES corpus of transcripts of children’s conversational speech (MacWhinney, 2000) to generate topic estimates for each remaining potentially unexpected word. For each of these words, we located every utterance in the CHILDES corpus containing that potentially unexpected word. We then measured the association of that word with every other open-class word that appeared in an utterance with that word using the log likelihood ratio (Dunning, 1993). The 20 words from the CHILDES corpus with the highest log likelihood ratio (i.e., the words most strongly associated with the potentially unexpected word), were assumed to collectively represent a particular topic. If

more than two of the words in the vector of words representing this topic were also present in the NNM source narrative or the adult retellings, the word that generated that topic was eliminated from the set of unexpected words.

We note that the optimized threshold described in Section 3.2, above, is determined after filtering. There is therefore potentially a different threshold for each condition tested, and hence we do not necessarily expect precision to increase and recall to decrease after filtering. Rather, since the threshold is selected in order to optimize F-measure, we expect that if the filtering is effective, F-measure will increase with each additional filtering condition applied.

4 Results

We evaluated the performance of our two word ranking techniques, both individually and combined by taking either the maximum of the two measures or the sum, against the set of manually annotations described in Section 2. In addition, we report the results of applying these word ranking techniques in combination with the two filtering techniques. We compare these results with a simple baseline method in which every word used in a retelling that is never used in another retelling is considered to be unexpected. Table 1 shows the precision, accuracy, and F-measure of these approaches. We see that all of the more sophisticated unexpected word identification approaches outperform the baseline by a wide margin, and that *tf-idf* and log odds perform comparably under the condition without filtering and both filtering conditions. Filtering improves F-measure under both word ranking schemes, and combining the two measures results in further improvements under both filtering conditions. Although applying topic-estimate filtering yields the highest precision, the simple WordNet-based approach results in the highest F-measure and a reasonable balance between precision and recall.

Recall that the purpose of identifying these unexpected words was to determine whether children with ASD produce unexpected and inappropriate words at a higher rate than children with typical development. This appears to be true in our manually annotated data. On average, 7.5% of the words

Unexpected word identification method	P	R	F1
Baseline	46.3	74.0	57.0
TF-IDF	72.1	79.5	75.6
Log-odds	70.5	79.5	74.7

Table 1: Accuracy of unexpected word identification.

types produced by children with ASD were marked as unexpected, while only 2.5% of words produced by children with TD were marked as unexpected, a significant difference ($p < 0.01$, using a one-tailed t-test). This significant between-group difference in rate of unexpected word use holds even when using the automated methods of unexpected word identification, with the best performing unexpected word identification method estimating a mean of 6.6% in the ASD group and 2.5% in the TD group ($p < 0.01$).

5 Conclusions and future work

The automated methods presented here for ranking and filtering words according to their distributions in different corpora, which are adapted from techniques originally developed for topic modeling in the context of information retrieval and extraction tasks, demonstrate the utility of automated approaches for the analysis of semantics and pragmatics. We were able to use these methods to identify unexpected or inappropriate words with high enough accuracy to replicate the patterns of unexpected word use manually observed in our two diagnostic groups. This work underscores the potential of automated techniques for improving our understanding of the prevalence and diagnostic utility of linguistic features associated with ASD and other communication and language disorders.

In future work, we plan to use a development set to determine the optimal number of topical words to select during the topic estimate filtering stage of the pipeline in order to maintain improvements in

precision without a loss in recall. We would also like to investigate using part-of-speech, word sense, and parse information to improve our approaches for both semantic expansion and topic estimation. Although the rate of unexpected word use alone is unlikely to provide sufficient power to classify the two diagnostic groups investigated here, we expect that it can serve as one feature in an array of features that capture the broad range of semantic and pragmatic atypicalities observed in the spoken language of children with autism. Finally, we plan to apply these same methods to identify the confabulations and topic shifts often observed in the narrative retellings of the elderly with neurodegenerative conditions.

Atypical Prosodic Structure as an Indicator of Reading Level and Text Difficulty

Julie Medero and Mari Ostendorf

Electrical Engineering Department

University of Washington

Seattle, WA 98195 USA

{jmedero, ostendorf}@uw.edu

Abstract

Automatic assessment of reading ability builds on applying speech recognition tools to oral reading, measuring words correct per minute. This work looks at more fine-grained analysis that accounts for effects of prosodic context using a large corpus of read speech from a literacy study. Experiments show that lower-level readers tend to produce relatively more lengthening on words that are not likely to be final in a prosodic phrase, i.e. in less appropriate locations. The results have implications for automatic assessment of text difficulty in that locations of atypical prosodic lengthening are indicative of difficult lexical items and syntactic constructions.

1 Introduction

Fluent reading is known to be a good indicator of reading comprehension, especially for early readers (Rasinski, 2006), so oral reading is often used to evaluate a student's reading level. One method that can be automated with speech recognition technology is the number of words that a student can read correctly of a normed passage, or Words Correct Per Minute (WCPM) (Downey et al., 2011). Since WCPM depends on speaking rate as well as literacy, we are interested in identifying new measures that can be automatically computed for use in combination with WCPM to provide a better assessment of reading level. In particular, we investigate fine-grained measures that, if useful in identifying points of difficulty for readers, can lead to new approaches for assessing text difficulty.

The WCPM is reduced when a person repeats or incorrectly reads a word, but also when they introduce pauses and articulate words more slowly. Pauses and lengthened articulation can be an indicator of uncertainty for a low-level reader, but these phenomena are also used by skilled readers to mark prosodic phrase structure, facilitating comprehension in listeners. Since prosodic phrase boundaries tend to occur in locations that coincide with certain syntactic constituent boundaries, it is possible to automatically predict prosodic phrase boundary locations from part-of-speech labels and syntactic structure with fairly high reliability for read news stories (Ananthakrishnan and Narayanan, 2008). Thus, we hypothesize that we can more effectively leverage word-level articulation and pause information by focusing on words that are less likely to be associated with prosodic phrase boundaries. By comparing average statistics of articulation rate and pausing for words at boundary vs. non-boundary locations, we hope to obtain a measure that could augment reading rate for evaluating reading ability. We also hypothesize that the specific locations of hesitation phenomena (word lengthening and pausing) observed for multiple readers will be indicative of particular points of difficulty in a text, either because a word is difficult or because a syntactic construction is difficult. Detecting these regions and analyzing the associated lexical and syntactic correlates is potentially useful for automatically characterizing text difficulty.

Our study of hesitation phenomena involves empirical analysis of the oral reading data from the Fluency Addition to the National Assessment of Adult

Literacy (FAN), which collected oral readings from roughly 12,000 adults, reading short (150-200 word) fourth- and eighth grade passages (Baer et al., 2009). The participants in that study were chosen to reflect the demographics of adults in the United States; thus, speakers of varying reading levels and non-native speakers were included. For our study, we had access to time alignments of automatic transcriptions, but not the original audio files.

2 Related Work

For low-level readers, reading rate and fluency are good indicators of reading comprehension (Miller and Schwanenflugel, 2006; Spear-Swerling, 2006). Zhang and colleagues found that features of children’s oral readings, along with their interactions with an automated tutor, could predict a single student’s comprehension question performance over the course of a document (2007). Using oral readings is appealing because it avoids the difficulty of separating question difficulty from passage difficulty (Ozuru et al., 2008) and of questions that can be answered through world knowledge (Keenan and Betjemann, 2006).

WCPM is generally used as a tool for assessing reading level by averaging across one or more passages. It is more noisy when comparing the readability of different texts, especially when the reading level is measured at a fine-grained (e.g. word) level. If longer words take longer to read orally, it may be merely a consequence of having more phonemes, and not of additional reading difficulty. Further, for communication reasons, pauses and slow average articulation rates tend to coincide with major phrase boundaries. In our work, we would like to account for prosodic context in using articulation rate to identify difficult words and constructions.

Much of the previous work on using automatic speech recognition (ASR) output for reading level or readability analysis has focused on assessing the reading level of children (Downey et al., 2011; Duchateau et al., 2007). Similar success has been seen in predicting fluency scores in oral reading tests for L2 learners of English (Balogh et al., 2012; Bernstein et al., 2011). Project LISTEN has a reading tutor for children that gives real-time feedback, and has used orthographic and phonemic features

of individual words to predict the likelihood of real word substitutions (Mostow et al., 2002).

3 FAN Literacy Scores

To examine the utility of word-level pause and articulation rate features for predicting reading level when controlled for prosodic context, we use the Basic Reading Skills (BRS) score available for each reader in the FAN data. The BRS score measures an individual’s average reading rate in WCPM. Each participant read three word lists, three pseudo-word lists, one easy text passage, and one harder text passage, and the BRS is the average WCPM over the eight different readings. Specifically, the WCPM for each case is computed automatically using Ordinate’s VersaReader system to transcribe the speech given the target text (Balogh et al., 2005). The system output is then automatically aligned to the target texts using the track-the-reader method of Rasmussen et al. (2011), which defines weights for regressions and skipped words and then identifies a least-cost alignment between the ASR output and a text. Automatic calculation of WCPM has high correlation (.96-1.0) with human judgment of WCPM (Balogh et al., 2012), so it has the advantage of being easy to automate.

Word Error Rate (WER) for the ASR component in Ordinate’s prototype reading tracker (Balogh et al., 2012) may be estimated to be between 6% and 10%. In a sample of 960 passage readings, where various sets of two passages were read by each of 480 adults (160 native Spanish speakers, 160 native English-speaking African Americans, and 160 other native English speakers), the Ordinate ASR system exhibited a 6.9% WER on the 595 passages that contained no spoken material that was unintelligible to human transcribers. On the complete set of 960 passages, the system exhibited a 9.9% WER, with each unintelligible length of speech contributing one or more errors to the word error count.

The greatest problem with speech recognition errors is for very low-level readers (Balogh et al., 2012). In order to have more reliable time alignments and BRS scores, approximately 15% of the FAN participants were excluded from the current analysis. This 15% were those participants whose BRS score was labeled “Below Basic” in the NAAL

reading scale. Additional participants were eliminated because of missing or incomplete (less than a few seconds) recordings. With these exclusions, the number of speakers in our study was 7587.

4 Prosodic Boundary Prediction

We trained a regression tree¹ on hand-annotated data from the Boston University Radio News Corpus (Ostendorf et al., 1995) to predict the locations where we expect to see prosodic boundaries. Each word in the Radio News Corpus is labeled with a prosodic boundary score from 0 (clitic, no boundary) to 6 (sentence boundary). For each word, we use features based on parse depth and structure and POS bigrams to predict the prosodic boundary value.

For evaluation, the break labels are grouped into: 0-2 (no intonational boundary marker), 3 (intermediate phrase), and 4-6 (intonational phrase boundary). Words with 0-2 breaks are considered non-boundary words; 4-6 are boundary words. We expect that, for fluent readers, lengthening and possibly pausing will be observed after boundary words but not after non-boundary words. Since the intermediate boundaries are the most difficult to classify, and may be candidates for both boundaries and non-boundaries for fluent readers, we omit them in our analyses. Our model achieves 87% accuracy in predicting \pm intonational phrase boundaries and 83% accuracy in predicting \pm no intonational boundary, treating intermediate phrase boundaries as negative instances in both cases.

Note that our 3-way prosodic boundary prediction is aimed at identifying locations where fluent readers are likely to place boundaries (or not), i.e., reliable locations for feature extraction, vs. acceptable locations for text-to-speech synthesis. Because of this goal and because work on prosodic boundary prediction labels varies in its treatment of intermediate phrase boundaries, our results are not directly comparable to prior studies. However, performance is in the range reported in recent studies predicting prosodic breaks from text features only. Treating intermediate phrase boundaries as positive examples, Ananthakrishnan and Narayanan (2008)

¹Our approach differs slightly from previous work in the use of a regression (vs. classification) model; this gave a small performance gain.

achieve 88% accuracy. Treating them as negative examples, Margolis and Ostendorf (2010) achieve similar results. Both report results on a single held-out test set, while our results are based on 10-fold cross validation.

5 Experiments with Prosodic Context

5.1 Word-level Rate Features

We looked at two acoustic cues related to hesitation or uncertainty: pause duration and word lengthening. While pause duration is straightforward to extract (and not typically normalized), various methods have been used for word lengthening. We explore two measures of word lengthening: i) the longest normalized vowel, and ii) the average normalized length of word-final phones (the last vowel and all following consonants). Word-final lengthening is known to be a correlate of fluent prosodic phrase boundaries (Wightman et al., 1992), and we hypothesized that the longest normalized vowel might be useful for hesitations though it can also indicate prosodic prominence.

For word-level measures of lengthening, it is standard to normalize to account for inherent phoneme durations. We use a z-score: measured duration minus phone mean divided by phone standard deviation. In addition, Wightman et al. (1992) found it useful to account for speaking rate in normalizing phone duration. We adopt the same model, which assumes that phone durations can be characterized by a Gamma distribution and that speaker variability is characterized by a linear scaling of the phone-dependent mean parameters, where the scaling term is shared by all phones. The linear scale factor α for a speaker is estimated as:

$$\alpha = \frac{1}{N} \sum_{i=1}^N \frac{d_i}{\mu_{p(i)}} \quad (1)$$

where d_i is the duration of the i -th phone which has label $p(i)$ and where μ_p is the speaker-independent mean of phone p . Here, we use a speaker-independent phone mean computed from the TIMIT Corpus,² which has hand-marked phonetic labels and times. We make use of the speaking rate model

²Available from the Linguistic Data Consortium.

to adjust the speaker-independent TIMIT phone durations to the speakers in the FAN corpus by calculating the linear scale factor α for each speaker. Thus, the phone mean and standard deviation used in the z-score normalization is $\alpha\mu_{p_i}$ and $\alpha\sigma_{p_i}$, respectively.

From the many readings of the eight passages, we identified roughly 777K spoken word instances at predicted phrase boundaries and 2.0M spoken words at predicted non-boundaries. For each uttered word, we calculated three features: the length of the following pause, the length of the longest normalized vowel, and the averaged normed length of all phones from the last vowel to the end of the word, as described above. The word-level features can be averaged across instances from a speaker for assessing reading level or across instances of a particular word in a text uttered by many speakers to assess local text difficulty.

The phone and pause durations are based on recognizer output, so they will be somewhat noisy. The fact that the recognizer is biased towards the intended word sequence and the omission of the lowest-level readers from this study together contribute to reducing the error rate ($< 10\%$) and increasing the reliability of the features. In addition, noise is reduced by averaging over multiple words or multiple speakers.

5.2 Reading Level Analysis

To assess the potential for prosodic context to improve the utility of word-level features for assessing reading difficulty, we looked at duration lengthening and pauses at boundary and non-boundary locations, where the boundary labels are predicted using the text-based algorithm and 3-class grouping described in section 4.

First, for each speaker, we averaged each feature across all boundary words read by that person and across all non-boundary words read by that person. We hypothesized that skilled readers would have shorter averages for all three features at non-boundary words compared to at boundary words, while the differences for lower-level readers would be smaller because of lengthening due to uncertainty at non-boundary words. The difference between the boundary and non-boundary word averages for normalized duration of end-of-word phones is plotted in

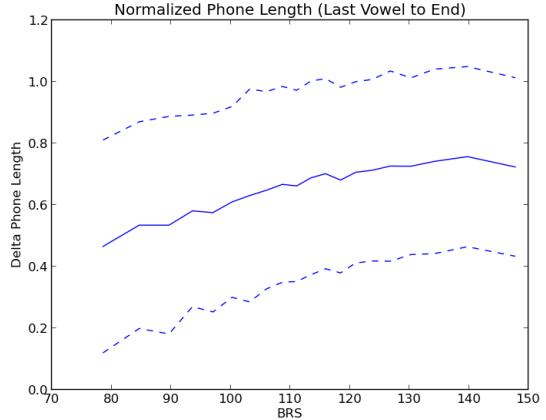

Figure 1: Mean end-of-word normalized phone duration (+/- standard deviation) as a function of BRS score

Figure 1 as a function of reading level. As expected, the difference increases with reading skill, as measured by BRS. A similar trend is observed for the longest normalized vowel in the word.

We also looked at pause duration, finding that the average pause duration decreases as reading skill increases for both boundary and non-boundary words. Since pauses are not always present at intonational phrase boundaries, but are more likely at sentence boundaries, we investigated dividing the cases by punctuation rather than prosodic context. Table 1 shows that for both the top 20% of readers and the bottom 20% of readers, sentence boundaries had much longer pauses on average, followed by comma boundaries, and unpunctuated word boundaries. The drop in both pause frequency and average pause duration is much greater for the more skilled readers.

Looking at all speakers, the unpunctuated words had an average pause duration that scaled with the speaking rate estimate for that passage, with high correlation (0.94). The correlation was much lower for sentence boundaries (0.44). Thus, we conclude that the length of pauses at non-boundary locations is related to the speaker's reading ability.

5.3 Identifying Difficult Texts

Instead of averaging over multiple words in a passage, we can average over multiple readings of a particular word. We identified difficult regions in texts by sorting all tokens by the average normalized length of their end-of-word phones for the lowest

	Top 20%		Bottom 20%	
	Pause Rate	Avg. Pause Duration	Pause Rate	Avg. Pause Duration
Sentence-final	81.0%	177 ms	84.7%	283 ms
Comma	26.1%	94 ms	47.0%	168 ms
No punctuation	4.6%	77 ms	16.6%	139 ms

Table 1: Frequency of occurrence and average duration of pauses at sentence boundaries, comma boundaries, and unpunctuated word boundaries for the top and bottom 20% of all readers, as sorted by BRS score

20% of readers. The examples suggest that lengthening may coincide with reading difficulty caused by syntactic ambiguity. Two sentences, with the lengthened word in bold, illustrate representative ambiguities:

- She was there for **me** the whole time my grandfather was in the hospital.
- Since dogs are **gentler** when raised by a family the dogs are given to children when the dogs are about fourteen months old.

In the first example, “me” could be the end of the sentence, while in the second example, readers may expect “gentler” to be the end of the subordinate clause started by “since”. The lengthening on these words is much smaller for the top 20% of readers, suggesting that the extra lengthening is associated with points of difficulty for the less skilled readers.

Similarly, we identified sentences with non-boundary locations where readers commonly paused, with the word after the pause in bold:

- We have always been able to share our **es-capades** and humor with our friends.
- Check with your doctor first if you are a man over forty or a woman over fifty **and** you plan to do vigorous activity instead of moderate activity.

We observe a wider variety of potential difficulties here. Some are associated with difficult words, as in the first example, while others involve syntactic ambiguities similar to the ones seen in the lengthening cases.

6 Summary

We have shown that duration lengthening and pause cues align with expected prosodic structure (predicted from syntactic features) more for skilled readers than for low-level readers, which we hope may lead to a richer assessment of individual reading difficulties. In addition, we have proposed a method

of characterizing text difficulty at a fine grain based on these features using multiple oral readings. In order to better understand the information provided by the different features, we are conducting eye tracking experiments on these passages, and future work will include an analysis of readers’ gaze during reading of these constructions that have been categorized in terms of their likely prosodic context.

In this work, where the original recordings were not available, the study was restricted to duration features. However, other work has suggested that other prosodic cues, particularly pitch and energy features, are useful for detecting speaker uncertainty (Litman et al., 2009; Litman et al., 2012; Pon-Barry and Shieber, 2011). Incorporating these cues may increase the reliability of detecting points of reading difficulty and/or offer complementary information for characterizing text difficulties.

Abstract

In this paper we leverage methods from submodular function optimization developed for document summarization and apply them to the problem of subselecting acoustic data. We evaluate our results on data subset selection for a phone recognition task. Our framework shows significant improvements over random selection and previously proposed methods using a similar amount of resources.

1 Introduction

Present-day applications in spoken language technology (speech recognizers, keyword spotters, etc.) can draw on an unprecedented amount of training data. However, larger data sets come with increased demands on computational resources; moreover, they tend to include redundant information as their size increases. Therefore, the performance gain curves of large-scale systems with respect to the amount of training data often show “diminishing returns”: new data is often less valuable (in terms of performance gain) when added to a larger pre-existing data set than when added to a smaller pre-existing set (e.g.,(Moore, 2003)). Therefore it is of prime importance to develop methods for data subset selection. We distinguish two data subselection scenarios: (a) a priori selection of a data set before (re-)training a system; in this case the goal is to subselect the existing data set as well as possible, eliminating redundant information; (b) selection for adaptation, where the goal

is to tune a system to a known development or test set. While many studies have addressed the second scenario, this paper investigates the first: our goal is to select a smaller subset of the data that fits a given ‘budget’ (e.g. maximum number of hours of data) but provides, to the extent possible, as much information as the complete data set. Additionally, our selection method should be a low-resource method that does not require an already-trained complex system such as an existing word recognizer.

This problem is akin to unsupervised data ‘summarization’. In (Lin and Bilmes, 2009) a novel class of summarization techniques based on submodular function optimization were proposed for extractive document summarization. Interestingly, these methods can also be applied to speech data ‘summarization’ with only small modifications. In the following sections we develop a submodular framework for speech data summarization and evaluate it on a proof-of-concept phone recognition task.

2 Related Work

Most approaches to data subset selection in speech have relied on “rank-and-select” approaches that determine the utility of each sample in the data set, rank all samples according to their utility scores, and then select the top N samples. In weakly supervised approaches (e.g.,(Kemp and Waibel, 1998; Lamel et al., 2002; Hakkani-Tur et al., 2002), utility is related to the confidence of an existing word recognizer on new data samples: untranscribed training data is automatically transcribed using an existing baseline speech recognizer, and individual utterances are selected as additional training data if they have low

*These authors are joint first authors with equal contributions.

confidence. These are active learning approaches suitable for a scenario where a well-trained speech recognizer is already available and additional data for retraining needs to be selected. However, we would like to reduce available training data ahead of time with a low-resource approach. In (Chen et al., 2009) individual samples are selected for the purpose of discriminative training by considering phone accuracy and the frame-level entropy of the Gaussian posteriors. (Itoh et al., 2012) use a utility function consisting of the entropy of word hypothesis N-best lists and the representativeness of the sample using a phone-based TF-IDF measure. The latter is comparable to methods used in this paper, though the first term in their objective function still requires a word recognizer. In (Wu et al., 2007) acoustic training data associated with transcriptions is subselected to maximize the entropy of the distribution over linguistic units (phones or words). Most importantly, all these methods select samples in a greedy fashion without optimality guarantees. As we will explain in the next section, greedy selection is near-optimal only when applied to monotone submodular functions.

3 Submodular Functions

Submodular functions (Edmonds, 1970) have been widely studied in mathematics, economics, and operations research and have recently attracted interest in machine learning (Krause and Guestrin, 2011). A submodular function is defined as follows: Given a finite ground set of objects (samples) $V = \{v_1, \dots, v_n\}$ and a function $f : 2^V \rightarrow \mathbb{R}^+$ that returns a real value for any subset $S \subseteq V$, f is submodular if $\forall A \subseteq B$, and $v \notin B$, $f(A + v) - f(A) \geq f(B + v) - f(B)$. That is, the incremental “value” of v decreases when the set in which v is considered grows from A to B . Powerful optimization guarantees exist for certain subtypes of submodular functions. If, for example, the function is *monotone submodular*, i.e. $\forall A \subseteq B$, $f(A) \leq f(B)$, then it can be maximized, under a cardinality constraint, by a greedy algorithm that scales to extremely large data sets, and finds a solution guaranteed to approximate the optimal solution to within a constant factor $1 - 1/e$ (Nemhauser et al., 1978). Submodular functions can be considered the discrete analog of convexity.

3.1 Submodular Document Summarization

In (Lin and Bilmes, 2011) submodular functions were recently applied to extractive document summarization. The problem was formulated as a monotone submodular function that had to be maximized subject to cardinality or knapsack constraints:

$$\operatorname{argmax}_{S \subseteq V} \{f(S) : c(S) \leq K\} \quad (1)$$

where V is the set of sentences to be summarized, K is the maximum number of sentences to be selected, and $c(\cdot) \geq 0$ is sentence cost. $f(S)$ was instantiated by a form of **saturated coverage**:

$$f_{SC}(S) = \sum_{i \in V} \min\{C_i(S), \alpha C_i(V)\} \quad (2)$$

where $C_i(S) = \sum_{j \in S} w_{ij}$, and where $w_{ij} \geq 0$ indicates the similarity between sentences i and j — $C_i : 2^V \rightarrow \mathbb{R}$ is itself monotone submodular (modular in fact) and $0 \leq \alpha \leq 1$ is a saturation coefficient. $f_{SC}(S)$ is monotone submodular and therefore has the previously mentioned performance guarantees. The weighting function w was implemented as the cosine similarity between TF-IDF weighted n-gram count vectors for the sentences in the dataset.

3.2 Submodular Speech Summarization

Similar to the procedure described above we can treat the task of subselecting an acoustic data set as an extractive summarization problem. For our *a priori* data selection scenario we would like to extract those training samples that jointly are representative of the total data set. Initial explorations of submodular functions for speech data can be found in (Lin and Bilmes, 2009), where submodular functions were used in combination with a purely acoustic similarity measure (Fisher kernel). In addition Equation 2 the **facility location** function was used:

$$f_{fac}(S) = \sum_{i \in V} \max_{j \in S} w_{ij} \quad (3)$$

Here our focus is on utilizing methods that move beyond purely acoustic similarity measures and consider kernels derived from discrete representations of the acoustic signal. To this end we first run a tokenizer over the acoustic signal that converts it into a sequence of discrete labels. In our case we use a

simple bottom-up monophone recognizer (without higher-level constraints such as a phone language model) that produces phone labels. We then use the hypothesized sequence of phonetic labels to compute two different sentence similarity measures: (a) cosine similarity using TF-IDF weighted phone n-gram counts, and (b) string kernels. We compare their performance to that of the Fisher kernel as a purely acoustic similarity measure.

TF-IDF weighted cosine similarity

The cosine similarity between phone sequences s_i and s_j is computed as

$$\text{sim}_{ij} = \frac{\sum_{w \in s_i} \text{tf}_{w,s_i} \times \text{tf}_{w,s_j} \times \text{idf}_w^2}{\sqrt{\sum_{w \in s_i} \text{tf}_{w,s_i}^2 \text{idf}_w^2} \sqrt{\sum_{w \in s_j} \text{tf}_{w,s_j}^2 \text{idf}_w^2}} \quad (4)$$

where tf_{w,s_i} is the count of n-gram w in s_i and idf_w is the inverse document count of w (each sentence is a “document”). We use $n = 1, 2, 3$.

String kernel

The particular string kernel we use is a gapped, weighted subsequence kernel of the type described in (Rousu and Shawe-Taylor, 2005). Formally, we define a sentence s as a concatenation of symbols from a finite alphabet Σ (here the inventory of phones) and an embedding function from strings to feature vectors, $\phi : \Sigma^* \rightarrow \mathcal{H}$. The string kernel function $\mathcal{K}(s, t)$ computes the distance between the resulting vectors for two sentences s_i and s_j . The embedding function is defined as

$$\phi_u^k(s) := \sum_{i: u=s(i)} \lambda^{|i|} \quad u \in \Sigma^k \quad (5)$$

where k is the maximum length of subsequences, $|i|$ is the length of i , and λ is a penalty parameter for each gap encountered in the subsequence. \mathcal{K} is defined as

$$\mathcal{K}(s_i, s_j) = \sum_u \langle \phi_u(s_i), \phi_u(s_j) \rangle w_u \quad (6)$$

where w is a weight dependent on the length of u , $l(u)$. Finally, the kernel score is normalized by $\sqrt{\mathcal{K}(s_i, s_i) \cdot \mathcal{K}(s_j, s_j)}$ to discourage long sentences from being favored.

Fisher kernel

The Fisher kernel is based on the vector of derivatives U_X of the log-likelihood of the acoustic data (X)

with respect to the parameters in the phone HMMs $\theta_1, \dots, \theta_m$ for m models, having similarity score:

$$\text{sim}_{ij} = (\max_{i', j'} d_{i'j'}) - d_{ij}, \text{ where } d_{ij} = ||U'_i - U'_j||_1, \\ U_X^\theta = \nabla_\theta \log P(X|\theta), \text{ and } U'_X = U_X^{\theta_1} \circ U_X^{\theta_2} \circ \dots \circ U_X^{\theta_m}.$$

4 Data and Systems

We evaluate our approach on subselecting training data from the TIMIT corpus for training a phone recognizer. Although this is not a large-scale data task, it is an appropriate proof-of-concept task for rapidly testing different combinations of submodular functions and similarity measures. Our goal is to focus on acoustic modeling only; we thus look at phone recognition performance and do not have to take into account potential interactions with a language model. We also chose a simple acoustic model, a monophone HMM recognizer, rather than a more powerful but computationally complex model in order to ensure quick experimental turnaround time. Note that the goal of this study is not to obtain the highest phone accuracy possible; what is important is the relative performance of the different subset selection methods, especially on small data subsets.

The sizes of the training, development and test data are 4620, 200 and 192 utterances, respectively. Pre-processing was done by extracting 39-dimensional MFCC feature vectors every 10 ms, with a window of 25.6ms. Speaker mean and variance normalization was applied. A 16-component Gaussian mixture monophone HMM system was trained on the full data set to generate parameters for the Fisher kernel and phone sequences for the string kernel and TF-IDF based similarity measures.

Following the selection of subsets (2.5%, 5%, 10%, 20%, 30%, 40%, 50%, 60%, 70% and 80% of the data, measured as percentage of non-silence speech frames), we train a 3-state HMM monophone recognizer for all 48 TIMIT phone classes on the resulting sets and evaluate the performance on the core test set of 192 utterances, collapsing the 48 classes into 39 in line with standard practice (Lee and Hon, 1989). The HMM state output distributions are modeled by diagonal-covariance Gaussian mixtures with the number of Gaussians ranging between 4 and 64, depending on the data size.

As a baseline we perform 100 random draws of the specified subset sizes and average the results.

The second baseline consists of the method in (Wu et al., 2007), where utterances are selected to maximize the entropy of the distribution over phones in the selected subset.

5 Experiments

We tested the three different similarity measures described above in combination with the submodular functions in Equations 2 and 3. The parameters of the gapped string kernel (i.e. the kernel order (k), the gap penalty (λ), and the contiguous substring length l) were optimized on the development set. The best values were $\lambda = 0.1, k = 4, l = 3$. We found that facility location was superior to saturated cover function across the board.

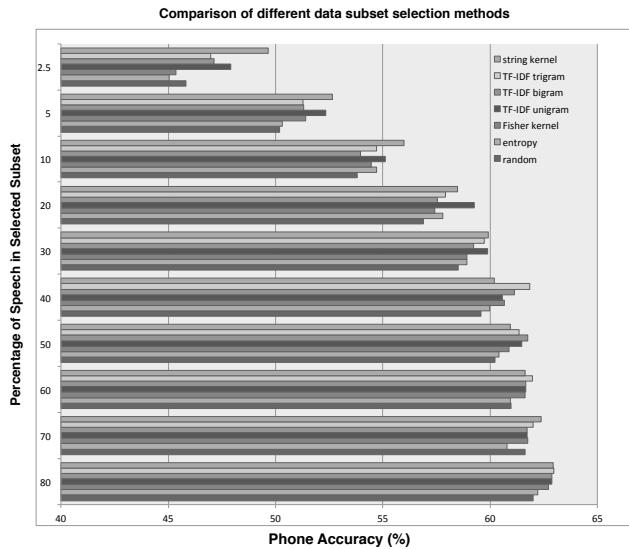

Figure 1: Phone accuracy for different subset sizes; each block of bars lists, from bottom to top: random baseline, entropy baseline, Fisher kernel, TF-IDF (unigram), TF-IDF (bigram), TF-IDF (trigram), string kernel.

Figure 1 shows the performance of the random and entropy-based baselines as well as the performance of the facility location function with different similarity measures. The entropy-based baseline beats the random baseline for most percentage cases but is otherwise the lowest-performing method overall. Note that this baseline uses the true transcriptions in line with (Wu et al., 2007) rather than the hypothesized phone labels output by our recognizer. The low performance and the fact that it is even outperformed by the random baseline in the 2.5% and 70% cases

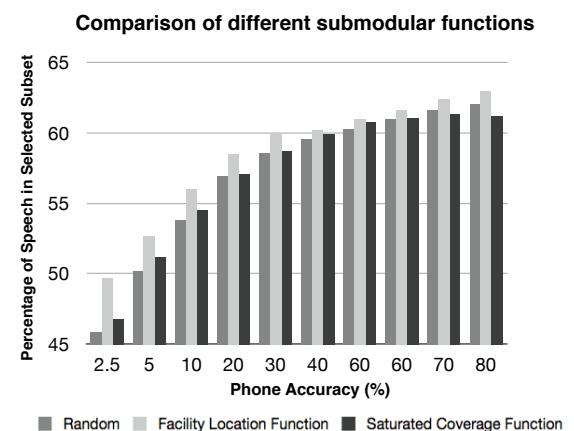

Figure 2: Phone accuracy obtained by random selection, facility location function, and saturated coverage function (string kernel similarity measure).

may be because the selection method encourages highly diverse but not very representative subsets. Furthermore, the entropy-based baseline utilizes a non-submodular objective function with a heuristic greedy search method. No theoretical guarantee of optimality can be made for the subset found by this method.

Among the different similarity measures the Fisher kernel outperforms the baseline methods but has lower performance than the TF-IDF kernel and the string kernel. The best performance is obtained with the string kernel, especially when using small training data sets (2.5%-10%). The submodular selection methods yield significant improvements ($p < 0.05$) over both the random baseline and over the entropy-based method.

We also investigated using different submodular functions, i.e. the facility location function and the saturated coverage function. Figure 2 shows the performance of the facility location (f_{fac}) and saturated coverage (f_{SC}) functions in combination with the string kernel similarity measure. The reason f_{fac} outperforms f_{SC} is that f_{SC} primarily controls for over-coverage of any element not in the subset via the α saturation hyper-parameter. However, it does not ensure that every non-selected element has good representation in the subset. f_{SC} measures the quality of the subset by how well each individual element outside the subset has a surrogate within the subset (via

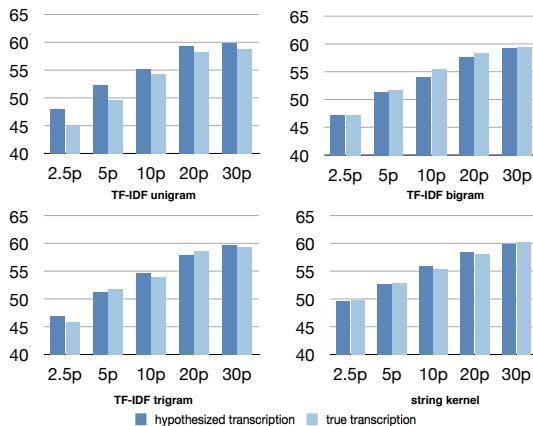

Figure 3: Phone accuracy for true vs. hypothesized phone labels, for string-based similarity measures.

the max function) and hence tends to model complete coverage better, leading to better results.

Finally we examined whether using hypothesized phone sequences vs. the true transcriptions has negative effects. Figure 3 shows that this is not the case: interestingly, the hypothesized labels even result in slightly better results. This may be because the recognized phone sequences are a function of both the underlying phonetic sequences that were spoken and the acoustic signal characteristics, such as the speaker and channel. The true transcriptions, on the other hand, are able to provide information only about phonetic as opposed to acoustic characteristics.

6 Discussion

We have presented a low-resource framework for acoustic data subset selection based on submodular function optimization, which was previously developed for document summarization. Evaluation on a proof-of-concept task has shown that the method is successful at selecting data subsets that outperform subsets selected randomly or by a previously proposed low-resource method. We note that the best selection strategies for the experimental conditions tested here involve similarity measures based on a discrete tokenization of the speech signal rather than direct acoustic similarity measures.

²Department of Electrical and Electronics Engineering

Boğaziçi University, Istanbul, Turkey

{arda.celebi, murat.saraclar}@boun.edu.tr

Abstract

One way to improve the accuracy of automatic speech recognition (ASR) is to use discriminative language modeling (DLM), which enhances discrimination by learning where the ASR hypotheses deviate from the uttered sentences. However, DLM requires large amounts of ASR output to train. Instead, we can simulate the output of an ASR system, in which case the training becomes semi-supervised. The advantage of using simulated hypotheses is that we can generate as many hypotheses as we want provided that we have enough text material. In typical scenarios, transcribed in-domain data is limited but large amounts of out-of-domain (OOD) data is available. In this study, we investigate how semi-supervised training performs with OOD data. We find out that OOD data can yield improvements comparable to in-domain data.

1 Introduction

Discriminative language modeling (DLM) helps ASR systems to discriminate between acoustically similar word sequences in the process of choosing the most accurate transcription of an utterance. DLM characterizes and learns from ASR errors by comparing the reference transcription of the utterance and the candidate hypotheses generated by the ASR system. Although previous studies based on this supervised setting have been successful (Roark et al., 2007; Arısoy et al., 2009; Arısoy et al., 2012; Sak et al., 2012), they require large amounts of transcribed speech data and a well-trained in-domain ASR system, both of which are hard to obtain. To

overcome this difficulty, instead of training with the real ASR output, we can use simulated output, in which case the training becomes semi-supervised.

Semi-supervised training for discriminative language modeling has been shown to achieve as good word error rate (WER) reduction as the training done with real ASR output (Sagae et al., 2012; Çelebi et al., 2012). In this approach, first a confusion model (CM) is estimated from supervised data. This CM contains all seen confusions and their occurrence probabilities in hypotheses generated by an ASR system. Then, the CM is used to generate a number of alternative-but-incorrect hypotheses, or simulated hypotheses, for a given sentence. Since the CM characterizes the errors that the ASR system makes, simulated hypotheses carry these characteristics. At the end, the DLM is trained on the reference sentences and their simulated hypotheses. Although being able to simulate the output of the ASR system allows us to generate as much output as we need for the DLM training, there is not always enough text data that is in the same domain as the ASR system. Yet, it is easier to find large amounts of out-of-domain (OOD) text data. In this study, we extend the previous studies where in-domain text data was used for hypothesis simulation. Instead of using limited in-domain data, we experiment with larger amounts of OOD data for hypothesis simulation.

The rest of the paper is organized as follows. In Section 2, we summarize the related work. In Section 3, we explain the methods to simulate the hypotheses and to train the DLM. We give the experimental results in Section 4 before concluding with Section 5.

2 Related Work

The earliest work on hypothesis simulation for DLM was done by Kurata et al. (2009; 2012). They generate the probable n-best lists that an ASR system may output for a hypothetical input utterance given a word sequence. In another study, Tan et al. (2010) propose a system for channel modeling of ASR for simulating the ASR corruption using a phrase-based machine translation system trained between the reference and output phoneme sequences from a phoneme recognizer. Jyothi and Fosler-Lussier (2010) also model the phonetic confusions using a confusion matrix that takes into account word-based phone confusion log likelihoods and distances between the phonetic acoustic models. This model is then used to generate confusable word graphs for training a DLM using the perceptron algorithm. Xu et al. (2009) propose the concept of cohorts and report significant WER improvement for self-supervised DLM. Similarly, Sagae et al. (2012) use phrasal cohorts to simulate ASR output and the perceptron algorithm for training. They observe half of the WER reduction that the fully supervised methods achieve. In another parallel study, Çelebi et al. (2012) work on a Turkish ASR system and consider various confusion models at four different granularities (word, morph, syllable, and phone) and different sampling methods to choose from a large list of simulated hypotheses. They observe that the strategy that matches the word error (WE) distribution of the simulated hypotheses to the WE distribution of the ASR outputs yields the best WER reduction.

While the previous studies use in-domain data sets for simulation, it is quite common to collect large amounts of OOD text data from the web. However, given the nature of web data, some kind of selection mechanism is needed to ensure quality. Bullyko et al. (2007) use perplexity-based filtering to select a relevant subset from vast amounts of web data in order to increase the training data of the generative LM used by the ASR system. There are also studies that use a relative-entropy based selection mechanism in order to match the n-gram distribution of the selected data against the in-domain data by Sethy et al. (2006; 2009). In this study, we consider the perplexity-based selection method for a start.

3 Method

3.1 Sentence Selection from OOD Data

In order to select sentences from the OOD data, we use three methods in addition to random selection. We calculate the perplexity of each sentence with SRILM toolkit, which gives normalized scores with respect to the length of the sentence. Then, we order sentences based on their perplexity scores in increasing order. Perplexity is calculated by a LM trained on in-domain data. After ordering, the top of the list contains those sentences that resemble the in-domain data the most whereas the sentences at the bottom resemble the in-domain data the least. We apply the three methods on this ordered list of sentences. The first two methods, TOP- N and BOTTOM- N , simply get the top and bottom N sentences, respectively. The third method, RC- $N \times M$, picks uniformly separated N clusters of M consecutive sentences, while making sure that top and bottom M sentences are among the selected ones.

3.2 Hypothesis Simulation

Semi-supervised DLM training uses artificially generated hypotheses which mimic the ASR system output. To generate the hypotheses, we follow the three-step finite state transducer based pipeline given in Çelebi et al. (2012) and summarized by the following composition sequence:

$$\text{sample}(N\text{-best}(\text{prune}(\mathcal{W} \circ \mathcal{L}_{\mathcal{W}} \circ \mathcal{CM}) \circ \mathcal{L}_{\mathcal{M}}^{-1} \circ \mathcal{G}_{\mathcal{M}}))$$

In the first step of the pipeline, we use the confusion model transducer (\mathcal{CM}) to generate all possible confusions that the ASR system can make for a given reference sentence \mathcal{W} . We consider syllable, morph and word based confusion models, and convert \mathcal{W} to these units using the lexicon $\mathcal{L}_{\mathcal{W}}$. The generated alternatives are pruned for efficiency reasons.

As the output of the first step may include many implausible sequences, the second step converts them to morphs using $\mathcal{L}_{\mathcal{M}}^{-1}$ and reweights them with a morph-based language model $\mathcal{G}_{\mathcal{M}}$ to favor the meaningful sequences. For this, we use three approaches. The first approach is to use the LM that is used by the ASR system, called GEN-LM. The second LM called ASR-LM is trained from the output of the ASR system, whereas the third approach is not to use any language model, denoted by NO-LM,

in which case we just use the scores coming from the confusion model in the first step. A large list of N -best ($N = 1000$) hypotheses are produced at this stage.

The third step, called sampling, involves picking a subset of the hypotheses from a larger set with broad variety. This step is done in order to pick samples so as to make sure that they include error variety instead of just high scoring hypotheses. As done by Çelebi et al. (2012), we use four sampling methods to pick 50 hypotheses out of the highest scoring 1000 hypotheses. The simplest of them is Top50, where we select the highest scoring 50 hypotheses. Another method is Uniform Sampling (US) which selects instances from the WER-ordered list in uniform intervals. Third method, called RC5x10, forms 5 clusters separated uniformly, each containing 10 hypotheses. Lastly, ASRdist-50 selects 50 hypotheses in such a way that the WE distribution of selected hypotheses resembles the WE distribution of the real ASR output as much as it can. We accomplish this by filling the WE bins with the hypotheses having required number of WEs.

3.3 DLM Estimation

The training of the DLM involves representing the training data as feature vectors and processing via a discriminative learning algorithm. We represent the simulated N -best lists using unigram features as described by Dikici et al. (2012). As the learning algorithm, we apply the WER-sensitive perceptron algorithm proposed by Sak et al. (2011b), which has been shown to perform better for reranking ASR hypotheses as it minimizes an objective function based on the WER rather than the number of misclassifications.

4 Experiments

4.1 Experimental Setup

We employ DLM on a Turkish broadcast news transcription data set (Arisoy et al., 2009), which comprises disjoint training (105356 sentences), held-out (1947 sentences) and test (1784 sentences) subsets consisting of ASR outputs represented as N -best lists. We use Morfessor (Creutz and Lagus, 2005) to obtain the morph level word segmentations from which we build the LMs. For semi-supervised ex-

periments, we use the first half of the training subset (t_1 : 53992 sentences, 965K morphs) to learn the confusion models, and the reference transcriptions of the second half (t_2 : 51364 sentences, 935K morphs) to generate in-domain simulated n-best lists to be compared against OOD simulated ones. For this setup, the generative baseline WER and oracle WER on the held-out set are 22.9% and 14.2% and on the test set are 22.4% and 13.9%, respectively. When we use ASR 50-best from t_1 for DLM training, WERs drop to 22.2% and 21.8% on the held-out and the test sets, respectively.

For OOD data, we use a data set of 10.8M sentences (140M morphs) from newspaper articles downloaded from the Internet (Sak et al., 2011a). To calculate the perplexity of OOD sentences for selection, we use a language model trained over the reference transcripts and 50-best lists of t_1 and t_2 .

4.2 Results on Out-of-Domain Data

We start our experiments with 500K randomly selected OOD sentences, or RAND-500K. We run the simulation pipeline with four sampling methods, three confusion and three language models, giving 36 experiments in total. We choose among the proposed sampling approaches and confusion models using a rank-based comparison as done by Dikici et al. (2012).

We look at which sampling method performs the best by first dividing experiments into 9 groups, each having 4 results from all sampling methods. Within each group, we rank the sampling methods based on the WER they achieve in increasing order and take the average of assigned ranks. ASRdist-50 gets the lowest average rank of 1.8, while RC5x10, US-50, and TOP-50 come after with the averages of 2.1, 2.4, and 3.4, respectively. This shows that ASRdist-50 gives the best WER reduction on OOD data, which is also true for in-domain data (Çelebi et al., 2012).

Doing the same rank-based comparison for the CMs this time, we observe that the syllable and morph-based models have the same average rank of 1.5, whereas the word-based model has 2.8. However, a closer look reveals that the syllable-based CM paired with NO-LM is an outlier because NO-LM approach allows variety at the output but when the unit of the confusion model is as small as syllables, it produces too much variety that deteriorates the WER.

rates the discriminative model. If we don't consider the ranks coming from NO-LM, the average rank of syllable- and morph-based models become 1.1 and 1.8, respectively. Thus, we use syllable-based models over the others for the rest of the experiments.

Knowing that the ASRdist-50 sampling method and syllable-based CM together give the best results for RAND-500K, we experiment with three more sentence selection methods described in Section 3.1. Table 1 shows all the results obtained from four 500K OOD data sets.

OOD Data sets	GEN-LM	ASR-LM	NO-LM
TOP-500K	22.6	22.6	22.6
BOTTOM-500K	22.4	22.2	22.5
RAND-500K	22.2	22.5	22.6
RC-5x100K	22.4	22.6	22.5

Table 1: WER (%) on held-out set obtained with syllable-based CMs and ASRdist-50 sampling method

According to Table 1, the highest WER reduction is achieved with BOTTOM-500K+ASR-LM and RAND-500K+GEN-LM combinations. While ASR-LM exceeds the other two LMs only in the case of BOTTOM-500K, for other three OOD data sets GEN-LM gives the best results. More interestingly, using OOD sentences resembling in-domain data (or TOP-500K) is outperformed in all cases, especially by BOTTOM-500K. To understand this, we look at the number of morphs in each data set given in Table 2. Even though each OOD data set has 500K sentences, BOTTOM-500K has the highest number of morphs ($\sim 6.5M$) and TOP-500K had the lowest ($\sim 3.5M$), while the other two have around 5.5M morphs. We also look at the morph unigram distribution (M) of all four data sets and calculating the KL divergence $KL(M \parallel U)$ ¹ of each M to uniform distribution (U). We observe that the unigram morph distribution of the TOP-500K data set is the least uniform with KL distance of 6.6, whereas BOTTOM-500K has KL distance of 2.7 and the other two have KL distances of around 4.3. In other words, this shows that TOP-500K has the lowest content variation, especially when compared to BOTTOM-500K. Note also the slightly high value of KL distance for t_2 , which can be attributed to the

¹ $KL(M \parallel U) = \sum_i p_i \log\left(\frac{p_i}{1/V}\right) = \log(V) - H(p)$, where $V = 61294$ and $H(p)$ is the entropy of p .

relatively low number of unique morphs (types).

Data set	KLD	Types	Tokens
t_2 (50K)	4.65	22,107	935,137
TOP-500K	6.63	20,689	3,519,012
BOTTOM-500K	2.71	54,458	6,474,385
RAND-500K	4.36	50,422	5,559,763
RC-5x100K	4.35	50,561	5,343,342

Table 2: KL distance, $KL(M \parallel U)$, between uniform distribution (U) and unigram morph distribution (M); number of unique morphs and tokens.

4.3 Out-of-Domain vs In-Domain Data

In this section, we compare the results for in-domain data with the results for four OOD data sets in Table 3. In order to see how the size of OOD data set affects the WER reduction, we start with 50K sentences and increase the size gradually up to 500K. The first row of Table 3 shows the WER obtained with the in-domain data t_2 , containing approximately 50K sentences.

Data	50K	100K	200K	500K
t_2	22.4	-	-	-
TOP	22.8	22.7	22.7	22.6
BOTTOM	22.6	22.4	22.3	22.2
RAND	22.5	22.3	22.3	22.2
RC-5	22.5	22.5	22.3	22.4

Table 3: WER (%) on held-out set for in-domain (Syllable+ASR-LM+ASRdist-50) and four OOD data sets in increasing sizes

According to Table 3, even though 50K OOD sentences yield worse results than the same amount of in-domain sentences, as the size of OOD data set increases, the amount of WER reduction increases and surpasses the level obtained by using in-domain data. What is more interesting is that RAND outperforms in-domain data starting from 100K, whereas BOTTOM starts at a higher WER but drops relatively fast, leveling with RAND starting at 200K. Note that the best WER achieved with the simulated data matches the supervised DLM performance using ASR 50-best from t_1 , reported in Section 4.1.

Then we go one step further and expand the BOTTOM data set to 1M sentences and we observe WER of 22.1% on the held-out set. This further supports

the observation that the more OOD data we use, the lower WER we can achieve.

As a side observation, when we calculate the WER of five 100K-blocks from the RAND-500K set, we find that the standard deviation of WER is 0.06%, which gives an idea about the significance level of the WER differences.

4.4 Merging Real and Simulated Hypotheses

We also evaluate whether merging simulated hypotheses with real ASR hypotheses yields further WER reductions. The result of merging the real hypotheses from t_1 with the simulated ones from in-domain and OOD data are shown in Table 4. The first row shows the WER of the combination with the simulated hypotheses from in-domain data t_2 .

Real	Simulated	WER (%)
t_1	t_2 (50K)	22.0
t_1	TOP-500K	22.3
t_1	BOTTOM-500K	22.1
t_1	RAND-500K	22.0
t_1	RC-5x100K	22.1
t_1	BOTTOM-1M	21.9

Table 4: WER (%) on held-out set obtained by merging real and simulated hypotheses

When combined with the real hypotheses from t_1 , RAND500K achieves the same level of WER reduction as the simulated hypotheses from t_2 on the heldout set. The results on the test set are also similar. On the test set, the combination of the real hypotheses from t_1 and the simulated hypotheses from t_2 achieve 21.5% WER, whereas the WER is 21.6% when the simulated hypotheses from t_2 are replaced by those from RAND500K. This indicates that enough OOD data can replace the in-domain data and yield similar performance, even in combination with in-domain real data.

Moreover, we further expand the OOD data to 1M for BOTTOM, however even though it reduces the WER on the heldout set, it achieves slightly higher WER on the test set (21.7%).

Next, we combine the in-domain real hypotheses from t_1 , simulated hypotheses from t_2 and simulated ones from the OOD data sets. However, compared to the combination of t_1 and t_2 , adding extra 500K OOD hypotheses on top of those two gives similar

WERs on the held-out set while WERs on the test set increases slightly. From another point of view, adding in-domain simulated hypotheses from t_2 on top of real ones from t_1 and 500K OOD data (rows 2-5 in Table 4) provides slight WER improvement on the held-out set but not on the test set.

5 Conclusion

In this study, we investigate whether we can achieve the same level of WER reduction for semi-supervised DLM with the large amounts of OOD data instead of in-domain data. We observe that ASRdist-50 sampling method and syllable-based CMs yield the best results with the OOD data. Moreover, selecting OOD sentences randomly rather than using perplexity-based methods is enough to achieve the best WER reduction. We also observe that simulated hypotheses from the OOD data is almost as good as in-domain simulated hypotheses or even real ones. As a future work, we will increase the size of the OOD data and examine other methods like relative entropy based OOD selection.

Abstract

Word Sense Disambiguation (WSD) approaches have reported good accuracies in recent years. However, these approaches can be classified as weak AI systems. According to the classical definition, a strong AI based WSD system should perform the task of sense disambiguation in the same manner and with similar accuracy as human beings. In order to accomplish this, a detailed understanding of the human techniques employed for sense disambiguation is necessary. Instead of building yet another WSD system that uses contextual evidence for sense disambiguation, as has been done before, we have taken a step back - we have endeavored to discover the cognitive faculties that lie at the very core of the human sense disambiguation technique.

In this paper, we present a hypothesis regarding the cognitive sub-processes involved in the task of WSD. We support our hypothesis using the experiments conducted through the means of an eye-tracking device. We also strive to find the levels of difficulties in annotating various classes of words, with senses. We believe, once such an in-depth analysis is performed, numerous insights can be gained to develop a robust WSD system that conforms to the principle of strong AI.

1 Introduction

Word Sense Disambiguation (WSD) is formally defined as the task of computationally identifying senses of a word *in a context*. The phrase ‘in a context’ is not defined explicitly in the literature. NLP researchers define it according to their convenience. In our current work, we strive to unravel

the appropriate meaning of contextual evidence used for the human annotation process. Chatterjee et al. (2012) showed that the contextual evidence is the predominant parameter for the human sense annotation process. They also state that WSD is successful as a *weak AI* system, and further analysis into human cognitive activities lying at the heart of sense annotation can aid in development of a WSD system built upon the principles of strong AI.

Knowledge based approaches, which can be considered to be closest form of WSD conforming to the principles of strong AI, typically achieve low accuracy. Recent developments in domain-specific knowledge based approaches have reported higher accuracies. A domain-specific approach due to Agirre et al. (2009) beats supervised WSD done in generic domains. Ponzetto andNavigli (2010) present a knowledge based approach which rivals the supervised approaches by using the semantic relations automatically extracted from Wikipedia. They reported approximately 7% gain over the closet supervised approach.

In this paper, we delve deep into the cognitive roles associated with sense disambiguation through the means of an eye-tracking device capturing the gaze patterns of lexicographers, during the annotation process. In-depth discussions with trained lexicographers indicate that there are multiple cognitive sub-processes driving the sense disambiguation task. The eye movement paths available from the screen recordings done during sense annotation conform to this theory.

Khapra et al. (2011) points out that the accuracy of various WSD algorithms is poor on certain

Part-of-speech (POS) categories, particularly, verbs. It is also a general observation for lexicographers involved in sense annotation that there are different levels of difficulties associated with various classes of words. This fact is also reflected in our analysis on sense annotation. The data available after the eye-tracking experiments gave us the fixation times and saccades pertaining to different classes of words. From the analysis of this data we draw conclusive remarks regarding the reasons behind this phenomenon. In our case, we classified words based on their POS categories.

In this paper, we establish that contextual evidence is the prime parameter for the human annotation. Further, we probe into the implication of context used as a clue for sense disambiguation, and the manner of its usage. In this work, we address the following questions:

- *What are the cognitive sub-processes associated with the human sense annotation task?*
- *Which classes of words are more difficult to disambiguate and why?*

By providing relevant answers to these questions we intend to present a comprehensive understanding of sense annotation as a complex cognitive process and the factors involved in it. The remainder of this paper is organized as follows. Section 2 contains related work. In section 3 we present the experimental setup. Section 4 displays the results. We summarize our findings in section 5. Finally, we conclude the paper in section 6 presenting the future work.

2 Related Work

As mentioned earlier, we used the eye-tracking device to ascertain the fact that contextual evidence is the prime parameter for human sense annotation as quoted by Chatterjee et al. (2012) who used different annotation scenarios to compare human and machine annotation processes. An eye movement experiment was conducted by Vainio et al. (2009) to examine effects of local lexical predictability on fixation durations and fixation locations during sentence reading. Their study indicates that local lexical predictability influences in decisions but not where the initial fixation lands in a word. In another work based on word grouping hypothesis and eye

movements during reading by Drieghe et al. (2008), the distribution of landing positions and durations of first fixations in a region containing a noun preceded by either an article or a high-frequency three-letter word were compared.

Recently, some work is done on the study of sense annotation. A study of sense annotations done on 10 polysemous words was conducted by Passonneau et al. (2010). They opined that the word meanings, contexts of use, and individual differences among annotators gives rise to inter-annotation variations. De Melo et al. (2012) present a study with a focus on MASC (Manually-Annotated SubCorpus) project, involving annotations done using WordNet sense identifiers as well as FrameNet lexical units.

In our current work we use eye-tracking as a tool to make findings regarding the cognitive processes connected to the human sense disambiguation procedure, and to gain a better understanding of “contextual evidence” which is of paramount importance for human annotation. Unfortunately, our work seems to be a first of its kind, and to the best of our knowledge we do not know of any such work done before in the literature.

3 Experimental Setup

We used a generic domain (*viz.*, News) corpus in Hindi language for experimental purposes. To identify the levels of difficulties associated with human annotation, across various POS categories, we conducted experiments on around 2000 words (including function words and stop words). The analysis was done only for open class words. The statistics pertaining to the our experiment are illustrated in table 1. For statistical significance of our experiments, we collected the data with the help of 3 skilled lexicographers and 3 unskilled lexicographers.

POS	Noun	Verb	Adjective	Adverb
#(senses)	2.423	3.814	2.602	3.723
#(tokens)	452	206	96	177

Table 1: Number of words (tokens) and average degree of corpus polysemy (senses) of words per POS category (taken from Hindi News domain) used for experiments

For our experiments we used a Sense Annotation

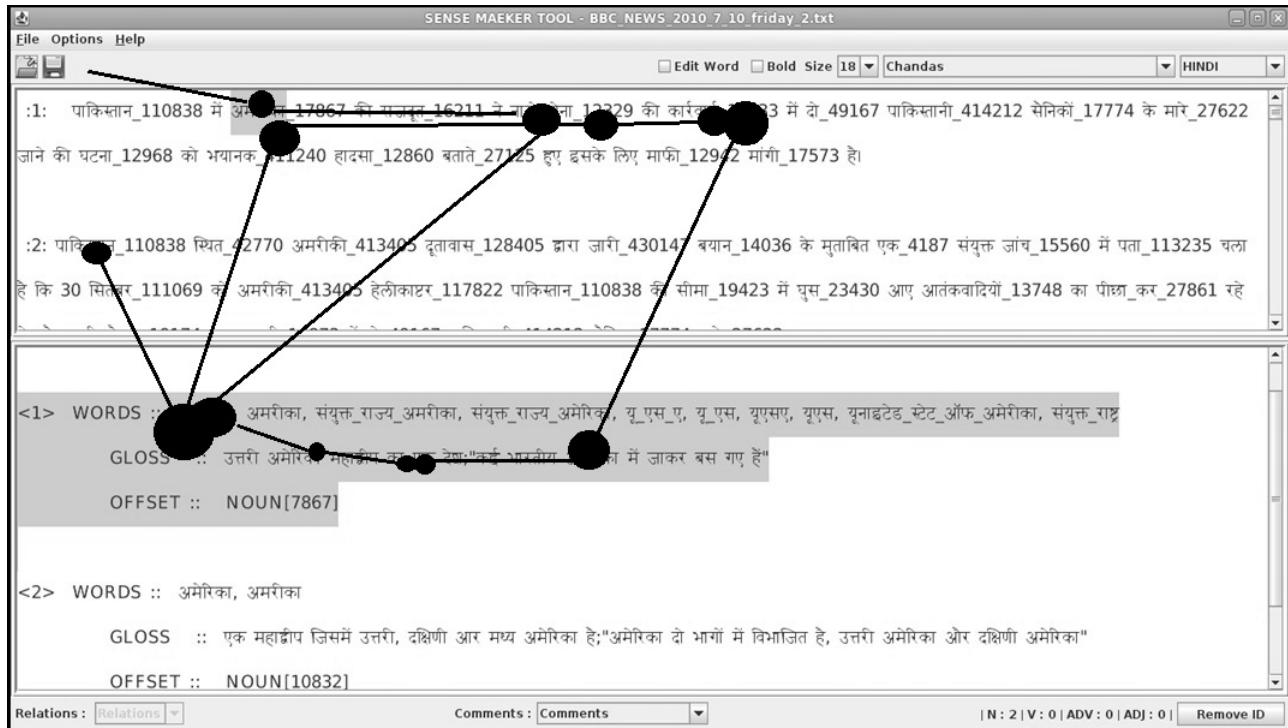

Figure 1: Sense marker tool showing an example Hindi sentence in the *Context Window* and the wordnet synsets of the highlighted word in the *Synset Window* with the black dots and lines indicating the scan path

Tool, designed at IIT Bombay and an eye-tracking device. The details of the tools and their purposes are explained below:

3.1 The Sense Marker Tool

A word may have a number of senses, and the task of identifying and marking which particular sense has been used in the given context, is known as *sense marking*.

The Sense Marker tool¹ is a Graphical User Interface based tool developed using Java, which facilitates the task of manual sense marking. This tool displays the senses of the word as available in the Marathi, Hindi and Princeton (English) WordNets and allows the user to select the correct sense of the word from the candidate senses.

3.2 Eye-Tracking device

An eye tracker is a device for measuring eye positions and eye movement. A *saccade* denotes move-

ment to another position. The resulting series of fixations and saccades is called a *scan path*. Figure 1 shows a sample scan path. In our experiments, we have used an eye tracking device manufactured by SensoMotoric Instruments². We recorded saccades, fixations, length of each fixation and scan paths on the stimulus monitor during the annotation process. A remote eye-tracking device (RED) measures gaze hotspots on a stimulus monitor.

4 Results

In our experiments, each lexicographer performed sense annotation on the stimulus monitor of the eye tracking device. Fixation times, saccades and scan paths were recorded during the sense annotation process. We analyzed this data and the corresponding observations are enumerated below.

Figure 2 shows the annotation time taken by different lexicographers across POS categories. It can be observed that the time taken for disambiguating the verbs is significantly higher than the remaining POS

Word	Degree of polysemy	Unskilled Lexicographer (Seconds)				Skilled Lexicographer (Seconds)			
		T_{hypo}	T_{clue}	T_{gloss}	T_{total}	T_{hypo}	T_{clue}	T_{gloss}	T_{total}
लाना (laanaa - to bring)	4	0.63	0.80	5.20	6.63	0.31	1.20	1.82	3.30
करना (karanaa - to do)	22	0.90	1.42	2.20	4.53	0.50	0.64	1.14	2.24
जताना (jataanaa - to express)	4	0.70	2.45	5.93	9.09	0.25	0.39	0.62	1.19

Table 2: Comparison of time taken across different cognitive stages of sense annotation by lexicographers for verbs

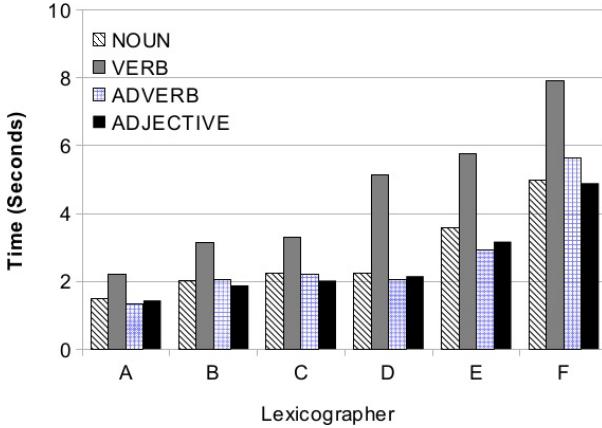

Figure 2: Histogram showing time taken (in seconds) by each lexicographer across POS categories for sense annotation

categories. This behavior can be consistently seen in the timings recorded for all the six lexicographers.

Table 2 presents the comparison of time taken across different cognitive stages of sense annotation by lexicographers for some of the most frequently occurring verbs.

To know if the results gathered from all the lexicographers are consistent, we present the correlation between each pair of lexicographers in table 3. The table also shows the value of the t-test statistic generated for each pair of lexicographers.

5 Discussion

The data obtained from the eye-tracking device and corresponding analysis of the fixation times, saccades and scan paths of the lexicographers' eyes reveal that sense annotation is a complex cognitive process. From the videos of the scan paths obtained from the eye-tracking device and from detailed discussion with lexicographers it can be inferred that

this cognitive process can be broken down into 3 stages:

1. When a lexicographer sees a word, he/she makes a hypothesis about the domain and consequently about the correct sense of the word, mentally. In cases of highly polysemous words, the hypothesis may narrow down to multiple senses. We denote the time required for this phase as T_{hypo} .
2. Next the lexicographer searches for clues to support this hypothesis and in some cases to eliminate false hypotheses, when the word is polysemous. These clues are available in the form of neighboring words around the target word. We denote the time required for this activity as T_{clue} .
3. The clue words aid the lexicographer to decide which one of the initial hypotheses was true. To narrow down the candidate synsets, the lexicographers use synonyms of the words in a synset to check if the sentence retains its meaning.

From the scan paths and fixation times obtained from the eye-tracking experiment, it is evident that stages 1, 2 and 3 are chronological stages in the human cognitive process associated with sense disambiguation. In cases of highly polysemous words and instances where senses are fine-grained, stages 2 and 3 get interleaved. It is also clear that each stage takes up separate proportions of the sense disambiguation time for humans. Hence time taken to disambiguate a word using the Sense Marker Tool (as explained in Section 3.1) can be factored as follows:

$$T_{total} = T_{hypo} + T_{clue} + T_{gloss}$$

Where:

T_{total} = Total time for sense disambiguation

Lexicographer	Correlation value					T-test statistic				
	B	C	D	E	F	B	C	D	E	F
A	0.933	0.976	0.996	0.996	0.769	0.007	0.123	0.185	0.036	0.006
B		0.987	0.960	0.915	0.945		0.009	0.028	0.084	0.026
C			0.989	0.968	0.879			0.483	0.088	0.067
D				0.988	0.820				0.367	0.709
E					0.734					0.418

Table 3: Pairwise correlation between annotation time taken by lexicographers

T_{hypo} = Time for hypothesis building

T_{clue} = Clue word searching time

T_{gloss} = Gloss Matching time and winner sense selection time.

The results in table 2 reveal the different ratios of time invested during each of the above stages. T_{hypo} takes the minimum amount of time among the different sub-processes. $T_{gloss} > T_{clue}$ in all cases.

- For unskilled lexicographers: $T_{gloss} \gg T_{clue}$ because of errors in the initial hypothesis.
- For skilled lexicographers: $T_{gloss} \sim T_{clue}$, as they can identify the POS category of the word and their hypothesis thus formed is pruned. Hence during selection of the winner sense, they do not browse through other POS categories, which unskilled lexicographers do.

The results shown in figure 2 reveal that verbs take the maximum disambiguation time. In fact the average time taken by verbs is around 75% more than the time taken by other POS categories. This supports the fact that verbs are the most difficult to disambiguate.

The analysis of the scan paths and fixation times available from the eye-tracking experiments in case of verbs show that the T_{gloss} covers around 66% of T_{total} , as shown in table 2. This means that the lexicographer takes more time in selecting a winner sense from the list of wordnet senses. This happens chiefly because of following reasons:

1. Higher degree of polysemy of verbs compared to other POS categories (as shown in tables 1 and 2).
2. In several cases the senses are fine-grained.

3. Sometimes the hypothesis of the lexicographers may not match any of the wordnet senses. The lexicographer then selects the wordnet sense closest to their hypothesis.

Adverbs and adjectives show higher degree of polysemy than nouns (as shown in table 1), but take similar disambiguation time as nouns (as shown in figure 2). In case of adverbs and adjectives, the lexicographer is helped by their position around a verb or noun respectively. So, T_{clue} only involves searching for the nearby verbs or nouns, as the case may be, hence reducing total disambiguation time T_{total} .

6 Conclusion and Future Work

In this paper we examined the cognitive process that enables the human sense disambiguation task. We have also laid down our findings regarding the varying levels of difficulty in sense annotation across different POS categories. These experiments are just a stepping stone for going deeper into finding the meaning and manner of usage of contextual evidence which is fundamental to the human sense annotation process.

In the future we aim to perform an in-depth analysis of clue words that aid humans in sense disambiguation. The distance of clue words from the target word and their pattern of occurrence could give us significant insights into building a ‘Discrimination Net’.

Improving Lexical Semantics for Sentential Semantics: Modeling Selectional Preference and Similar Words in a Latent Variable Model

Weiwei Guo

Department of Computer Science

weiwei@cs.columbia.edu

Mona Diab

Department of Computer Science
George Washington University
mtdiab@gwu.edu

Abstract

Sentence Similarity [SS] computes a similarity score between two sentences. The SS task differs from document level semantics tasks in that it features the sparsity of words in a data unit, i.e. a sentence. Accordingly it is crucial to robustly model each word in a sentence to capture the complete semantic picture of the sentence. In this paper, we hypothesize that by better modeling lexical semantics we can obtain better sentential semantics. We incorporate both corpus-based (selectional preference information) and knowledge-based (similar words extracted in a dictionary) lexical semantics into a latent variable model. The experiments show state-of-the-art performance among unsupervised systems on two SS datasets.

1 Introduction

Sentence Similarity [SS] is emerging as a crucial step in many NLP tasks that focus on sentence level semantics such as word sense disambiguation (Guo and Diab, 2010; Guo and Diab, 2012a), summarization (Zhou et al., 2006), text coherence (Lapata and Barzilay, 2005), tweet clustering (Sankaranarayanan et al., 2009; Jin et al., 2011), etc. SS operates in a very small context, on average 11 words per sentence in Semeval-2012 dataset (Agirre et al., 2012), resulting in inadequate evidence to generalize to robust sentential semantics.

Weighted Textual Matrix Factorization [WTMF] (Guo and Diab, 2012b) is a latent variable model that outperforms Latent Semantic Analysis [LSA] (Deerwester et al., 1990) and Latent Dirichelet Allocation [LDA] (Blei et al., 2003) models by a large margin in

the SS task, yielding state-of-the-art performance on the LI06 (Li et al., 2006) SS dataset. However, all of these models make harsh simplifying assumptions on how a token is generated: (1) in LSA/WTMF, a token is generated by the inner product of the word latent vector and the document latent vector; (2) in LDA, all the tokens in a document are sampled from the same document level topic distribution. Under this framework, they ignore rich linguistic phenomena such as inter-word dependency, semantic scope of words, etc. This is a result of simply using document IDs as features to represent a word.

Modeling quality lexical semantics in latent variable models does not draw enough attention in the community, since people usually apply dimension reduction techniques for documents, which have abundant words for extracting the document level semantics. However, in the SS setting, it is crucial to make good use of each word, given the limited number of words in a sentence. We believe a reasonable word generation story will avoid introducing noise in sentential semantics, encouraging robust lexical semantics which can further boost the sentential semantics. In this paper, we explicitly encode lexical semantics, both corpus-based and knowledge-based information, in the WTMF model, by which we are able to achieve even better results in SS task.

The additional corpus-based information we exploit is selectional preference semantics (Resnik, 1997), a feature already existing in the data yet ignored by most latent variable models. Selectional preference focuses on the admissible arguments for a word, thus capturing more nuanced semantics than the sentence IDs (when applied to a corpus of sentences as opposed to documents). Consider the following example:

Figure 1: matrix factorization

Many analysts say the global Brent crude oil benchmark price, currently around \$111 a barrel ...

In WTMF/LSA/LDA, a word will receive semantics from all the other words in a sentence, hence, the word *oil*, in the above example, will be assigned the incorrect *finance* topic that reflects the sentence level semantics. Moreover, the problem worsens for adjectives, adverbs and verbs, which have a much narrower semantic scope than the whole sentence. For example, the verb *say* should only be associated with *analyst* (only receiving semantics from *analyst*), as it is not related to other words in the sentence. In contrast, *oil*, according to its selectional preference, should be associated with *crude* indicating the *resource* topic. We believe modeling selectional preference capturing local evidence completes the semantic picture for words, hence further rendering better sentential semantics. To our best knowledge, this is the first work to model selectional preference for sentence/document semantics.

We also integrate knowledge-based semantics in the WTMF framework. Knowledge-based semantics, a human-annotated clean resource, is an important complement to corpus-based noisy co-occurrence information. We extract similar word pairs from Wordnet (Fellbaum, 1998). Leveraging these pairs, an infrequent word such as *purchase* can exploit robust latent vectors from its synonyms such as *buy*. Similar words pairs can be seamlessly modeled in WTMF, since in the matrix factorization framework a latent vector profile is explicitly created for each word, while in LDA all the data structures are designed for documents/sentences. We construct a graph to connect words according to the extracted similar word pairs, to encourage similar words to share similar latent vector profiles. We will refer to our proposed novel model as WTMF+PK.

2 Weighted Textual Matrix Factorization

Our previous work (Guo and Diab, 2012b) models the sentences in the weighted matrix factorization

framework (Figure 1). The corpus is stored in an $M \times N$ matrix X , with each cell containing the TF-IDF values of words. The rows of X are M distinct words and columns are N sentences. As in Figure 1, X is approximated by the product of a $K \times M$ matrix P and a $K \times N$ matrix Q . Accordingly, each sentence s_j is represented by a K dimensional latent vector $Q_{\cdot,j}$. Similarly a word w_i is generalized by $P_{\cdot,i}$. P and Q is optimized by minimize the objective function:

$$\sum_i \sum_j W_{ij} (P_{\cdot,i} \cdot Q_{\cdot,j} - X_{ij})^2 + \lambda \|P\|_2^2 + \lambda \|Q\|_2^2 \quad (1)$$

$$W_{i,j} = \begin{cases} 1, & \text{if } X_{ij} \neq 0 \\ w_m, & \text{if } X_{ij} = 0 \end{cases}$$

where λ is a regularization term. Missing tokens are modeled by assigning a different weight w_m for each 0 cell in the matrix X . We can see the inner product of a word vector $P_{\cdot,i}$ and a sentence vector $Q_{\cdot,j}$ is used to approximate the cell X_{ij} .

The graphical model of WTMF is illustrated in Figure 2a. A w_i/s_j node is a latent vector $P_{\cdot,i}/Q_{\cdot,j}$, corresponding to a word/sentence, respectively. A shaded node is a non-zero cell in X , representing an observed token in a sentence. For simplicity, the missing tokens and weights are not shown in the graph.

3 Corpus-based Semantics: Selectional Preference

In this paper, we focus on selectional preference that reflects the association of two words: if two words form a bigram, then the two words should share similar latent dimensions. In the previous example, *crude* and *oil* form a bigram, and they share the *resource* topic. In our framework, this is implemented by adding extra columns in X , so that each additional column corresponds to a bigram, treating each bigram as a *pseudo-sentence* for the two words. The graphical model is illustrated in Figure 2b. Therefore, *oil* will receive more *resource* topic from *crude* through the bigram *crude oil*, instead of only *finance* topic from the sentence as a whole.

Each non-zero cell in the new columns of X , i.e. an observed token in a bigram (pseudo-sentence), is given a different weight:

$$W_{i,j} = \begin{cases} 1, & \text{if } X_{ij} \neq 0 \text{ and } j \text{ is a sentence index} \\ \gamma \cdot freq(j), & \text{if } X_{ij} \neq 0 \text{ and } j \text{ is a bigram index} \\ w_m, & \text{if } X_{ij} = 0 \end{cases}$$

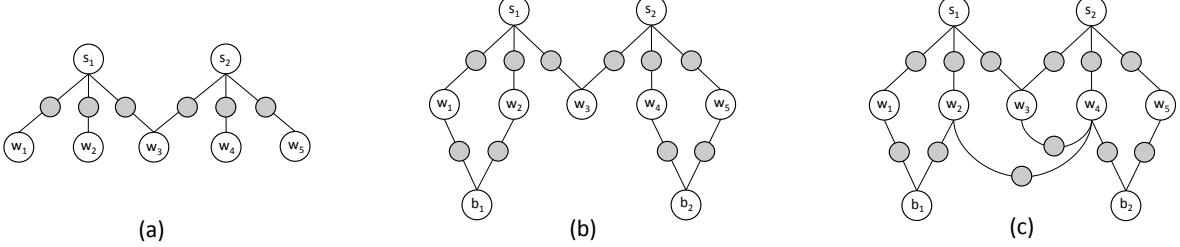

Figure 2: WTMF+PK model (WTMF + corpus-based Selectional [P]references semantics + [K]nowledge-based semantics): a *w/s/b* node represents a word/sentence/bigram, respectively

$freq(j)$ denotes the frequency of bigram j appearing in the corpus, hence the strength of association is differentiated such that higher weights are assigned on the more probable bigrams. The coefficient γ is the importance of selectional preference. A larger γ indicates that we trust the selectional preference over the global sentential semantics.

4 Knowledge-based Semantics: Similar Word Pairs

We first extract synonym pairs from WordNet, which are words associated with the same sense, synset. We further expand the set by exploiting the relations defined in WordNet. For the extracted words, we consider the first sense of each word, and if it is connected to other senses by any of the WordNet defined relations (*hypernym*, *similar words*, etc.), then we treat the words associated with the other senses as similar words. In total, we are able to discover $80K$ pairs of similar words for the $46K$ distinct words in our corpus.

Given a pair of similar words w_{i_1}/w_{i_2} , we want the two corresponding latent vectors $P_{\cdot,i_1}/P_{\cdot,i_2}$ to be as close as possible, namely the cosine similarity to be close to 1. Accordingly, a term is added in equation 1 for each similar word pair w_{i_1}/w_{i_2} :

$$\delta \cdot (P_{\cdot,i_1} \cdot P_{\cdot,i_2} - |P_{\cdot,i_1}| |P_{\cdot,i_2}|)^2 \quad (2)$$

$|P_{\cdot,i}|$ denotes the length of the vector $P_{\cdot,i}$. The coefficient δ , analogous to γ , denotes the importance of the knowledge-based evidence. The Figure 2c shows the final WTMF+PK model.

5 Inference

In (Guo and Diab, 2012b) we use Alternating Least Square [ALS] for inference, which is to set the

derivative of equation 1 for P/Q to 0 and iteratively compute P/Q by fixing the other matrix (Srebro and Jaakkola, 2003). However, it is no longer applicable with the new term (equation 2) involving the length of word vectors $|P_{\cdot,i}|$. Therefore we approximate the objective function by treating the vector length $|P_{\cdot,i}|$ as fixed values during the ALS iterations:

$$\begin{aligned} Q_{\cdot,j} &= \left(P \tilde{W}^{(j)} P^\top + \lambda I \right)^{-1} P \tilde{W}^{(j)} X_{\cdot,j} \\ P_{\cdot,i} &= \left(Q \tilde{W}^{(i)} Q^\top + \lambda I + \delta P_{\cdot,s(i)} P_{\cdot,s(i)}^\top \right)^{-1} \\ &\quad \left(Q \tilde{W}^{(i)} X_{\cdot,i}^\top + \delta L_i P_{\cdot,s(i)} L_{s(i)} \right) \end{aligned} \quad (3)$$

where $P_{\cdot,s(i)}$ are the latent vectors of similar words of word i ; the length of these vectors in the current iteration are stored in $L_{s(i)}$ (similarly L_i is the current length of $P_{\cdot,i}$) (cf. (Steck, 2010; Guo and Diab, 2012b) for optimization details).

6 Experimental Setting

We build the model WTMF+PK on the same **corpora** as used in our previous work (Guo and Diab, 2012b), comprising the following: Brown corpus (each sentence is treated as a document), sense definitions from Wiktionary and Wordnet (only definitions without target words and usage examples). We follow the preprocessing steps in (Guo and Diab, 2012c): tokenization, pos-tagging, lemmatization and further merge lemmas. The corpus is used for building matrix X .

The **evaluation datasets** are LI06 dataset and SemEval-2012 STS [STS12] (Agirre et al., 2012) dataset. LI06 consists of 30 sentence pairs (dictionary definitions). For STS12,¹ the training data (2000 pairs) are used as the tuning set for setting the

¹A detailed description of the data sets is provided in (Agirre et al., 2012).

parameters of our models. This data comprises msr-par, msr-vid, smt-eur. Once the models are tuned, we evaluate them on the STS12 test data that comprises 3150 sentence pairs from msr-par, msr-vid, smt-eur, smt-news, On-WN. It is worth noting that smt-news and On-WN are not part of the tuning data. We use cosine similarity to measure the similarity scores between two sentences. Pearson correlation between the system’s answer and gold standard similarity scores is used as the evaluation metric.

We include three **baselines** LSA, LDA and WTMF using the setting described in (Guo and Diab, 2012b). We run Gibbs Sampling based LDA for 2000 iterations and average the model over the last 10 iterations. For WTMF, we run 20 iterations and fix the missing words weight at $w_m = 0.01$ with a regularization coefficient set at $\lambda = 20$, which is the best condition found in (Guo and Diab, 2012b).

7 Experiments

Table 1 summarizes the results at dimension $K = 100$ (the dimension of latent vectors). To remove randomness, each reported number is the averaged results of 10 runs. Based on the STS tuning set, we experiment with different values for the selectional preference weight ($\gamma = \{0, 1, 2\}$), and likewise for the similar word pairs weight varying the δ value as follows $\delta = \{0, 0.1, 0.3, 0.5, 0.7\}$. The performance on STS12 tuning and test dataset as well as on the LI06 dataset are illustrated in Figures 3a, 3b and 3d. The parameters of model 6 in Table 1 ($\gamma = 2, \delta = 0.3$) are the chosen values based on tuning set performance.

7.1 Evaluation on the STS12 datasets

Table 1 shows WTMF is already a very strong baseline: it outperforms LSA and LDA by a large margin. Same as in (Guo and Diab, 2012b), LSA performance degrades dramatically when trained on a corpus of sentence sized documents, yielding results worse than the surface words baseline 31% (Agirre et al., 2012). Using corpus-based selectional preference semantics **alone** (model 4 WTMF+P in Table 1) boosts the performance of WTMF by +1.17% on the test set, while using knowledge-based semantics **alone** (model 5 WTMF+K) improves the over the WTMF results by an absolute +2.31%. Combining

them (model 6 WTMF+PK) yields the best results, with an absolute increase of +3.39%, which suggests that the two sources of semantic evidence are useful, but more importantly, they are complementary for each other.

Table 1 also presents the performance on each individual dataset. The gain on each individual source is not as much as the overall gain, which suggests part of the overall gain comes from the correct ranking of intra-source pairs. Note that WTMF+PK improves all individual datasets except smt-eur. This may be caused by too many overlapping words in the sentence pairs in smt-eur, while our approach focuses on extracting similarity between different words.

Observing the performance using different values of weights in figure 3a and 3b, we can conclude that the selectional preference and similar word pairs yield very promising results. The trends hold in different parameter conditions with a consistent improvement. Figure 3c illustrates the impact of dimension $K = \{50, 75, 100, 125, 150\}$ on WTMF and WTMF+PK. Generally a larger K leads to a higher Pearson correlation, but the improvement is tiny when $K \geq 100$ (0.1% increase).

Compared to all the unsupervised systems that participated in Semeval STS 2012 task, WTMF+PK yields state-of-the-art performance (70.70%).² In (Guo and Diab, 2012c) we also apply WTMF ($K = 100$) on STS12, achieving a correlation of 69.5%. However, additional data is incorporated in the training corpora: (1) STS12 tuning set; (2) for WordNet and Wiktionary data, the target words are also included in the definitions (hence synonym pairs were used); (3) the usage examples of target words were also appended to the definitions.³ While trained with this experimental setting, our model WTMF+PK ($\gamma = 2, \delta = 0.3, K = 100$) is able to reach an even higher correlation of 72.0%.

²WTMF+PK is an unsupervised system, since the gold standard similarly scores are never used in the objective function. Moreover, even without a tuning set, a non-zero value of γ or δ will always improve the baseline WTMF according to figure 3a and 3b.

³We do not adopt this corpora schema, since some definitions are test set sentences in On-WN, thereby adding target words and usage examples introduces additional information for some of the test set sentences

Models	Parameters	STS12 tune	STS12 test	msr-par	msr-vid	On-WN	smt-eur	smt-news	LI06
1. LSA	-	21.67%	24.41%	27.18%	9.91%	50.93%	27.86%	19.73%	63.77%
2. LDA	$\alpha = 0.05, \beta = 0.05$	71.10%	63.18%	29.15%	76.73%	62.81%	47.81%	27.2%	83.71%
3. WTMF	-	71.41%	67.31%	44.00%	82.59%	70.78%	50.89%	37.77%	89.81%
4. WTMF+P	$\gamma = 2, \delta = 0$	72.94%	68.48%	46.21%	83.29%	70.61%	49.54%	39.50%	90.16%
5. WTMF+K	$\gamma = 0, \delta = 0.3$	73.84%	69.64%	45.04%	83.04%	70.40%	49.88%	41.66%	90.11%
6. WTMF+PK	$\gamma = 2, \delta = 0.3$	75.29%	70.70%	46.77%	83.90%	71.03%	49.77%	40.48%	90.17%

Table 1: Evaluation Results using Pearson Correlation on STS12 and LI06

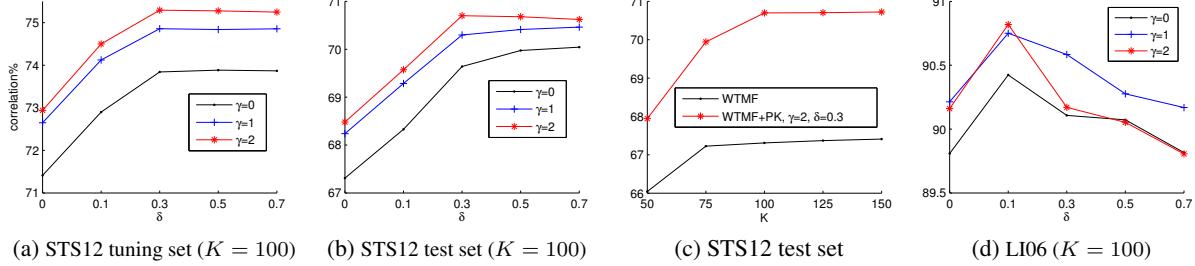

Figure 3: Pearson correlation at different parameter settings

7.2 Evaluation on the LI06 dataset

Figure 3d presents the results obtained on the LI06 data set at different weight values for the corpus-based selectional preference semantics γ and for the knowledge-based semantics δ . Our previous experiments (Guo and Diab, 2012b) show that WTMF is the state-of-the-art model on LI06. With lexical semantics explicitly modeled, WTMF+PK yields better results than WTMF (see Table 1). It should be noted that LI06 prefers a smaller similar word pair weight (a $\delta = 0.1$ yields the best performance around of 90.75%), yet in almost all conditions WTMF+PK outperforms WTMF as shown in Figure 3d.

8 Related Work

SS has progressed immensely in recent years, especially with the establishment of the Semantic Textual Similarity task in SEMEVAL 2012. Early work in SS focused on word pair similarity in the high dimensional space (Li et al., 2006; Liu et al., 2007; Islam and Inkpen, 2008; Tsatsaronis et al., 2010; Ho et al., 2010), where co-occurrence information was not efficiently exploited. Researchers (O’Shea et al., 2008) find LSA does not yield good performance. In (Guo and Diab, 2012b; Guo and Diab, 2012c), we show the superiority of the latent space approach in WTMF. In this paper, we improve the WTMF model

and achieve state-of-the-art Pearson correlation on two standard SS datasets.

There are latent variable models designed for lexical semantics, such as word senses (Boyd-Graber et al., 2007; Guo and Diab, 2011), function words (Griffiths et al., 2005), selectional preference (Ritter et al., 2010), synonyms and antonyms (Yih et al., 2012), etc. However little improvement is shown on document/sentence level semantics: (Ritter et al., 2010) and (Yih et al., 2012) focus on selectional preference and antonym identification, respectively; in (Griffiths et al., 2005) the LDA performance degrades in the text categorization task including the modeling of function words. Rather, we concentrate on nuanced lexical semantics phenomena that could benefit sentential semantics.

9 Conclusion

We incorporate corpus-based (selectional preference) and knowledge-based (similar word pairs) lexical semantics into a latent variable model. Our system yields state-of-the-art unsupervised performance on two most popular and standard SS datasets.

Linguistic Regularities in Continuous Space Word Representations

Tomas Mikolov*, Wen-tau Yih, Geoffrey Zweig

Microsoft Research

Redmond, WA 98052

Abstract

Continuous space language models have recently demonstrated outstanding results across a variety of tasks. In this paper, we examine the vector-space word representations that are implicitly learned by the input-layer weights. We find that these representations are surprisingly good at capturing syntactic and semantic regularities in language, and that each relationship is characterized by a relation-specific vector offset. This allows vector-oriented reasoning based on the offsets between words. For example, the male/female relationship is automatically learned, and with the induced vector representations, “King - Man + Woman” results in a vector very close to “Queen.” We demonstrate that the word vectors capture syntactic regularities by means of syntactic analogy questions (provided with this paper), and are able to correctly answer almost 40% of the questions. We demonstrate that the word vectors capture semantic regularities by using the vector offset method to answer SemEval-2012 Task 2 questions. Remarkably, this method outperforms the best previous systems.

1 Introduction

A defining feature of neural network language models is their representation of words as high dimensional real valued vectors. In these models (Bengio et al., 2003; Schwenk, 2007; Mikolov et al., 2010), words are converted via a learned lookup table into real valued vectors which are used as the

inputs to a neural network. As pointed out by the original proposers, one of the main advantages of these models is that the distributed representation achieves a level of generalization that is not possible with classical n -gram language models; whereas a n -gram model works in terms of discrete units that have no inherent relationship to one another, a continuous space model works in terms of word vectors where similar words are likely to have similar vectors. Thus, when the model parameters are adjusted in response to a particular word or word-sequence, the improvements will carry over to occurrences of similar words and sequences.

By training a neural network language model, one obtains not just the model itself, but also the learned word representations, which may be used for other, potentially unrelated, tasks. This has been used to good effect, for example in (Collobert and Weston, 2008; Turian et al., 2010) where induced word representations are used with sophisticated classifiers to improve performance in many NLP tasks.

In this work, we find that the learned word representations in fact capture meaningful syntactic and semantic regularities in a very simple way. Specifically, the regularities are observed as constant vector offsets between pairs of words sharing a particular relationship. For example, if we denote the vector for word i as x_i , and focus on the singular/plural relation, we observe that $x_{apple} - x_{apples} \approx x_{car} - x_{cars}$, $x_{family} - x_{families} \approx x_{car} - x_{cars}$, and so on. Perhaps more surprisingly, we find that this is also the case for a variety of semantic relations, as measured by the SemEval 2012 task of measuring relation similarity.

*Currently at Google, Inc.

The remainder of this paper is organized as follows. In Section 2, we discuss related work; Section 3 describes the recurrent neural network language model we used to obtain word vectors; Section 4 discusses the test sets; Section 5 describes our proposed vector offset method; Section 6 summarizes our experiments, and we conclude in Section 7.

2 Related Work

Distributed word representations have a long history, with early proposals including (Hinton, 1986; Pollack, 1990; Elman, 1991; Deerwester et al., 1990). More recently, neural network language models have been proposed for the classical language modeling task of predicting a probability distribution over the “next” word, given some preceding words. These models were first studied in the context of feed-forward networks (Bengio et al., 2003; Bengio et al., 2006), and later in the context of recurrent neural network models (Mikolov et al., 2010; Mikolov et al., 2011b). This early work demonstrated outstanding performance in terms of word-prediction, but also the need for more computationally efficient models. This has been addressed by subsequent work using hierarchical prediction (Morin and Bengio, 2005; Mnih and Hinton, 2009; Le et al., 2011; Mikolov et al., 2011b; Mikolov et al., 2011a). Also of note, the use of distributed topic representations has been studied in (Hinton and Salakhutdinov, 2006; Hinton and Salakhutdinov, 2010), and (Bordes et al., 2012) presents a semantically driven method for obtaining word representations.

3 Recurrent Neural Network Model

The word representations we study are learned by a recurrent neural network language model (Mikolov et al., 2010), as illustrated in Figure 1. This architecture consists of an input layer, a hidden layer with recurrent connections, plus the corresponding weight matrices. The input vector $w(t)$ represents input word at time t encoded using 1-of-N coding, and the output layer $y(t)$ produces a probability distribution over words. The hidden layer $s(t)$ maintains a representation of the sentence history. The input vector $w(t)$ and the output vector $y(t)$ have dimensionality of the vocabulary. The values in the hidden and

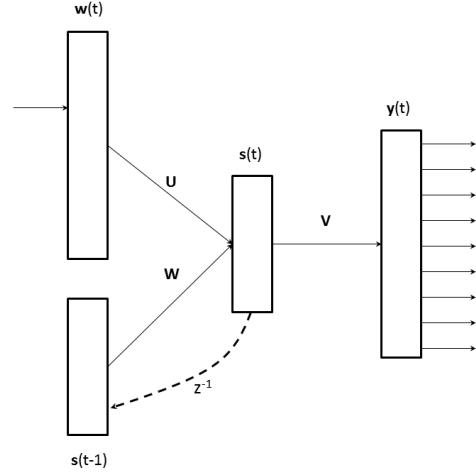

Figure 1: Recurrent Neural Network Language Model.

output layers are computed as follows:

$$s(t) = f(\mathbf{U}w(t) + \mathbf{W}s(t-1)) \quad (1)$$

$$y(t) = g(\mathbf{V}s(t)), \quad (2)$$

where

$$f(z) = \frac{1}{1 + e^{-z}}, \quad g(z_m) = \frac{e^{z_m}}{\sum_k e^{z_k}}. \quad (3)$$

In this framework, the word representations are found in the columns of \mathbf{U} , with each column representing a word. The RNN is trained with back-propagation to maximize the data log-likelihood under the model. The model itself has no knowledge of syntax or morphology or semantics. Remarkably, training such a purely lexical model to maximize likelihood will induce word representations with striking syntactic and semantic properties.

4 Measuring Linguistic Regularity

4.1 A Syntactic Test Set

To understand better the syntactic regularities which are inherent in the learned representation, we created a test set of analogy questions of the form “ a is to b as c is to ___” testing base/comparative/superlative forms of adjectives; singular/plural forms of common nouns; possessive/non-possessive forms of common nouns; and base, past and 3rd person present tense forms of verbs. More precisely, we tagged 267M words of newspaper text with Penn

Category	Relation	Patterns Tested	# Questions	Example
Adjectives	Base/Comparative	JJ/JJR, JJR/JJ	1000	good:better rough:___
Adjectives	Base/Superlative	JJ/JJS, JJS/JJ	1000	good:best rough:___
Adjectives	Comparative/ Superlative	JJS/JJR, JJR/JJS	1000	better:best rougher:___
Nouns	Singular/Plural	NN/NNS, NNS/NN	1000	year:years law:___
Nouns	Non-possessive/ Possessive	NN/NN_POS, NN_POS/NN	1000	city:city's bank:___
Verbs	Base/Past	VB/VBD, VBD/VB	1000	see:saw return:___
Verbs	Base/3rd Person Singular Present	VB/VBZ, VBZ/VB	1000	see:sees return:___
Verbs	Past/3rd Person Singular Present	VBD/VBZ, VBZ/VBD	1000	saw:sees returned:___

Table 1: Test set patterns. For a given pattern and word-pair, both orderings occur in the test set. For example, if “see:saw return:___” occurs, so will “saw:see returned:___”.

Treebank POS tags (Marcus et al., 1993). We then selected 100 of the most frequent comparative adjectives (words labeled JJR); 100 of the most frequent plural nouns (NNS); 100 of the most frequent possessive nouns (NN_POS); and 100 of the most frequent base form verbs (VB). We then systematically generated analogy questions by randomly matching each of the 100 words with 5 other words from the same category, and creating variants as indicated in Table 1. The total test set size is 8000. The test set is available online.¹

4.2 A Semantic Test Set

In addition to syntactic analogy questions, we used the SemEval-2012 Task 2, *Measuring Relation Similarity* (Jurgens et al., 2012), to estimate the extent to which RNNLM word vectors contain semantic information. The dataset contains 79 fine-grained word relations, where 10 are used for training and 69 testing. Each relation is exemplified by 3 or 4 gold word pairs. Given a group of word pairs that supposedly have the same relation, the task is to order the target pairs according to the *degree* to which this relation holds. This can be viewed as another analogy problem. For example, take the *Class-Inclusion:Singular_Collective* relation with the pro-

totypical word pair *clothing:shirt*. To measure the degree that a target word pair *dish:bowl* has the same relation, we form the analogy “*clothing* is to *shirt* as *dish* is to *bowl*,” and ask how valid it is.

5 The Vector Offset Method

As we have seen, both the syntactic and semantic tasks have been formulated as analogy questions. We have found that a simple vector offset method based on cosine distance is remarkably effective in solving these questions. In this method, we assume relationships are present as vector offsets, so that in the embedding space, all pairs of words sharing a particular relation are related by the same constant offset. This is illustrated in Figure 2.

In this model, to answer the analogy question $a:b$ $c:d$ where d is unknown, we find the embedding vectors x_a, x_b, x_c (all normalized to unit norm), and compute $y = x_b - x_a + x_c$. y is the continuous space representation of the word we expect to be the best answer. Of course, no word might exist at that exact position, so we then search for the word whose embedding vector has the greatest cosine similarity to y and output it:

$$w^* = \operatorname{argmax}_w \frac{x_w y}{\|x_w\| \|y\|}$$

When d is given, as in our semantic test set, we simply use $\cos(x_b - x_a + x_c, x_d)$ for the words

¹<http://research.microsoft.com/en-us/projects/rnn/default.aspx>

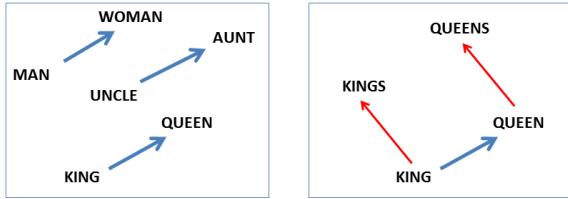

Figure 2: Left panel shows vector offsets for three word pairs illustrating the gender relation. Right panel shows a different projection, and the singular/plural relation for two words. In high-dimensional space, multiple relations can be embedded for a single word.

provided. We have explored several related methods and found that the proposed method performs well for both syntactic and semantic relations. We note that this measure is qualitatively similar to relational similarity model of (Turney, 2012), which predicts similarity between members of the word pairs $(x_b, x_d), (x_c, x_d)$ and dis-similarity for (x_a, x_d) .

6 Experimental Results

To evaluate the vector offset method, we used vectors generated by the RNN toolkit of Mikolov (2012). Vectors of dimensionality 80, 320, and 640 were generated, along with a composite of several systems, with total dimensionality 1600. The systems were trained with 320M words of Broadcast News data as described in (Mikolov et al., 2011a), and had an 82k vocabulary. Table 2 shows results for both RNNLM and LSA vectors on the syntactic task. LSA was trained on the same data as the RNN. We see that the RNN vectors capture significantly more syntactic regularity than the LSA vectors, and do remarkably well in an absolute sense, answering more than one in three questions correctly.²

In Table 3 we compare the RNN vectors with those based on the methods of Collobert and Weston (2008) and Mnih and Hinton (2009), as implemented by (Turian et al., 2010) and available online³. Since different words are present in these datasets, we computed the intersection of the vocabularies of the RNN vectors and the new vectors, and restricted the test set and word vectors to those. This resulted in a 36k word vocabulary, and a test set with 6632

²Guessing gets a small fraction of a percent.

Table 3: Comparison of RNN vectors with Turian’s Collobert and Weston based vectors and the Hierarchical Log-Bilinear model of Mnih and Hinton. Percent correct.

questions. Turian’s Collobert and Weston based vectors do poorly on this task, whereas the Hierarchical Log-Bilinear Model vectors of (Mnih and Hinton, 2009) do essentially as well as the RNN vectors. These representations were trained on 37M words of data and this may indicate a greater robustness of the HLBL method.

We conducted similar experiments with the semantic test set. For each target word pair in a relation category, the model measures its relational similarity to each of the prototypical word pairs, and then uses the average as the final score. The results are evaluated using the two standard metrics defined in the task, Spearman’s rank correlation coefficient ρ and MaxDiff accuracy. In both cases, larger values are better. To compare to previous systems, we report the average over all 69 relations in the test set.

From Table 4, we see that as with the syntactic regularity study, the RNN-based representations perform best. In this case, however, Turian’s CW vectors are comparable in performance to the HLBL vectors. With the RNN vectors, the performance improves as the number of dimensions increases. Surprisingly, we found that even though the RNN vec-

Method	Spearman's ρ	MaxDiff Acc.

tors are not trained or tuned specifically for this task, the model achieves better results (RNN-320, RNN-640 & RNN-1600) than the previously best performing system, UTD-NB (Rink and Harabagiu, 2012).

7 Conclusion

We have presented a generally applicable vector offset method for identifying linguistic regularities in continuous space word representations. We have shown that the word representations learned by a RNNLM do an especially good job in capturing these regularities. We present a new dataset for measuring syntactic performance, and achieve almost 40% correct. We also evaluate semantic generalization on the SemEval 2012 task, and outperform the previous state-of-the-art. Surprisingly, both results are the byproducts of an unsupervised maximum likelihood training criterion that simply operates on a large amount of text data.

Abstract

We propose a novel semantic annotation type of assigning truth values to predicate occurrences, and present TRUTHTELLER, a standalone publicly-available tool that produces such annotations. TRUTHTELLER integrates a range of semantic phenomena, such as negation, modality, presupposition, implicativity, and more, which were dealt only partly in previous works. Empirical evaluations against human annotations show satisfactory results and suggest the usefulness of this new type of tool for NLP.

1 Introduction

In a text, the action or relation denoted by every predicate can be seen as being either positively or negatively inferred from its sentence, or otherwise having an unknown truth status. Only in (3) below can we infer that Gal sold her shop, hence the positive *truth value* of the predicate *sell*, while according to (2) and (4) Gal did not sell it, hence the negative truth values, and in (1) we do not know if she sold it or not (the notations PT+, PT- and PT? denote truth states, defined in Subsection 2.3). Identifying these predicate truth values is an important sub-task within many semantic processing scenarios, including various applications such as Question Answering (QA), Information Extraction (IE), paraphrasing and summarization. The following examples illustrate the phenomenon:

- (1) *Gal made an attempt* pt^+ *to sell* $pt?$ *her shop.*
- (2) *Gal did not try* pt^- *to sell* pt^- *her shop after* hearing pt^+ *the offers.*
- (3) **Maybe** *Gal wasn't smart* $pt?$ *to sell* pt^+ *her shop.*
- (4) *Gal wasn't smart* pt^- **enough** *to sell* pt^- *the shop that she had bought* $pt^+.$

Previous works addressed specific aspects of the truth detection problem: Laird et al. (2006), and later MacCartney & Manning (2007; 2009), were the first to build paraphrasing and inference systems that combine negation (see *try* in (2)), modality (*smart* in (3)) and “natural logic”, a recursive truth value calculus (*sell* in (1-3)); recently, Mausam et al. (2012) built an open IE system that identifies granulated variants of modality and conditions on predicates (*smart* in (3)); and Kiparsky & Kiparsky (1970) and Karttunen (1971; 2012) laid the ground work for factive and implicative entailment calculus (*sell* in (1-4)), as well as many generic constructions of *presupposition* (*hearing* in (2) is presupposed because it heads an adverbial clause and *bought* in (4) heads a finite relative clause), which, to our knowledge, have not yet been implemented computationally. Notice in the examples that presuppositions persist under negation, in questions and if-clauses, while entailments do not. In addition, there is a growing research line of negation and modality detection. See, for example, Morante & Daelemans (2012).

We present TRUTHTELLER¹, a novel algorithm and system that identifies the truth value of each predicate in a given sentence. It annotates nodes in the text’s dependency parse-tree via a combination of pattern-based annotation rules and a recursive algorithm based on natural logic. In the course of computing truth value, it also computes the implicativity/factivity signature of predicates, and their negation and modality to a basic degree, both of which are made available in the system output. It addresses and combines the aforementioned phenomena (see Section 2), many of which weren’t dealt in previous systems.

TRUTHTELLER is an open source and publicly available annotation tool, offers a relatively simple algebra for truth value computation, and is accompanied by a publicly available lexicon of over 1,700 implicative and factive predicates. Also, we provide an intuitive GUI for viewing and modifying the algorithm’s annotation rules.

2 Annotation Types and Algorithm

This section summarizes the annotation algorithm (a detailed report is available with the system release). We perform the annotations over dependency parse trees, generated according to the Stanford Dependencies standard (de Marneffe and Manning, 2008). For all verbs, nouns and adjectives in a sentence’s parse tree, we produce the following 4 annotation types, given in the order they are calculated, as described in the following subsections:

1. Predicate Implication Signature (*sig*) - describes the pattern by which the predicate entails or presupposes its complements, e.g., the verb *refuse* entails the negative of its complements: *Ed refused to pay* entails that *Ed didn’t pay*.
2. Negation and Uncertainty (NU) - indicates whether the predicate is modified by an uncertainty modifier like *might*, *probably*, etc., or whether it’s negated by *no*, *never* etc.
3. Clause-Truth (CT) - indicates whether the

entire clause headed by the predicate is entailed by the complete sentence

4. Predicate Truth (PT) - indicates whether the predicate itself is entailed by the sentence, as defined below

Before presenting the detailed definitions and descriptions below, we give a high-level description of TRUTHTELLER’s algorithm, where each step relies on the results of its predecessor: a) every predicate in the parse tree is annotated with a predicate implication signature, identified by lexicon lookup; b) NU annotations are added, according to the presence of uncertainty modifiers (*maybe*, *might*, *etc.*) and negation modifies (*not*, *never*, *etc.*); c) predicates in certain presupposition constructions (e.g., adverbial clauses, WH arguments) are annotated with positive CT values; d) the parse tree is depth-first scanned, in order to compute both CT and PT annotations by the recursive effects of factives and implicatives; e) in conjunction with the previous step, relative clause constructions are identified and annotated with CT and PT.

Except for steps a) and d), all of the procedure is implemented as an ordered sequence of *annotation rule* applications. An annotation rule is a dependency parse tree template, possibly including variables, which assigns certain annotations to any parse tree node that matches against it. Step a) is implemented with signature lexicon lookups, and step d) is an algorithm implemented in code.

To illustrate this entire process, Figure 1 presents the annotation process of a simple sentence, step by step, resulting in TRUTHTELLER’s complete output, fully specified below. Most other examples in this paper show only partial annotations for brevity.

2.1 Predicate Implication Signature

Our system marks the signature of each predicate, as defined in Table 1. There, each signature has a left sign and a right sign. The *left* sign determines the *clause truth value* of the predicate’s complements, when the predicate is in *positive* contexts (e.g., not negated), while the *right* sign applies in *negative* contexts (clause

#	Sig	Positive context example	Negative context example
1	+/-	Ed <i>managed</i> to escape \Rightarrow Ed escaped	Ed didn't <i>manage</i> to escape \Rightarrow Ed didn't escape
2	+/?	Ed was <i>forced</i> to sell \Rightarrow Ed sold	Ed wasn't <i>forced</i> to sell \Rightarrow no entailments
3	?/-	Ed was <i>allowed</i> to go \Rightarrow no entailments	Ed wasn't <i>allowed</i> to go \Rightarrow Ed didn't go
4	-/+	Ed <i>forgot</i> to pay \Rightarrow Ed didn't pay	Ed didn't <i>forget</i> to pay \Rightarrow Ed paid
5	-/?	Ed <i>refused</i> to fight \Rightarrow Ed didn't fight	Ed didn't <i>refuse</i> to fight \Rightarrow no entailments
6	?/+	Ed <i>hesitated</i> to ask \Rightarrow no entailments	Ed didn't <i>hesitate</i> to ask \Rightarrow Ed asked
7	+/+	Ed was <i>glad</i> to come \Rightarrow Ed came	Ed wasn't <i>glad</i> to come \Rightarrow Ed came
8	-/-	Ed <i>pretended</i> to pay \Rightarrow Ed didn't pay	Ed didn't <i>pretend</i> to pay \Rightarrow Ed didn't pay
9	?/?	Ed <i>wanted</i> to fly \Rightarrow no entailments	Ed didn't <i>want</i> to fly \Rightarrow no entailments

Table 1: Implication signatures, based on MacCartney & Manning (2009) and Karttunen (2012). The first six signatures are named implicatives, and the last three factive, counter factive and regular, respectively.

- a) Annotate signatures via lexicons lookup
 $Gal \text{ wasn't allowed}^{?/-} \text{ to come}^{?/?}$
- b) Annotate NU
 $Gal \text{ wasn't allowed}^{?/-,nu-} \text{ to come}^{?/?},nu+$
- c) Annotate CT to presupposition constructions
 $Gal \text{ wasn't allowed}^{?/-,nu-,ct+} \text{ to come}^{?/?},nu+,ct+$
- d) Recursive CT and PT annotation
 $Gal \text{ wasn't allowed}^{?/-,nu-,ct+,pt-} \text{ to come}^{?/?},nu+,ct-,pt-$
- e) Annotate CT and PT of relative clauses
(has no effect on this example)
 $Gal \text{ wasn't allowed}^{?/-,nu-,ct+,pt-} \text{ to come}^{?/?},nu+,ct-,pt-$

Figure 1: An illustration of the annotation process

truth is defined in Subsection 2.3). See examples for both context types in the table. Each sign can be either + (positive), - (negative) or ? (unknown). The unknown sign signifies that the predicate does not entail its complements in any way.

Signatures are identified via lookup, using two lexicons, one for single-word predicates and the other for *verb+noun* phrasal verbs, e.g., *take the time to X*. Our single-word lexicon is similar to those used in (Nairn et al., 2006) and (Bar-Haim et al., 2007), but is far greater, holding over 1,700 entries, while each of the previous two has, to the best of our knowledge, less than 300 entries. It was built semi automatically, out of a kernel of 320 manually inspected predicates,

which was then expanded with WordNet synonyms (Fellbaum, 1998). The second lexicon is the implicative phrasal verb lexicon of Karttunen (2012), adapted into our framework. The +/? implicative serves as the default signature for all unlisted predicates.

Signature is also sensitive to the type of the complement. Consider:

- (6) $Ed \text{ forgot}^{-/+} \text{ to call } pt^- \text{ Joe}$
- (7) $Ed \text{ forgot}^{+/+} \text{ that he called } pt^+ \text{ Joe}$

Therefore, signatures are specified separately for finite and non finite complements of each predicate.

After the initial signature lookup, two annotation rules correct the signatures of +/+ factives modified by *enough* and *too*, into +/- and -/+, correspondingly, see Kiparsky & Kiparsky (1970). Compare:

- (8) $Ed \text{ was mad}^{+/+} \text{ to go} \Rightarrow Ed \text{ went}$
- (9) $Ed \text{ was too mad}^{-/+} \text{ to go} \Rightarrow Ed \text{ didn't go}$
- (10) $Workers \text{ were pushed / maddened / managed}^{+/?} \text{ into signing} \Rightarrow They \text{ signed}$
- (11) $Workers \text{ weren't pushed / maddened / managed}^{+/?} \text{ into signing} \Rightarrow It \text{ is unknown whether they signed}$

so we captured this construction in another rule.

2.2 Negation and Uncertainty (NU)

NU takes the values {NU+, NU-, NU?}, standing for non-negated certain actions, negated certain actions, and uncertain actions. The first NU rules match against a closed set of negation modifiers around the predicate, like *not*, *never*, *neither* etc. (see (2)), while later rules detect uncertainty modifiers, like *maybe*, *probably*, etc. Therefore, NU? takes precedence over NU-.

Many constructions of subject-negation, object-negation and “double negation” are accounted for in our rules, as in:

- (12) **Nobody** was seen^{nu-} at the site
- (13) **Almost nobody** was seen^{nu+} at the site

2.3 Clause Truth and Predicate Truth

Clause Truth (CT, denoted as $ct(p)$) corresponds to POLARITY of Nairn et al. (2006). It represents whether the clause headed by a predicate p is entailed by the sentence, contradicted or unknown, and thus takes three values {CT+, CT-, CT?}.

Predicate Truth (PT) (denoted as $pt(p)$) represents whether we can infer from the sentence that the action described by the predicate happened (or that its relation holds). It is defined as the binary product of NU and CT:

Definition 1. $PT = NU \cdot CT$

and takes analogous values: {PT+, PT-, PT?}. Intuitively, the product of two identical positive/negative values yields PT+, a positive and a negative yield PT-, and NU? or CT? always yield PT?. To illustrate these definitions, consider:

- (14) Meg **may** have slept^{ct+,pt?} **after** eating^{ct+,pt+} the meal Ed cooked^{ct+,pt+}, **while** no one was there^{ct+,pt-}

After signatures and NU are annotated, CT and PT are calculated. At first, we apply a set of rules that annotate generic presupposition constructions with CT+. These include adverbial clauses opening with {*while*, *before*, *after*, *where*, *how come*, *because*, *since*, *owing to*, *though*, *despite*, *yet*, *therefore...*}, WH arguments (*who*, *which*, *whom*, *what*), and

$$ct(p) = \begin{cases} \text{CT+ : } & p \text{ was already annotated} \\ & \text{by a presupposition rule} \\ ct(gov(p)) : & p \text{ heads a relative} \\ \text{compCT}(p) : & \text{clause} \\ & \text{otherwise, and } p \text{ is} \\ & \text{a complement} \\ \text{CT? : } & \text{otherwise (default)} \end{cases}$$

Figure 2: Formula of $ct(p)$, for any predicate p . $ct(gov(p))$ is the CT of p 's governing predicate.

parataxis². See for example the effects of *after* and *while* in (14).

Then, we apply the following recursive sequential procedure. The tree root always gets CT+ (see *slept* in (14)). The tree is then scanned downwards, predicate by predicate. At each one, we compute CT by the formula in Figure 2, as follows. First, we check if one of the aforementioned presupposition rules already matched the node. Second, if none matched, we apply to the node's entire subtree another set of rules that annotate each relative clause with the CT of its governing noun³, $ct(gov(p))$ (see *failed* in (15)). Third, if no previous rule matched, and p is a complement of another predicate $gov(p)$, then $compCT(p)$ is calculated, by the following logic: when $pt(gov(p))$ is PT+ or PT-, the corresponding left or right sign of $sig(gov(p))$ is copied. Otherwise, if $pt(gov(p)) = PT?$, CT? is returned, except when the signature of $gov(p)$ is +/+ (or -/-) factive, which always yields CT+ (or CT-).

Third, if nothing applied to p , CT? is returned by default. Finally, PT is set, according to Definition 1.

To illustrate, consider these annotations:

- (15) Gal managed^{+/-,ct+,pt+} a building^{+/?+,ct+,pt+}, which Ginger failed^{-/+?,ct+,pt+} to sell^{+/?-,ct-,pt-}

First, *managed* gets CT+ as the tree root. Then, we get $compCT(\text{building}) = \text{CT+}$, as the complement of $\text{managed}^{+/-,pt+}$. Next, a relative clause rule copies CT+ from *building* to *failed*.

²The placing of clauses or phrases one after another, without words to indicate coordination, as in “veni, vidi, vici” in contrast to “veni, vidi and vici”.

³We also annotate nouns and adjectives as predicates in copular constructions, and in instances where nouns have complements.

Finally, $\text{compCT}(\text{sell}) = \text{CT-}$ is calculated, as the complement of $\text{failed}^{-/+,\text{pt}+}$.

3 Evaluation

To evaluate TRUTHTELLER’s accuracy, we sampled 25 sentences from each of the RTE5 and RTE6 Test datasets (Bentivogli et al., 2009; Bentivogli et al., 2010), widely used for textual inference benchmarks. In these 50 sentences, we manually annotated each predicate, 153 in total, forming a gold standard. As baseline, we report the most frequent value for each annotation. The results, in Table 2, show high accuracy for all types, reducing the baseline CT and PT errors by half. Furthermore, most of the remaining errors were due to parser errors, according to a manual error analysis we conducted.

The baseline for NU annotations shows that negations are scarce in these RTE datasets, which was also the case for CT- and PT- annotations. Thus, Table 2 mostly indicates TruthTeller’s performance in distinguishing positive CT and PT annotations from unknown ones, the latter constituting $\sim 20\%$ of the gold standard. To further assess CT- and PT- annotations we performed two targeted measurements. Precision for CT- and PT- was measured by manually judging the correctness of such annotations by TRUTHTELLER, on a sample from RTE6 Test including 50 CT- and 124 PT- annotations. This test yielded 78% and 83% precision, respectively. PT- is more frequent as it is typically triggered by CT-, as well as by other constructions involving negation. Recall was estimated by employing a human annotator to go through the dataset and look for CT- and PT- gold standard annotations. The annotator identified 40 “CT-”s and 50 “PT-”s, out of which TRUTHTELLER found 47.5% of the “CT-”s and 74% of the “PT-”s. In summary, TRUTHTELLER’s performance on our target PT annotations is quite satisfactory with 89% accuracy overall, having 83% precision and 74% recall estimates specifically for PT-.

4 Conclusions and Future Work

We have presented TRUTHTELLER, a novel algorithm and system that identifies truth values of

Annotation	TruthTeller	Baseline
Signature	89.5%	81% (+/?)
NU	98%	97.3% (NU+)
CT	90.8%	78.4% (CT+)
PT	89%	77% (PT+)

Table 2: The accuracy measures for TRUTHTELLER’s 4 annotations. The right column gives the accuracy for the corresponding most-frequent baseline: {+/?}, NU+, CT+, PT+}.

predicates, the first such system to a) address or combine a wide variety of relevant grammatical constructions; b) be an open source annotation tool; c) address the truth value annotation task as an independent tool, which makes it possible for client systems to use its output, while previous works only embedded annotations in their task-specific systems; and d) annotate *unknown* truth values extensively and explicitly.

TRUTHTELLER may be used for several purposes, such as inferring parts of a sentence from the whole and improving textual entailment (and contradiction) detection. It includes a novel, large and accurate, lexicon of predicate implication signatures.

While in this paper we evaluated the correctness of TRUTHTELLER as an individual component, in the future we propose integrating it in a state-of-the-art RTE system and report its impact. One challenge in this scenario is having other system components interact with TRUTHTELLER’s decisions, possibly masking its effects. In addition, we plan to incorporate monotonicity calculations in the annotation process, like in MacCartney and Manning (2009).

Abstract

We present the 1.0 release of our paraphrase database, PPDB. Its English portion, PPDB:Eng, contains over 220 million paraphrase pairs, consisting of 73 million phrasal and 8 million lexical paraphrases, as well as 140 million paraphrase patterns, which capture many meaning-preserving syntactic transformations. The paraphrases are extracted from bilingual parallel corpora totaling over 100 million sentence pairs and over 2 billion English words. We also release PPDB:Spa, a collection of 196 million Spanish paraphrases. Each paraphrase pair in PPDB contains a set of associated scores, including paraphrase probabilities derived from the bitext data and a variety of monolingual distributional similarity scores computed from the Google n -grams and the Annotated Gigaword corpus. Our release includes pruning tools that allow users to determine their own precision/recall tradeoff.

1 Introduction

Paraphrases, i.e. differing textual realizations of the same meaning, have proven useful for a wide variety of natural language processing applications. Past paraphrase collections include automatically derived resources like DIRT (Lin and Pantel, 2001), the MSR paraphrase corpus and phrase table (Dolan et al., 2004; Quirk et al., 2004), among others. Although several groups have independently extracted paraphrases using Bannard and Callison-Burch (2005)’s bilingual pivoting technique (see Zhou et al. (2006), Riezler et al. (2007), Snover et al. (2010), among others), there has never been an official release of this resource.

In this work, we release version 1.0 of the *Paraphrase DataBase* PPDB,¹ a collection of ranked English and Spanish paraphrases derived by:

- Extracting lexical, phrasal, and syntactic paraphrases from large bilingual parallel corpora (with associated paraphrase probabilities).
- Computing distributional similarity scores for each of the paraphrases using the Google n -grams and the Annotated Gigaword corpus.

In addition to the paraphrase collection itself, we provide tools to filter PPDB to only retain high precision paraphrases, scripts to limit the collection to phrasal or lexical paraphrases (synonyms), and software that enables users to extract paraphrases for languages other than English.

2 Extracting Paraphrases from Bitexts

To extract paraphrases we follow Bannard and Callison-Burch (2005)’s bilingual pivoting method. The intuition is that two English strings e_1 and e_2 that translate to the same foreign string f can be assumed to have the same meaning. We can thus *pivot* over f and extract $\langle e_1, e_2 \rangle$ as a pair of paraphrases, as illustrated in Figure 1. The method extracts a diverse set of paraphrases. For *thrown into jail*, it extracts *arrested*, *detained*, *imprisoned*, *incarcerated*, *jailed*, *locked up*, *taken into custody*, and *thrown into prison*, along with a set of incorrect/noisy paraphrases that have different syntactic types or that are due to misalignments.

For PPDB, we formulate our paraphrase collection as a weighted *synchronous context-free grammar* (SCFG) (Aho and Ullman, 1972; Chiang, 2005)

¹Freely available at <http://paraphrase.org>.

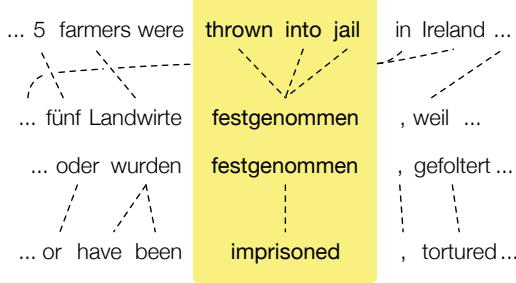

Figure 1: Phrasal paraphrases are extracted via bilingual pivoting.

with syntactic nonterminal labels, similar to Cohn and Lapata (2008) and Ganitkevitch et al. (2011). An SCFG rule has the form:

$$\mathbf{r} \stackrel{\text{def}}{=} C \rightarrow \langle f, e, \sim, \vec{\varphi} \rangle,$$

where the left-hand side of the rule, C , is a nonterminal and the right-hand sides f and e are strings of terminal and nonterminal symbols. There is a one-to-one correspondence, \sim , between the nonterminals in f and e : each nonterminal symbol in f has to also appear in e . Following Zhao et al. (2008), each rule \mathbf{r} is annotated with a vector of feature functions $\vec{\varphi} = \{\varphi_1 \dots \varphi_N\}$ which are combined in a log-linear model (with weights $\vec{\lambda}$) to compute the *cost* of applying \mathbf{r} :

$$\text{cost}(\mathbf{r}) = - \sum_{i=1}^N \lambda_i \log \varphi_i. \quad (1)$$

To create a syntactic paraphrase grammar we first extract a foreign-to-English translation grammar from a bilingual parallel corpus, using techniques from syntactic machine translation (Koehn, 2010). Then, for each pair of translation rules where the left-hand side C and foreign string f match:

$$\begin{aligned} \mathbf{r}_1 &\stackrel{\text{def}}{=} C \rightarrow \langle f, e_1, \sim_1, \vec{\varphi}_1 \rangle \\ \mathbf{r}_2 &\stackrel{\text{def}}{=} C \rightarrow \langle f, e_2, \sim_2, \vec{\varphi}_2 \rangle, \end{aligned}$$

we *pivot* over f to create a paraphrase rule \mathbf{r}_p :

$$\mathbf{r}_p \stackrel{\text{def}}{=} C \rightarrow \langle e_1, e_2, \sim_p, \vec{\varphi}_p \rangle,$$

with a combined nonterminal correspondency function \sim_p . Note that the common source side f implies that e_1 and e_2 share the same set of nonterminal symbols.

The paraphrase rules obtained using this method are capable of making well-formed generalizations of meaning-preserving rewrites in English. For instance, we extract the following example paraphrase, capturing the English possessive rule:

$$NP \rightarrow \text{the } NP_1 \text{ of } NNS_2 \mid \text{the } NNS_2 \text{ 's } NP_1.$$

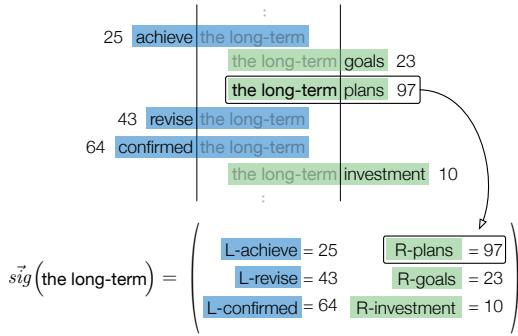

The paraphrase feature vector $\vec{\varphi}_p$ is computed from the translation feature vectors $\vec{\varphi}_1$ and $\vec{\varphi}_2$ by following the pivoting idea. For instance, we estimate the conditional paraphrase probability $p(e_2|e_1)$ by marginalizing over all shared foreign-language translations f :

$$p(e_2|e_1) \approx \sum_f p(e_2|f)p(f|e_1). \quad (2)$$

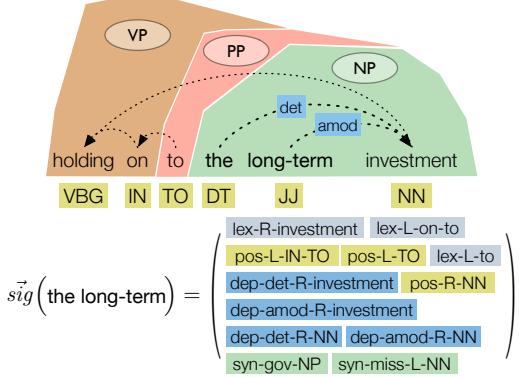

3 Scoring Paraphrases Using Monolingual Distributional Similarity

The bilingual pivoting approach anchors paraphrases that share an interpretation because of a shared foreign phrase. Paraphrasing methods based on monolingual text corpora, like DIRT (Lin and Pantel, 2001), measure the similarity of phrases based on distributional similarity. This results in a range of different types of phrases, including paraphrases, inference rules and antonyms. For instance, for *thrown into prison* DIRT extracts good paraphrases like *arrested*, *detained*, and *jailed*. However, it also extracts phrases that are temporally or causally related like *began the trial of*, *cracked down on*, *interrogated*, *prosecuted* and *ordered the execution of*, because they have similar distributional properties. Since bilingual pivoting rarely extracts these non-paraphrases, we can use monolingual distributional similarity to re-rank paraphrases extracted from bitexts (following Chan et al. (2011)) or incorporate a set of distributional similarity scores as features in our log-linear model.

Each similarity score relies on precomputed distributional signatures that describe the contexts that a phrase occurs in. To describe a phrase e , we gather counts for a set of contextual features for each occurrence of e in a corpus. Writing the context vector for the i -th occurrence of e as $\vec{s}_{e,i}$, we can aggregate over all occurrences of e , resulting in a *distributional* signature for e , $\vec{s}_e = \sum_i \vec{s}_{e,i}$. Following the intuition that phrases with similar meanings occur in

(a) The n -gram corpus records *the long-term* as preceded by *revise* (43 times), and followed by *plans* (97 times). We add corresponding features to the phrase’s distributional signature retaining the counts of the original n -grams.

(b) Here, position-aware lexical and part-of-speech n -gram features, labeled dependency links , and features reflecting the phrase’s CCG-style label *NP/NN* are included in the context vector.

Figure 2: Features extracted for the phrase *the long term* from the n -gram corpus (2a) and Annotated Gigaword (2b).

similar contexts, we can then quantify the goodness of e' as a paraphrase of e by computing the cosine similarity between their distributional signatures:

$$sim(e, e') = \frac{\vec{s}_e \cdot \vec{s}_{e'}}{|\vec{s}_e| |\vec{s}_{e'}|}.$$

A wide variety of features have been used to describe the distributional context of a phrase. Rich, linguistically informed feature-sets that rely on dependency and constituency parses, part-of-speech tags, or lemmatization have been proposed in work such as by Church and Hanks (1991) and Lin and Pantel (2001). For instance, a phrase is described by the various syntactic relations such as: “what verbs have this phrase as the subject?”, or “what adjectives modify this phrase?”. Other work has used simpler n -gram features, e.g. “what words or bigrams have we seen to the left of this phrase?”. A substantial body of work has focussed on using this type of feature-set for a variety of purposes in NLP (Lapata and Keller, 2005; Bhagat and Ravichandran, 2008; Lin et al., 2010; Van Durme and Lall, 2010).

For PPDB, we compute n -gram-based context signatures for the 200 million most frequent phrases in the Google n -gram corpus (Brants and Franz, 2006; Lin et al., 2010), and richer linguistic signatures for 175 million phrases in the Annotated Gigaword corpus (Napoles et al., 2012). Our features extend beyond those previously used in the work by Ganitkevitch et al. (2012). They are:

- n -gram based features for words seen to the left and right of a phrase.
- Position-aware lexical, lemma-based, part-of-speech, and named entity class unigram and bigram features, drawn from a three-word window to the right and left of the phrase.
- Incoming and outgoing (wrt. the phrase) dependency link features, labeled with the corresponding lexical item, lemmata and POS.
- Syntactic features for any constituents governing the phrase, as well as for CCG-style slashed constituent labels for the phrase.

Figure 2 illustrates the feature extraction for an example phrase.

4 English Paraphrases – PPDB:Eng

We combine several English-to-foreign bitext corpora to extract PPDB:Eng: Europarl v7 (Koehn, 2005), consisting of bitexts for the 19 European languages, the 10^9 French-English corpus (Callison-Burch et al., 2009), the Czech, German, Spanish and French portions of the News Commentary data (Koehn and Schroeder, 2007), the United Nations French- and Spanish-English parallel corpora (Eisele and Chen, 2010), the JRC Acquis corpus (Steinberger et al., 2006), Chinese and Arabic

	Identity	Paraphrases	Total
Lexical	0.6M	7.6M	8.1M
Phrasal	4.9M	68.4M	73.2M
Syntactic	46.5M	93.6M	140.1M
All	52.0M	169.6M	221.4M

Table 1: A breakdown of PPDB:Eng size by paraphrase type. We distinguish lexical (i.e. one-word) paraphrases, phrasal paraphrases and syntactically labeled paraphrase patterns.

newswire corpora used for the GALE machine translation campaign,² parallel Urdu-English data from the NIST translation task,³ the French portion of the OpenSubtitles corpus (Tiedemann, 2009), and a collection of Spanish-English translation memories provided by TAUS.⁴

The resulting composite parallel corpus has more than 106 million sentence pairs, over 2 billion English words, and spans 22 pivot languages. To apply the pivoting technique to this multilingual data, we treat the various pivot languages as a joint *Non-English* language. This simplifying assumption allows us to share statistics across the different languages and apply Equation 2 unaltered.

Table 1 presents a breakdown of PPDB:Eng by paraphrase type. We distinguish *lexical* (a single word), *phrasal* (a continuous string of words), and *syntactic* paraphrases (expressions that may contain both words and nonterminals), and separate out identity paraphrases. While we list lexical and phrasal paraphrases separately, it is possible that a single word paraphrases as a multi-word phrase and vice versa – so long they share the same syntactic label.

5 Spanish Paraphrases – PPDB:Spa

We also release a collection of Spanish paraphrases: PPDB:Spa is extracted analogously to its English counterpart and leverages the Spanish portions of the bitext data available to us, totaling almost 355 million Spanish words, in nearly 15 million sentence pairs. The paraphrase pairs in PPDB:Spa are anno-

	Identity	Paraphrases	Total
Lexical	1.0M	33.1M	34.1M
Phrasal	4.3M	73.2M	77.5M
Syntactic	29.4M	55.3M	84.7M
All	34.7M	161.6M	196.3M

Table 2: An overview of PPDB:Spa. Again, we partition the resource into lexical (i.e. one-word) paraphrases, phrasal paraphrases and syntactically labeled paraphrase patterns.

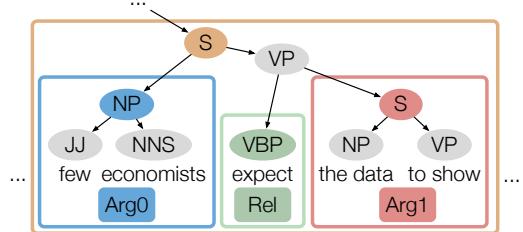

Figure 3: To inspect our coverage, we use the Penn Treebank’s parses to map from Propbank annotations to PPDB’s syntactic patterns. For the above annotation predicate, we extract $VBP \rightarrow \text{expect}$, which is matched by paraphrase rules like $VBP \rightarrow \text{expect} \mid \text{anticipate}$ and $VBP \rightarrow \text{expect} \mid \text{hypothesize}$. To search for the entire relation, we replace the argument spans with syntactic nonterminals. Here, we obtain $S \rightarrow NP \text{ expect } S$, for which PPDB has matching rules like $S \rightarrow NP \text{ expect } S \mid NP \text{ would hope } S$, and $S \rightarrow NP \text{ expect } S \mid NP \text{ trust } S$. This allows us to apply sophisticated paraphrases to the predicate while capturing its arguments in a generalized fashion.

tated with distributional similarity scores based on lexical features collected from the Spanish portion of the multilingual release of the Google n -gram corpus (Brants and Franz, 2009), and the Spanish Gigaword corpus (Mendonca et al., 2009). Table 2 gives a breakdown of PPDB:Spa.

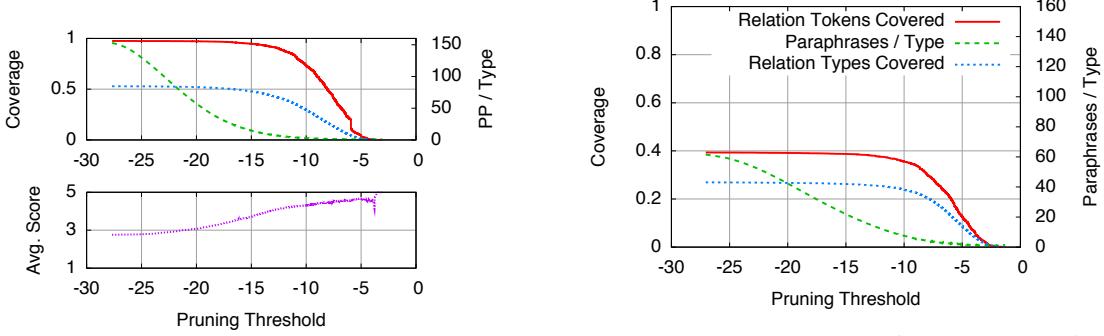

6 Analysis

To estimate the usefulness of PPDB as a resource for tasks like semantic role labeling or parsing, we analyze its coverage of Propbank predicates and predicate-argument tuples (Kingsbury and Palmer, 2002). We use the Penn Treebank (Marcus et al., 1993) to map Propbank annotations to patterns which allow us to search PPDB:Eng for paraphrases that match the annotated predicate. Figure 3 illus-

²<http://projects.ldc.upenn.edu/gale/data/Catalog.html>

³LDC Catalog No. LDC2010T23

⁴<http://www.translationautomation.com/>

(a) PPDB:Eng coverage of Propbank predicates (top), and average human judgment score (bottom) for varying pruning thresholds.

(b) PPDB:Eng's coverage of Propbank predicates with up to two arguments. Here we consider rules that paraphrase the full predicate-argument expression.

Figure 4: An illustration of PPDB’s coverage of the manually annotated Propbank predicate phrases (4a) and binary relations with argument non-terminals (4b). The curves indicate the coverage on tokens (solid) and types (dotted), as well as the average number of paraphrases per covered type (dashed) at the given pruning level.

brates this mapping.

In order to quantify PPDB’s precision-recall tradeoff in this context, we perform a sweep over our collection, beginning with the full set of paraphrase pairs and incrementally discarding the lowest-scoring ones. We choose a simple estimate for each paraphrase pair’s score by uniformly combining its paraphrase probability features in Eq. 1.

The top graph in Figure 4a shows PPDB’s coverage of predicates (e.g. $VBP \rightarrow \text{expect}$) at the type level (i.e. counting distinct predicates), as well as the token level (i.e. counting predicate occurrences in the corpus). We also keep track of average number of paraphrases per covered predicate type for varying pruning levels. We find that PPDB has a predicate type recall of up to 52% (accounting for 97.5% of tokens). Extending the experiment to full predicate-argument relations with up to two arguments (e.g. $S \rightarrow NNS \text{ expect } S$), we obtain a 27% type coverage rate that accounts for 40% of tokens (Figure 4b). Both rates hold even as we prune the database down to only contain high precision paraphrases. Our pruning method here is based on a simple uniform combination of paraphrase probabilities and similarity scores.

To gauge the quality of our paraphrases, the authors judged 1900 randomly sampled predicate paraphrases on a scale of 1 to 5, 5 being the best. The bottom graph in Figure 4a plots the resulting human score average against the sweep used in the cover-

age experiment. It is clear that even with a simple weighing approach, the PPDB scores show a clear correlation with human judgements. Therefore they can be used to bias the collection towards greater recall or higher precision.

7 Conclusion and Future Work

We present the 1.0 release of PPDB:Eng and PPDB:Spa, two large-scale collections of paraphrases in English and Spanish. We illustrate the resource’s utility with an analysis of its coverage of Propbank predicates. Our results suggest that PPDB will be useful in a variety of NLP applications.

Future releases of PPDB will focus on expanding the paraphrase collection’s coverage with regard to both data size and languages supported. Furthermore, we intend to improve paraphrase scoring by incorporating additional sources of information, as well as by better utilizing information present in the data, like domain or topic. We will also address points of refinement such as handling of phrase ambiguity, and effects specific to individual pivot languages. Our aim is for PPDB to be a continuously updated and improving resource.

Finally, we will explore extensions to PPDB to include aspects of related large-scale resources such as lexical-semantic hierarchies (Snow et al., 2006), textual inference rules (Berant et al., 2011), relational patterns (Nakashole et al., 2012), and (lexical) conceptual networks (Navigli and Ponzetto, 2012).

Exploiting the Scope of Negations and Heterogeneous Features for Relation Extraction: A Case Study for Drug-Drug Interaction Extraction

Md. Faisal Mahbub Chowdhury ^{†‡} and Alberto Lavelli [‡]

[‡]Fondazione Bruno Kessler (FBK-irst), Italy

[†]University of Trento, Italy

fmchowdhury@gmail.com, lavelli@fbk.eu

Abstract

This paper presents an approach that exploits the scope of negation cues for relation extraction (RE) without the need of using any specifically annotated dataset for building a separate negation scope detection classifier. New features are proposed which are used in two different stages. These also include non-target entity specific features. The proposed RE approach outperforms the previous state of the art for drug-drug interaction (DDI) extraction.

1 Introduction

Negation is a linguistic phenomenon where a *negation cue* (e.g. *not*) can alter the meaning of a particular text segment or of a fact. This text segment (or fact) is said to be inside the *scope of that negation cue*. In the context of RE, there is not much work that aims to exploit the scope of negations.¹ The only work on RE that we are aware of is Sanchez-Graillet and Poesio (2007) where they used various heuristics to extract negative protein interaction.

Despite the recent interest on automatically detecting the scope of negation² till now there seems to be no empirical evidence supporting its exploitation for the purpose of RE. Even if we could manage to obtain highly accurate automatically detected

¹In the context of event extraction (a closely related task of RE), there have been efforts in BioNLP shared tasks of 2009 and 2011 for (non-mandatory sub-task of) event negation detection (3 participants in 2009; 2 in 2011) (Kim et al., 2009; Kim et al., 2011). The participants approached the sub-task using either pre-defined patterns or some heuristics.

²This task is popularized by various recently held shared tasks (Farkas et al., 2010; Morante and Blanco, 2012).

negation scopes, it is not clear how to feed this information inside the RE approach. Simply considering whether a pair of candidate mentions falls under the scope of a negation cue might not be helpful.

In this paper, we propose that the scope of negations can be exploited at two different levels. Firstly, the system would check whether all the target entity³ mentions inside a sentence along with possible relation clues (or trigger words), if any, fall (directly or indirectly) under the scope of a negation cue. If such a sentence is found, then it should be discarded (i.e. candidate mention pairs⁴ inside that sentence would not be considered). Secondly, for each of the remaining pairs of candidate mentions, the system should exploit features related to the scope of negation (rather than simply adding a feature for negation cue, approach adopted in various RE systems) that can provide indication (if any such evidence exists) that the corresponding relation of interest actually does not hold in that particular context.

In the subsequent sections, we describe our approach. The RE task considered is drug-drug interaction (DDI) extraction. The task has significant importance for public health safety.⁵ We used

³The target entities, for example, for *DDI* extraction and for *EMP-ORG* relation extraction would be {*DRUG*} and {*PER*, *GPE*, *ORG*} respectively. Any entity other than the target entities (w.r.t. the particular RE task) belongs to non-target entities.

⁴Candidate mention pairs for RE are taken from target entity mentions.

⁵After the death of pop star Michael Jackson, allegedly due to DDI, it was reported that about 2.2 million people in USA, age 57 to 85, were taking potentially dangerous combinations of drugs (Landau, 2009). An earlier report mentioned that deaths from accidental drug interactions rose 68 percent between 1999 and 2004 (Payne, 2007).

the DDIExtraction-2011 challenge corpus (Segura-Bedmar et al., 2011). The official training and test data of the corpus contain 4,267 and 1,539 sentences, and 2,402 and 755 DDI annotations respectively.

2 Proposed Approach

2.1 Stage 1: Exploiting scope of negation to filter out sentences

We propose a two stage RE approach. In the first stage, our goal is to exploit the scope of negations to reduce the number of candidate mention pairs by discarding sentences. For this purpose, we propose the following features to train a binary classifier:

- *has2TM*: If the sentence has exactly 2 target entity mentions (i.e. drug mentions for DDI extraction).
- *has3OrMoreTM*: Whether the sentence has more than 2 target entity mentions.
- *allTMonRight*: Whether all target entity mentions inside the sentence appear after the negation cue.
- *neitherAllTMonLeftOrRight*: Whether some but not all target entity mentions appear after the negation cue.
- *negCue*: The negation cue itself.
- *immediateGovernor*: The word on which the cue is directly syntactically dependent.
- *nearestVerbGovernor*: The nearest verb in the dependency graph on which the cue is syntactically dependent.
- *isVerbGovernorRoot*: Whether the *nearestVerbGovernor* is root of the dependency graph of the sentence.
- *allTMdependentOnNKG*: Whether all target entity mentions are syntactically dependent (directly/indirectly) on the *nearestVerbGovernor*.
- *allButOneTMdependentOnNKG*: Whether all but one target entity mentions are syntactically dependent on the *nearestVerbGovernor*.
- *although*PrecedeCue*: Whether the syntactic clause containing the negation cue begins with “although / though / despite / in spite”.
- *commaBeforeNextTM*: Whether there is a comma in the text between the negation cue and the next target entity mention after the cue.
- *commaAfterPrevTM*: Whether there is a comma in the text between the previous target entity mention before the negation cue and the cue itself.

- *sentHasBut*: Whether the sentence contains the word “but”.

The objective of the classifier is to decide whether all of the target entity mentions (i.e. drugs) as well as any possible evidence of the relation of interest (for which we assume the immediate and the nearest verb governors of the negation cue would be good candidates) inside the corresponding sentence fall under the scope of a negation cue in such a way that the sentence is unlikely to contain a DDI.

At present, we limit our focus only on the first occurrence of the following negation cues: “*no*”, “*n’t*” or “*not*”.⁶ In the Stage 1, any sentence that contains at least one DDI is considered by the classifier as a positive (training/test) instance. Other sentences are considered as negative instances. We rule out any sentence (i.e. we do not consider as training/test instance for the classifier that filters less informative sentences) during both training and testing if any of the following conditions holds:

- The sentence contains less than two target entity mentions (such sentence would not contain the relation of interest anyway).
- It has any of the following phrases – “*not recommended*”, “*should not be*” or “*must not be*”.⁷
- There is no “*no*”, “*n’t*” or “*not*” in the sentence.
- No target entity mention appears in the sentence after “*no*”, “*n’t*” or “*not*”.

To assess the effectiveness of the proposed Stage 1 classifier, we defined a **baseline** classifier that filters any sentence that contains “*no*”, “*n’t*” or “*not*”.

2.2 Stage 2

Once the sentences which are likely to have no DDI are identified and removed, the next step is to apply a state-of-the-art RE approach on the remaining sentences. In this section, we propose a new hybrid kernel, K_{Hybrid} , for this purpose. It is defined as follows:

$$K_{Hybrid}(R_1, R_2) = K_{HF}(R_1, R_2) + K_{SL}(R_1, R_2) + w * K_{PET}(R_1, R_2)$$

⁶These cues usually occur more frequently and generally have larger negation scope than other negation cues.

⁷These expressions often provide clues that one of the bio-entity mentions negatively influences the level of activity of the other.

Here, K_{HF} stands for a new feature based kernel (proposed in this paper) that uses a heterogeneous set of features. K_{SL} stands for the Shallow Linguistic (SL) kernel proposed by Giuliano et al. (2006). K_{PET} stands for the Path-enclosed Tree (PET) kernel (Moschitti, 2004). w is a multiplicative constant used for the PET kernel. It allows the hybrid kernel to assign more (or less) weight to the information obtained using tree structures depending on the corpus.

The proposed kernel composition is valid according to the closure properties of kernels. We exploit the SVM-Light-TK toolkit (Moschitti, 2006; Joachims, 1999) for kernel computation. In Stage 2, each candidate drug mention pair represents an instance.

2.2.1 Proposed K_{HF} kernel

As mentioned earlier, this proposed kernel uses heterogeneous features. The first version of the heterogeneous feature set (henceforth, $HF\ v1$) combines features proposed by two previous RE works. The former is Zhou et al. (2005), which uses 51 different features. We select the following 27 of their features for our feature set:

*WBNUL, WBFL, WBF, WBL, WBO,
BMIF, BMIL, AM2F, AM2L, #MB, #WB,
CPHBNUL, CPHBFL, CPHBF, CPHBL,
CPHBO, CPHBMIF, CPHBMIL, CPHAM2F,
CPHAM2F, CPP, CPPH, ET12SameNP,
ET12SamePP, ET12SameVP, PTP, PTPH*

The latter is the TPWF kernel (Chowdhury and Lavelli, 2012a) from which we use following features:

HasTriggerWord, Trigger-X, DepPattern-i, e-walk, v-walk

The TPWF kernel extracts the *HasTriggerWord*, *Trigger-X* and *DepPattern-i* features from a sub-graph called *reduced graph*. We also follow this approach with one minor difference. Unlike Chowdhury and Lavelli (2012a), we look for trigger words in the whole reduced graph instead of using only the root of the sub-graph.

Due to space limitation we refer the readers to the corresponding papers for the description of the above mentioned features and the definition of *reduced graph*.

In addition, $HF\ v1$ also includes surrounding tokens within the window of {-2,+2} for each candidate mention. We are unaware of any available list of trigger words for drug-drug interaction. So, we created such a list.⁸

We extend the heterogeneous feature set by adding features related to the scope of negation (henceforth, $HF\ v2$). We use a list of 13 negation cues⁹ to search inside the reduced graph of a candidate pair. If the reduced graph contains any of the negation cues or their morphological variants then we add the following features:

- *negCue*: The corresponding negation cue.
- *immediateNegatedWord*: If the word following the negation cue is neither a preposition nor a “be verb”, then that word, otherwise the word after the next word.¹⁰

Furthermore, if the corresponding matched negation cue is either “no”, “n’t” or “not”, then we add additional features related to negation scope:

- *bothEntDependOnImmediateGovernor*: Whether the immediate governor (if any) of the negation cue is also governor of a dependency sub-tree (of the dependency graph of the corresponding sentence) that includes both of the candidate mentions.
- *immediateGovernorIsVerbGovernor*: Whether the immediate governor of the negation cue is a verb.
- *nearestVerbGovernor*: The closest verb governor (i.e. parent or grandparent inside the dependency graph), if any, of the negation cue.

We further extend the heterogeneous feature set by adding features related to relevant non-target entities (with respect to the relation of interest; henceforth, $HF\ v3$). For the purpose of DDI extraction, we deem the presence of *DISEASE* mentions (which might result as a consequence of a DDI) can provide some clues. So, we use a publicly available state-of-the-art disease NER system called BioEnEx (Chowdhury and Lavelli, 2010) to annotate the DDIExtraction-2011 challenge corpus. For

⁸The RE system developed for this work and the created list of trigger words for DDI can be downloaded from <https://github.com/fmchowdhury/HyREX>.

⁹No, not, neither, without, lack, fail, unable, abrogate, absence, prevent, unlikely, unchanged, rarely.

¹⁰For example, “interested” from “... not interested ...”, and “confused” from “... not to be confused ...”.

each candidate (drug) mention pair, we add the following features in $HF\ v3$:

- $NTEM_{insideSentence}$: Whether the corresponding sentence contains important non-target entity mention(s) (e.g. disease for DDI).
- $immediateGovernorIsVerbGovernorOfNTEM$: The immediate governor (if any) of the non-target entity mention, only if such governor is also governing a dependency sub-tree that includes both of the target candidate entity mentions.
- $nearestVerbGovernorOfNTEM$: The closest verb governor (if any) of the non-target entity mention, only if it also governs the candidate entity mentions.
- $immediateGovernorIsVerbGovernorOfNTEM$: Whether the immediate governor is a verb.

3 Results and Discussion

We train a linear SVM classifier in Stage 1 and tune the hyper-parameters (by doing 5-fold cross-validation) for obtaining maximum possible recall. In this way we minimize the number of false negatives (i.e. sentences that contain DDIs but are wrongly identified as not having any).

During the cross-validation experiments on the training data, 334 sentences (7.83% of the total sentences) containing at least 2 drug mentions were identified by our proposed classifier (in Section 2.1) as unlikely to have any DDI and hence are candidates for discarding. Only 19 of these sentences were incorrectly identified. When we trained on the training data and tested on the official test data of DDIExtraction-2011 challenge corpus, 121 sentences (7.86% of the total test sentences) were identified by the classifier as candidates for discarding. Only 5 of them were incorrectly identified.

Unlike Stage 1, in Stage 2 where we train the hybrid kernel based RE classifier and use it for RE (i.e. DDI extraction) from the test data, sentences are not the RE training/test instances. Instead, a RE instance corresponds to a candidate mention pair.

All the DDIs (i.e. positive RE instances) of the incorrectly identified sentences in Stage 1 (i.e. the sentences which are incorrectly labelled as not having any DDI and filtered) are automatically considered as false negatives during the calculation of DDI extraction results in Stage 2.

To verify whether our proposed hybrid kernel achieves state-of-the-art results without taking benefits of the output of Stage 1, we did some experiments without discarding any sentence. These experiments are done using Zhou et al. (2005), TPWF kernel, SL kernel, different versions of proposed K_{HF} kernel and K_{Hybrid} kernel. Table 1 shows the results of 5-fold cross-validation experiments (hyper-parameters are tuned for obtaining maximum F-score). As the results show, there is a gain +0.9 points in F-score (mainly due to the boost in recall) after the addition of features related to negation scope. There is also some minor improvement due to the proposed non-target entity specific features.

We also performed (5-fold cross validation) experiments by combining the Stage 1 classifier with each of the Zhou et al. (2005), TPWF kernel, SL kernel, PET kernel, K_{HF} kernel and K_{Hybrid} kernel separately (only the results of K_{Hybrid} are reported in Table 1 due to space limitation). In each case, there were improvements in precision, recall and F-score. The gain in F-score ranged from 1.0 to 1.4 points.

	P / R / F-score
Using SL kernel (Giuliano et al., 2006)	51.3 / 64.7 / 57.3
Using (Zhou et al., 2005)	58.7 / 37.1 / 45.5
Using PET kernel (Moschitti, 2004)	46.8 / 602 / 52.7
TPWF (Chowdhury and Lavelli, 2012a)	43.7 / 60.7 / 50.8
Proposed approaches	
Proposed $K_{HF}\ v1$	53.4 / 51.5 / 52.4
$K_{HF}\ v2$ (i.e. + neg scope feat.)	53.9 / 52.6 / 53.3 (+0.9)
$K_{HF}\ v3$ (i.e. + non-target entity feat.)	53.6 / 53.5 / 53.6 (+0.3)
Proposed K_{Hybrid}	56.3 / 68.5 / 61.8
Proposed K_{Hybrid} with Stage 1	57.3 / 69.4 / 62.8 (+1.0)

Table 1: 5-fold cross-validation results on training data.

Table 2 reports the results of the previously published studies that used the same corpus. Our proposed K_{Hybrid} kernel obtains an F-score that is higher than that of the previous state of the art.

When the Stage 1 classifier (based on negation scope features) is exploited before using the K_{Hybrid} kernel, the F-score reaches up to 67.4. This is +1.0 points higher than without exploiting the Stage 1 classifier and +1.7 higher than previous state of

the art. We did separate experiments (also reported in Table 2) to assess the performance improvement when the output of Stage 1 is used to filter sentences from either training or test data only. The results remain the same when only training sentences are filtered; while there are some improvements when only test sentences are filtered. Filtering both training and test sentences provides the larger gain which is statistically significant.

Usually, the number of negative instances in a corpus is much higher than that of the positive instances. In a recent work, Chowdhury and Lavelli (2012b) showed that by removing less informative (negative) instances (henceforth, *LII*s), not only the skewness in instance distribution could be reduced but it also leads to a better result. The proposed Stage 1 classifier, presented in this work, also reduces skewness in instance distribution. This is because we are only removing those sentences that are unlikely to contain any positive instance. So, in principle, the Stage 1 classifier is focused on removing only negative instances (although the classifier mistakenly discards few positive instances, too).

We wanted to study how the Stage 1 classifier would contribute if we use it on top of the techniques that were proposed in Chowdhury and Lavelli (2012b) to remove LII_s. As Table 2 shows, by using the Stage 1 classifier along with LLI filtering, we could further improve the results (+3.2 points difference in F-score with the previous state of the art).

4 Conclusion

A major flexibility in the proposed approach is that it does not require a separate dataset (which needs to match the genre of the text to be used for RE) annotated with negation scopes. Instead, the proposed Stage 1 classifier uses the RE training data (which do not have negation scope annotations) to self-supervise itself. Various new features have been exploited (both in stages 1 and 2) that can provide strong indications of the scope of negation cues with respect to the relation to be extracted. The only thing needed is the list of possible negation cues (Morante (2010) includes such a comprehensive list).

Our proposed kernel, which has a component that exploits a heterogeneous set of features including negation scope and presence of non-target entities, already obtains better results than previous studies.

	P	R	F-score
(Thomas et al., 2011)	60.5	71.9	65.7
(Chowdhury et al., 2011)	58.6	70.5	64.0
(Chowdhury and Lavelli, 2011)	58.4	70.1	63.7
(Bjorne et al., 2011)	58.0	68.9	63.0
Proposed K_{Hybrid}	60.0	74.3	66.4
K_{Hybrid} + Stage 1 baseline	61.8	68.9	65.1
K_{Hybrid} + proposed Stage 1 (only training sentences are filtered)	60.0	74.2	66.4
K_{Hybrid} + proposed Stage 1 (only test sentences are filtered)	61.4	73.8	67.0
K_{Hybrid} + proposed Stage 1 (both training and test sentences are filtered)	62.1	73.8	67.4 stat. sig.
Proposed K_{Hybrid} + LII filtering + proposed Stage 1	61.1	75.1	67.4 stat. sig.
Proposed K_{Hybrid} + LII filtering + proposed Stage 1	63.5	75.2	68.9 stat. sig.

Table 2: Results obtained on the official test set of the 2011 DDI Extraction challenge. LII filtering refers to the techniques proposed in Chowdhury and Lavelli (2012b) for reducing skewness in RE data distribution. stat. sig. indicates that the improvement of F-score, due to usage of Stage 1 classifier, is statistically significant (verified using *Approximate Randomization Procedure* (Noreen, 1989); number of iterations = 1,000, confidence level = 0.01).

The results considerably improve when possible irrelevant sentences from both training and test data are filtered by exploiting features related to the scope of negations.

In future, we would like to exploit the scope of more negation cues, apart from the three cues that are used in this study. We believe our approach would help to improve RE in other genres of text (such as newspaper) as well.

Abstract

Iterative bootstrapping methods are widely employed for relation extraction, especially because they require only a small amount of human supervision. Unfortunately, a phenomenon known as *semantic drift* can affect the accuracy of iterative bootstrapping and lead to poor extractions. This paper proposes an alternative bootstrapping method, which ranks relation tuples by measuring their distance to the seed tuples in a bipartite tuple-pattern graph. In contrast to previous bootstrapping methods, our method is not susceptible to semantic drift, and it empirically results in better extractions than iterative methods.

1 Introduction

The goal of relation extraction is to extract tuples of a particular relation from a corpus of natural language text. A widely employed approach to relation extraction is based on iterative bootstrapping (Brin, 1998; Agichtein and Gravano, 2000; Pasca et al., 2006; Pantel and Pennacchiotti, 2006), which can be applied with only small amounts of supervision and which scales well to very large datasets.

A well-known problem with iterative bootstrapping is a phenomenon known as *semantic drift* (Curran et al., 2007): as bootstrapping proceeds it is likely that unreliable patterns will lead to false extractions. These extraction errors are amplified in the following iterations and the extracted relation will drift away

from the intended target. Semantic drift often results in low precision extractions and therefore poses a major limitation of iterative bootstrapping algorithms. Previous work on iterative bootstrapping has addressed the issue of reducing semantic drift for example by bagging the results of various runs employing differing seed tuples, constructing filters which identify false tuples or patterns and adding further constraints to the bootstrapping process (T. McIntosh, 2010; McIntosh and Curran, 2009; Curran et al., 2007).

However, the analysis of Komachi et al. (2008) has shown that semantic drift is an inherent property of iterative bootstrapping algorithms and therefore poses a fundamental problem. They have shown that iterative bootstrapping without pruning corresponds to an eigenvector computation and thus as the number of iterations increases the resulting ranking will always converge towards the same static ranking of tuples, *regardless of the particular choice of seed instances*.

In this paper, we describe an alternative method, that is not susceptible to semantic drift. We represent our data as a bipartite graph, whose vertices correspond to patterns and tuples respectively and whose edges capture cooccurrences and then measure the distance of a tuple to the seed set in terms of random walk hitting times. Experimental results confirm that semantic drift is avoided by our method and show that substantial improvements over iterative forms of bootstrapping are possible.

2 Scoring with Hitting Times

From a given corpus, we extract a dataset consisting of *tuples* and *patterns*. Tuples are pairs of co-occurring strings in the corpus, such as (*Bill Gates, Microsoft*), which potentially belong to a particular relation of interest. In our case, patterns are simply the sequence of tokens occurring between tuple elements, e.g. “*is the founder of*”. We represent all the tuple types¹ X and all the extraction pattern types Y contained in a given corpus through an undirected, weighted, bipartite graph $G = (V, E)$ with vertices $V = X \cup Y$ and edges $E \subset X \times Y$, where an edge $(x, y) \in E$ indicates that tuple x occurs with pattern y somewhere in the corpus. Edge weights are defined through a weight matrix W which holds the weight $W_{i,j} = w(v_i, v_j)$ for edges $(v_i, v_j) \in E$. Specifically, we use the count of how many times a tuple occurs with a pattern in the corpus and weights for unconnected vertices are zero.

Our goal is to compute a score vector σ holding a score $\sigma_i = \sigma(x_i)$ for each tuple $x_i \in X$, which quantifies how well the tuple matches the seed tuples. Higher scores indicate that the tuple is more likely to belong to the relation defined through the seeds and thus the score vector effectively provides a ranking of the tuples.

We define scores of tuples based on their *distance*² to the seed tuples in the graph. The distance of some tuple x to the seed set S can be naturally formalized in terms of the average time it takes until a random walk starting in S reaches x , the *hitting time*. The random walk is defined through the probability distribution over start vertices and through a matrix of transition probabilities. Edge weights are constrained to be non-negative, which allows us to define the transition matrix P with $P_{i,j} = p(v_j|v_i) = \frac{1}{d_{v_i}}w(v_i, v_j)$, where $d_v = \sum_{v_k \in V} w(v, v_k)$ is the degree of a vertex $v \in V$.

The distance of two vertices is measured in terms of the average time of a random walk be-

¹Note that we are using tuple and pattern types rather than particular mentions in the corpus.

²The term is used informally. In particular, hitting times are not a *distance metric*, since they can be asymmetric.

tween the two. Specifically, we adopt the notion of *T-truncated hitting time* (Sarkar and Moore, 2007) defined as the expected number of steps it takes until a random walk of at most T steps starting at v_i reaches v_j for the first time:

$$h^T(v_j|v_i) = \begin{cases} 0 & \text{iff. } v_j = v_i \text{ or } T=0 \\ 1 + \sum_{v_k \in V} p(v_k|v_i) h^{T-1}(v_j|v_k) & \end{cases}$$

The truncated hitting time $h^T(v_j|v_i)$ can be approximately computed by sampling M independent random walks starting at v_i of length T and computing

$$\hat{h}^T(v_j|v_i) = \frac{1}{M} \sum_{k=1}^m t_k + (1 - \frac{m}{M})T \quad (1)$$

where $\{t_1 \dots t_m\}$ are the sampled first-hit times of random walks which reach v_j within T steps (Sarkar et al., 2008).

The score $\sigma_{HT}(v)$ of a vertex $v \notin S$ to the seed set S is then defined as the inverse of the average T -truncated hitting time of random walks starting at a randomly chosen vertex $s \in S$:

$$\frac{1}{\sigma_{HT}(v)} = h^T(v|S) = \frac{1}{|S|} \sum_{s \in S} h^T(v|s) \quad (2)$$

3 Experiments

We extracted tuples and patterns from the fifth edition of the Gigaword corpus (Parker et al., 2011), by running a named entity tagger and extracting all pairs of named entities and extracting occurring within the same sentence which do not have another named entity standing between them. Gold standard seed and test tuples for a set of relations were obtained from YAGO (Suchanek et al., 2007). Specifically, we took all relations for which there are at least 300 tuples, each of which occurs at least once in the corpus. This resulted in the set of relations shown in Table 1, plus the development relation *hasWonPrize*.

For evaluation, we use the *percentile rank of the median test set element* (PRM, see Francois et al. 2007), which reflects the quality of the

full produced ranking, not just the top N elements and is furthermore computable with only a small set of labeled test tuples³.

We compare our proposed method based on hitting times (HT) with two variants of iterative bootstrapping. The first one (IB1) does not employ pruning and corresponds to the algorithm described in Komachi et al. (2008). The second one (IB2) corresponds to a standard bootstrapping algorithm which employs pruning after each step in order to reduce semantic drift. Specifically, scores are pruned after projecting from X onto Y and from Y onto X , retaining only the top $N^{(t)} = N_0 t$ scores at iteration t and setting all other scores to zero.

3.1 Parametrizations

The experiments in this section were conducted on the held out development relation *hasWonPrize*. The ranking produced by both forms of iterative bootstrapping IB1 and IB2 depend on the number of iterations, as shown in Figure 1. IB1 achieves an optimal ranking after just one iteration and thereafter scores get worse due to semantic drift. In contrast, pruning helps avoid semantic drift for IB2, which attains an optimal score after 2 iterations and achieves relatively constant scores for several iterations. However, during iteration 9 an incorrect pattern is kept and this at once leads to a drastic loss in accuracy, showing that semantic drift is only deferred and not completely eliminated.

Our method HT has parameter T , corresponding to the truncation time, i.e., maximal number of steps of a random walk. Figure 2 shows the PRM of our method for different values of T . Performance gets better as T increases and is optimal for $T = 12$, whereas for larger values, the performance gets slightly worse again. The figure shows that, if T is large enough (> 5), the PRM is relatively constant and there is no phenomenon comparable to semantic drift, which causes instability in the produced rankings.

³other common metrics do not satisfy these conditions.

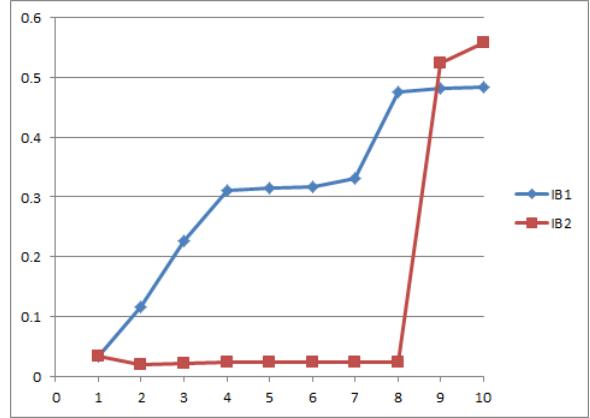

Figure 1: PRM for iterative bootstrapping without pruning (IB1) and with pruning (IB2). A lower PRM is better.

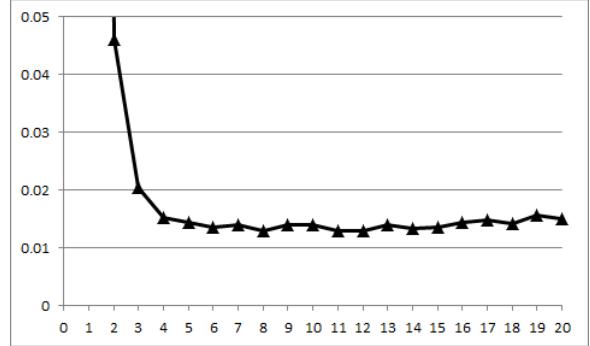

Figure 2: PRM for our method based on hitting times, for different values of the truncation time parameter T .

3.2 Method Comparison

To evaluate the methods, firstly the parameters for each method were set to the optimal values as determined in the previous section. For the experiments here, we again use 200 randomly chosen tuples as the seeds for each relation. All the remaining gold standard tuples are used for testing.

Table 1 shows the PRM for the three methods. For a majority of the relations (12/16) HT attains the best, i.e. lowest, PRM, which confirms that hitting times constitute an accurate way of measuring the distance of tuples to the seed set. IB1 and IB2 each perform best on 2/16 of the relations. A sign test on these results yields that

Relation	IB1	IB2	HT

Table 1: PRM in percent for all relations, for all three models. A lower PRM corresponds to a better model, with the best score indicated in bold.

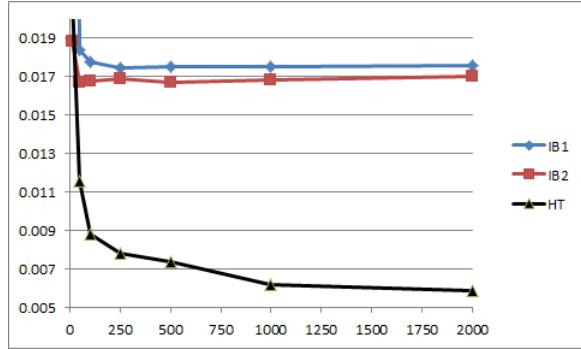

Figure 3: PRM for the three methods, as a function of the size of the seed set for the relation *created*.

HT is better than both IB1 and IB2 at significance level $\alpha < 0.01$.

Moreover, the ranking produced by HT is stable and not affected by semantic drift, given that even where results are worse than for IB1 or IB2, they are still close to the best performing method. In contrast, when semantic drift occurs, the performance of IB1 and IB2 can deteriorate drastically, e.g. for the *worksAt* relation, where both IB1 and IB2 produce rankings that are a lot worse than the one produced by HT.

3.3 Sensitivity to Seed Set Size

Figure 3 shows the PRM for each of the three methods as a function of the size of the seed set for the relation *created*. For small seed sets, the performance of the iterative methods can be increased by adding more seeds. However, from a seed set size of 50 onwards, performance remains relatively constant. In other words, iterative bootstrapping is not benefitting from the information provided by the additional labeled data, and thus has a poor learning performance. In contrast, for our method based on hitting times, the performance continually improves as the seed set size is increased. Thus, also in terms of learning performance, our method is more sound than iterative bootstrapping.

4 Conclusions

The paper has presented a graph-based method for seed set expansion which is not susceptible to semantic drift and on most relations outperforms iterative bootstrapping. The method measures distance between vertices through random walk hitting times. One property which makes hitting times an appropriate distance measure is their ability to reflect the overall connectivity structure of the graph, in contrast to measures such as the shortest path between two vertices. The hitting time will decrease when the number of paths from the start vertex to the target vertex increases, when the length of paths decreases or when the likelihood (weights) of paths increases. These properties are particularly important when the observed graph edges must be assumed to be merely a sample of all plausible edges, possibly perturbated by noise. This has also been asserted by previous work, which has shown that hitting times successfully capture the notion of similarity for other natural language processing problems such as learning paraphrases (Kok and Brockett, 2010) and related problems such as query suggestion (Mei et al., 2008). Future work will be aimed towards employing our hitting time based method in combination with a richer feature set.

Abstract

Distant supervision, heuristically labeling a corpus using a knowledge base, has emerged as a popular choice for training relation extractors. In this paper, we show that a significant number of “negative” examples generated by the labeling process are *false negatives* because the knowledge base is incomplete. Therefore the heuristic for generating negative examples has a serious flaw. Building on a state-of-the-art distantly-supervised extraction algorithm, we proposed an algorithm that learns from only *positive* and *unlabeled* labels at the pair-of-entity level. Experimental results demonstrate its advantage over existing algorithms.

1 Introduction

Relation Extraction is a well-studied problem (Miller et al., 2000; Zhou et al., 2005; Kambhatla, 2004; Min et al., 2012a). Recently, Distant Supervision (DS) (Craven and Kumlien, 1999; Mintz et al., 2009) has emerged to be a popular choice for training relation extractors without using manually labeled data. It automatically generates training examples by labeling relation mentions¹ in the source corpus according to whether the argument pair is listed in the target relational tables in a knowledge base (KB). This method significantly reduces human efforts for relation extraction.

The labeling heuristic has a serious flaw. Knowledge bases are usually highly incomplete. For exam-

ple, 93.8% of *persons* from Freebase² have no *place of birth*, and 78.5% have no *nationality* (section 3). Previous work typically assumes that if the argument entity pair is not listed in the KB as having a relation, all the corresponding relation mentions are considered *negative* examples.³ This crude assumption labeled many entity pairs as *negative* when in fact some of their mentions express a relation. The number of such *false negative matches* even exceeds the number of *positive* pairs, by 3 to 10 times, leading to a significant problem for training. Previous approaches (Riedel et al., 2010; Hoffmann et al., 2011; Surdeanu et al., 2012) bypassed this problem by heavily under-sampling the “negative” class.

We instead deal with a learning scenario where we only have entity-pair level labels that are either *positive* or *unlabeled*. We proposed an extension to Surdeanu et al. (2012) that can train on this dataset. Our contribution also includes an analysis on the incompleteness of Freebase and the *false negative match* rate in two datasets of labeled examples generated by DS. Experimental results on a realistic and challenging dataset demonstrate the advantage of the algorithm over existing solutions.

2 Related Work

Distant supervision was first proposed by Craven and Kumlien (1999) in the biomedical domain.

²Freebase is a large collaboratively-edited KB. It is available at <http://www.freebase.com>.

³There are variants of labeling heuristics. For example, Surdeanu et al. (2011) and Sun et al. (2011) use a pair $\langle e, v \rangle$ as a negative example, when it is not listed in Freebase, but e is listed with a different v' . These assumptions are also problematic in cases where the relation is not functional.

¹An occurrence of a pair of entities with the source sentence.

Since then, it has gain popularity (Mintz et al., 2009; Bunescu and Mooney, 2007; Wu and Weld, 2007; Riedel et al., 2010; Hoffmann et al., 2011; Surdeanu et al., 2012; Nguyen and Moschitti, 2011). To tolerate noisy labels in positive examples, Riedel et al. (2010) use Multiple Instance Learning (MIL), which assumes only at-least-one of the relation mentions in each “bag” of mentions sharing a pair of argument entities which bears a relation, indeed expresses the target relation. MultiR (Hoffmann et al., 2011) and Multi-Instance Multi-Label (MIML) learning (Surdeanu et al., 2012) further improve it to support multiple relations expressed by different sentences in a bag. Takamatsu et al. (2012) models the probabilities of a pattern showing relations, estimated from the heuristically labeled dataset. Their algorithm removes mentions that match low-probability patterns. Sun et al. (2011) and Min et al. (2012b) also estimate the probabilities of patterns showing relations, but instead use them to relabel examples to their most likely classes. Their approach can correct highly-confident false negative matches.

3 Problem Definition

Distant Supervision: Given a KB \mathcal{D} (a collection of relational tables $r(e_1, e_2)$, in which $r \in R$ (R is the set of relation labels), and $\langle e_1, e_2 \rangle$ is a pair of entities that is known to have relation r) and a corpus C , the key idea of distant supervision is that we align \mathcal{D} to C , label each *bag*⁴ of relation mentions that share argument pair $\langle e_1, e_2 \rangle$ with r , otherwise *OTHER*. This generates a dataset that has labels on entity-pair (bag) level. Then a relation extractor is trained with single-instance learning (by assuming all mentions have the same label as the bag), or Multiple-Instance Learning (by assuming at-least-one of the mentions expresses the bag-level label), or Multi-Instance Multi-Label learning (further assuming a bag can have multiple labels) algorithms. All of these works treat the *OTHER* class as examples that are labeled as *negative*.

The incomplete KB problem: KBs are usually incomplete because they are manually constructed, and it is not possible to cover all human knowledge

⁴A bag is defined as a set of relation mentions sharing the same entity pair as relation arguments. We will use the terms *bag* and *entity pair* interchangeably in this paper.

nor stay current. We took frequent relations, which involve an entity of type PERSON, from Freebase for analysis. We define the incompleteness $\partial(r)$ of a relation r as follows:

$$\partial(r) = \frac{|\{e\}| - |\{e | \exists e' \text{ s.t. } r(e, e') \in \mathcal{D}\}|}{|\{e\}|}$$

$\partial(r)$ is the percentage of all *persons* $\{e\}$ that do not have an attribute e' (with which $r(e, e')$ holds). Table 1 shows that 93.8% of *persons* have no *place of birth*, and 78.5% of them have no *nationality*. These are must-have attributes for a person. This shows that Freebase is highly incomplete.

Freebase relation types	Incompleteness
/people/person/education	0.792
/people/person/employment_history	0.923
/people/person/nationality*	0.785
/people/person/parents*	0.988
/people/person/place_of_birth*	0.938
/people/person/places_lived*	0.966

Table 1: The incompleteness of Freebase (* are must-have attributes for a person).

We further investigate the rate of *false negative matches*, as the percentage of entity-pairs that are not listed in Freebase but one of its mentions generated by DS does express a relation in the target set of types. We randomly picked 200 *unlabeled* bags⁵ from each of the two datasets (Riedel et al., 2010; Surdeanu et al., 2012) generated by DS, and we manually annotate all relation mentions in these bags. The result is shown in Table 2, along with a few examples that indicate a relation holds in the set of false negative matches (bag-level). Both datasets have around 10% false negative matches in the *unlabeled* set of bags. Taking into consideration that the number of *positive* bags and *unlabeled* bags are highly imbalanced (1:134 and 1:37 in the *Riedel* and *KBP* dataset respectively, before undersampling the *unlabeled* class), the number of false negative matches are 11 and 4 times the number of *positive* bags in *Riedel* and *KBP* dataset, respectively. Such a large ratio shows false negatives do have a significant impact on the learning process.

4 A semi-supervised MIML algorithm

Our goal is to model the bag-level label noise, caused by the incomplete KB problem, in addition

⁵85% and 95.7% of the bags in the Riedel and KBP datasets have only one relation mention.

Dataset	# training bags	# positive	# unlabeled	% false negatives	# positive : # false negative	has human assessment	Examples of false negative mentions
Riedel	4,700	1:134(BD*)	8.5%		1:11.4	no	(/location/location/contains)... in Brooklyn 's Williamsburg .
KBP	183,062	1:37(BD*)	11.5%		1:4	yes	(/people/person/place_lived) Cheryl Rogowski , a farmer from Orange County ... (per:city_of_birth) Juan Martn Maldacena (born September 10, 1968) is a theoretical physicist born in Buenos Aires (per:employee_of) Dave Matthews , from the ABC News , ...

Table 2: False negative matches on the *Riedel* (Riedel et al., 2010) and *KBP* dataset (Surdeanu et al., 2012). All numbers are on bag (pairs of entities) level. *BD** are the numbers before downsampling the *negative* set to 10% and 5% in *Riedel* and *KBP* dataset, respectively.

to modeling the instance-level noise using a 3-layer MIL or MIML model (e.g., Surdeanu et al. (2012)). We propose a 4-layer model as shown in Figure 1.

The input to the model is a list of n bags with a vector of binary labels, either *Positive* (P), or *Unlabeled* (U) for each relation r . Our model can be viewed as a semi-supervised⁶ framework that extends a state-of-the-art Multi-Instance Multi-Label (MIML) model (Surdeanu et al., 2012). Since the input to previous MIML models are bags with per-relation binary labels of either *Positive* (P) or *Negative* (N), we add a set of latent variables ℓ which models the true bag-level labels, to bridge the observed bag labels y and the MIML layers. We consider this as our main contribution to the model. Our hierarchical model is shown in Figure 1.

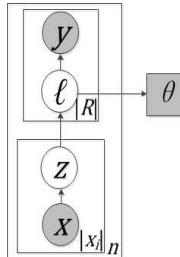

Figure 1: Plate diagram of our model.

Let i, j be the index in the bag and mention level, respectively. Following Surdeanu et al. (2012), we model mention-level extraction $p(z_{ij}^r | \mathbf{x}_{ij}; \mathbf{w}_z)$ and multi-instance multi-label aggregation $p(\ell_i^r | \mathbf{z}_i; \mathbf{w}_\ell^r)$ in the bottom 3 layers. We define:

- r is a relation label. $r \in R \cup \{\text{OTHER}\}$, in which *OTHER* denotes no relation expressed.
- $y_i^r \in \{P, U\}$: r holds for i th bag or the bag is unlabeled.

⁶We use the term *semi-supervised* because the algorithm uses *unlabeled* bags but existing solutions requires bags to be labeled either *positive* or *negative*.

- $\ell_i^r \in \{P, N\}$: a hidden variable that denotes whether r holds for the i th bag.
- θ is an observed constant controlling the total number of bags whose latent label is *positive*.

We define the following conditional probabilities:

$$\bullet p(y_i^r | \ell_i^r) = \begin{cases} 1/2 & \text{if } y_i^r = P \wedge \ell_i^r = P; \\ 1/2 & \text{if } y_i^r = U \wedge \ell_i^r = P; \\ 1 & \text{if } y_i^r = U \wedge \ell_i^r = N; \\ 0 & \text{otherwise;} \end{cases}$$

It encodes the constraints between true bag-level labels and the entity pair labels in the KB.

- $p(\theta | \ell) \sim \mathcal{N}(\frac{\sum_{i=1}^n \sum_{r \in R} \delta(\ell_i^r, P)}{n}, \frac{1}{k})$ where $\delta(x, y) = 1$ if $x = y$, 0 otherwise. k is a large number. θ is the fraction of the bags that are positive. It is an observed parameter that depends on both the source corpus and the KB used.

Similar to Surdeanu et al. (2012), we also define the following parameters and conditional probabilities (details are in Surdeanu et al. (2012)):

- $z_{ij} \in R \cup \{\text{OTHER}\}$: a latent variable that denotes the relation type of the j th mention in the i th bag.
- \mathbf{x}_{ij} is the feature representation of the j th relation mention in the i th bag. We use the set of features in Surdeanu et al. (2012).
- \mathbf{w}_z is the weight vector for the multi-class relation mention-level classifier.
- \mathbf{w}_ℓ^r is the weight vector for the r th binary top-level aggregation classifier (from mention labels to bag-level prediction). We use \mathbf{w}_ℓ to represent $\mathbf{w}_\ell^1, \mathbf{w}_\ell^2, \dots, \mathbf{w}_\ell^{|R|}$.
- $p(\ell_i^r | \mathbf{z}_i; \mathbf{w}_\ell^r) \sim \text{Bern}(f_\ell(\mathbf{w}_\ell^r, \mathbf{z}_i))$ where f_ℓ is probability produced by the r th top-level classifier, from the mention-label level to the bag-label level.
- $p(z_{ij}^r | \mathbf{x}_{ij}; \mathbf{w}_z) \sim \text{Multi}(f_z(\mathbf{w}_z, \mathbf{x}_{ij}))$ where f_z

is probability produced by the mention-level classifier, from the mentions to the mention-label level.⁷

4.1 Training

We use hard Expectation-Maximization (EM) algorithm for training the model. Our objective function is to maximize log-likelihood:

$$\begin{aligned} L(\mathbf{w}_z, \mathbf{w}_\ell) &= \log p(\mathbf{y}, \theta | \mathbf{x}; \mathbf{w}_z, \mathbf{w}_\ell) \\ &= \log \sum_{\ell} p(\mathbf{y}, \theta, \ell | \mathbf{x}; \mathbf{w}_z, \mathbf{w}_\ell) \end{aligned}$$

Since solving it exactly involves exploring an exponential assignment space for ℓ , we approximate and iteratively set $\ell^* = \arg \max p(\ell | \mathbf{y}, \theta, \mathbf{x}; \mathbf{w}_z, \mathbf{w}_\ell)$

$$\begin{aligned} p(\ell | \mathbf{y}, \theta, \mathbf{x}; \mathbf{w}_z, \mathbf{w}_\ell) &\propto p(\mathbf{y}, \theta, \ell | \mathbf{x}; \mathbf{w}_z, \mathbf{w}_\ell) \\ &= p(\mathbf{y}, \theta | \ell, \mathbf{x}) p(\ell | \mathbf{x}; \mathbf{w}_z, \mathbf{w}_\ell) \\ &= p(\mathbf{y} | \ell) p(\theta | \ell) p(\ell | \mathbf{x}; \mathbf{w}_z, \mathbf{w}_\ell) \end{aligned}$$

Rewriting in log form:

$$\begin{aligned} \log p(\ell | \mathbf{y}, \theta, \mathbf{x}; \mathbf{w}_z, \mathbf{w}_\ell) &= \log p(\mathbf{y} | \ell) + \log p(\theta | \ell) + \log p(\ell | \mathbf{x}; \mathbf{w}_z, \mathbf{w}_\ell) \\ &= \sum_{i=1}^n \sum_{r \in R} \log p(y_i^r | \ell_i^r) - k \left(\frac{\sum_{i=1}^n \sum_{r \in R} \delta(\ell_i^r, P)}{n} - \theta \right)^2 \\ &+ \sum_{i=1}^n \sum_{r \in R} \log p(\ell_i^r | \mathbf{x}_i; \mathbf{w}_z, \mathbf{w}_\ell) + \text{const} \end{aligned}$$

Algorithm 1 Training (E-step:2-11; M-step:12-15)

```

1: for  $i = 1, 2$  to  $T$  do
2:    $\ell_i^r \leftarrow N$  for all  $y_i^r = U$  and  $r \in R$ 
3:    $\ell_i^r \leftarrow P$  for all  $y_i^r = P$  and  $r \in R$ 
4:    $I = \{<i, r> | \ell_i^r = N\}; I' = \{<i, r> | \ell_i^r = P\}$ 
5:   for  $k = 0, 1$  to  $\theta n - |I'|$  do
6:      $< i', r' > = \arg \max_{<i, r> \in I} p(\ell_i^r | \mathbf{x}_i; \mathbf{w}_z, \mathbf{w}_\ell)$ 
7:      $\ell_{i'}^{r'} \leftarrow P; I = I \setminus \{<i', r'\>\}$ 
8:   end for
9:   for  $i = 1, 2$  to  $n$  do
10:     $\mathbf{z}_i^* = \arg \max_{\mathbf{z}_i} p(\mathbf{z}_i | \ell_i, \mathbf{x}_i; \mathbf{w}_z, \mathbf{w}_\ell)$ 
11:   end for
12:    $\mathbf{w}_z^* = \arg \max_{\mathbf{w}_z} \sum_{i=1}^n \sum_{j=1}^{|\mathbf{x}_i|} \log p(z_{ij} | \mathbf{x}_{ij}, \mathbf{w}_z)$ 
13:   for all  $r \in R$  do
14:      $\mathbf{w}_\ell^{r(*)} = \arg \max_{\mathbf{w}_\ell} \sum_{i=1}^n p(\ell_i^r | \mathbf{z}_i, \mathbf{w}_\ell^r)$ 
15:   end for
16: end for
17: return  $\mathbf{w}_z, \mathbf{w}_\ell$ 

```

⁷All classifiers are implemented with L2-regularized logistic regression with Stanford CoreNLP package.

In the E-step, we do a greedy search (steps 5-8 in algorithm 1) in all $p(\ell_i^r | \mathbf{x}_i; \mathbf{w}_z, \mathbf{w}_\ell)$ and update ℓ_i^r until the second term is maximized. $\mathbf{w}_z, \mathbf{w}_\ell$ are the model weights learned from the previous iteration.

After fixed ℓ , we seek to maximize:

$$\begin{aligned} \log p(\ell | \mathbf{x}_i; \mathbf{w}_z, \mathbf{w}_\ell) &= \sum_{i=1}^n \log p(\ell_i | \mathbf{x}_i; \mathbf{w}_z, \mathbf{w}_\ell) \\ &= \sum_{i=1}^n \log \sum_{z_i} p(\ell_i, z_i | \mathbf{x}_i; \mathbf{w}_z, \mathbf{w}_\ell) \end{aligned}$$

which can be solved with an approximate solution in Surdeanu et al. (2012) (step 9-11): update \mathbf{z}_i independently with: $\mathbf{z}_i^* = \arg \max_{\mathbf{z}_i} p(\mathbf{z}_i | \ell_i, \mathbf{x}_i; \mathbf{w}_z, \mathbf{w}_\ell)$. More details can be found in Surdeanu et al. (2012).

In the M-step, we retrain both of the mention-level and the aggregation level classifiers.

The full EM algorithm is shown in algorithm 1.

4.2 Inference

Inference on a bag \mathbf{x}_i is trivial. For each mention:

$$z_{ij}^* = \arg \max_{z_{ij} \in R \cup \{OTHER\}} p(z_{ij} | \mathbf{x}_{ij}, \mathbf{w}_z)$$

Followed by the aggregation (directly with \mathbf{w}_ℓ):

$$y_i^{r(*)} = \arg \max_{y_i^r \in \{P, N\}} p(y_i^r | \mathbf{z}_i, \mathbf{w}_\ell^r)$$

4.3 Implementation details

We implement our model on top of the MIML(Surdeanu et al., 2012) code base.⁸ We use the same mention-level and aggregate-level feature sets as Surdeanu et al. (2012). We adopt the same idea of using cross validation for the E and M steps to avoid overfitting. We initialize our algorithm by sampling 5% *unlabeled* examples as *negative*, in essence using 1 epoch of MIML to initialize. Empirically it performs well.

5 Experiments

Data set: We use the KBP (Ji et al., 2011) dataset⁹ prepared and publicly released by Surdeanu et al. (2012) for our experiment since it is 1) large and realistic, 2) publicly available, 3) most importantly, it is the only dataset that has associated human-labeled ground truth. Any KB held-out evaluation without manual assessment will be significantly affected by KB incompleteness. In KBP

⁸Available at <http://nlp.stanford.edu/software/mimlre.shtml>

⁹Available from Linguistic Data Consortium (LDC). <http://projects.ldc.upenn.edu/kbp/data/>

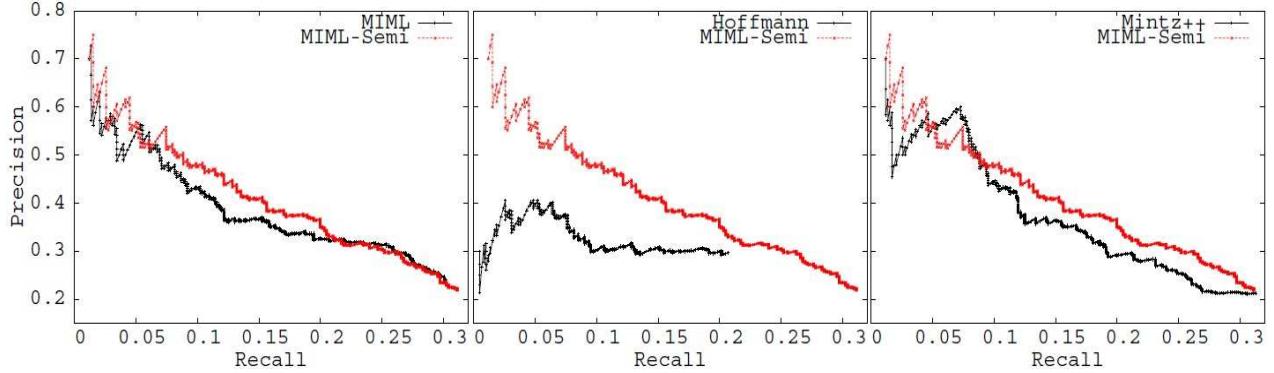

Figure 2: Performance on the KBP dataset. The figures on the left, middle and right show *MIML*, *Hoffmann*, and *Mintz++* compared to the same *MIML-Semi* curve, respectively. *MIML-Semi* is shown in red curves (lighter curves in black and white) while other algorithms are shown in black curves (darker curves in black and white).

dataset, the training bags are generated by mapping Wikipedia (<http://en.wikipedia.org>) infoboxes (after merging similar types following the KBP 2011 task definition) into a large unlabeled corpus (consisting of 1.5M documents from the KBP source corpus and a complete snapshot of Wikipedia). The KBP shared task provided 200 query named entities with their associated slot values (in total several thousand pairs). We use 40 queries as development dataset (*dev*), and the rest (160 queries) as evaluation dataset. We set $\theta = 0.25$ by tuning on the *dev* set and use it in the experiments. For a fair comparison, we follow Surdeanu et al. (2012) and begin by downsampling the “negative” class to 5%. We also set T=8 and use the following noisy-or (for i th bag) of mention-level probability to rank predicted types (r) of pairs and plot the precision-recall curves for all experiments.

$$\text{Prob}_i(r) = 1 - \prod_j (1 - p(z_{ij} = r | \mathbf{x}_{ij}; \mathbf{w}_z))$$

Evaluation: We compare our algorithm (*MIML-semi*) to three algorithms: 1) *MIML* (Surdeanu et al., 2012), the Multiple-Instance Multiple Label algorithm which labels the bags directly with the KB ($y = \ell$). 2) *MultiR* (denoted as *Hoffmann*) (Hoffmann et al., 2011), a Multiple-Instance algorithm that supports overlapping relations. It also imposes $y = \ell$. 3) *Mintz++* (Surdeanu et al., 2012), a variant of the single-instance learning algorithm (section 3). The first two are stat-of-the-art Multi-Instance Multi-Label algorithms. *Mintz++* is a strong baseline (Surdeanu et al., 2012) and an improved version of Mintz et al. (2009). Figure 2 shows that our algorithm consistently outperforms all three al-

gorithms at almost all recall levels (with the exception of a very small region in the PR-curve). This demonstrates that by treating unlabeled data set differently and leveraging the missing positive bags, *MIML-semi* is able to learn a more accurate model for extraction. Although the proposed solution is a specific algorithm, we believe the idea of treating unlabeled data differently can be incorporated into any of these algorithms that only use unlabeled data as negative examples.

6 Conclusion

We show that the distant-supervision labeling process generates a significant number of false negatives because the knowledge base is incomplete. We proposed an algorithm that learns from only positive and unlabeled bags. Experimental results demonstrate its advantage over existing algorithms.

Abstract

In this paper, we propose a novel Rhetorical Structure Index (RSI) to measure the structural importance of a word or a phrase. Unlike TF-IDF and other content-driven measurements, RSI identifies words or phrases that are structural cues in an unstructured document. We show structurally motivated features with high RSI values are more useful than content-driven features for applications such as segmenting unstructured lecture transcripts into meaningful segments. Experiments show that using RSI significantly improves the segmentation accuracy compared to TF-IDF, a traditional content-based feature weighting scheme.

1 Introduction

Online learning, a new trend in distance learning, provides numerous lectures to students all over the world. More than 19,000 colleges offer thousands of free online lectures¹. Starting from video recordings of lectures which sometimes also come with the presentation material, a set of processes can be applied to extract information from the unstructured data to assist students in browsing, searching and understanding the content of the lecture. These processes include *automatic speech recognition* (ASR) which converts the audio to text, *lecture segmentation* which inserts paragraph boundaries and adds section titles to the lecture transcriptions, *automatic summarization* that generates a short summary from

the full lecture, and *lecture translation* that translates the lecture from the original language to the native language of the student.

The transcription of a lecture generated by the ASR system is a sequence of words which does not contain any *structural* information such as paragraph, section boundaries and section titles. Zhang et al. (2007; 2008; 2010) used acoustic and linguistic features for rhetorical structure detection and summarization. They showed that linguistic features such as TF-IDF are the most influential in segmentation and summarization and that knowing the structure of a lecture can significantly improve the performance of lecture summarization. Our experiments with a real-time lecture translation system also show that displaying the rolling translation results of a live lecture with proper paragraphing and inserted section titles makes it easier for students to grasp the key points during a lecture.

In this paper, we apply existing algorithms, namely the Hidden Markov Model (HMM) (Gales and Young, 2007) to unstructured lecture transcription to infer the underlying structure for better lecture segmentation and summarization. HMM has been successfully applied in early works (van Mulbregt et al., 1998; Sherman and Liu, 2008) for text segmentation, event tracking and boundary detection. The focus of this work is to identify cue words and phrases that are good indicators of lecture structure. Intuitively, words and phrases such as “last week we talked about”, “this is an outline of my talk”, “now I am going to talk about”, “in conclusion”, and “any questions” should be important features to recognize lecture structure.

¹[http://www.thebestcolleges.org/
free-online-classes-and-course-lectures/](http://www.thebestcolleges.org/free-online-classes-and-course-lectures/)

These words/phrases, however, may not be so important content-wise. Thus, content-driven metrics such as the TF-IDF score usually do not assign higher weights to these structurally important words/phrases. We propose a novel metric called Rhetorical Structural Index (RSI) to weigh words/phrases based on their structural importance.

2 Rhetorical Structural Index

RSI incorporates both frequency of occurrences and, more importantly, the position distribution of occurrences of a word/phrase. The intuition is that if a term is a structural marker, it usually occurs at a certain *position* in a lecture. Because the term is mainly about the structure rather than the content of a lecture, it can appear with high *frequency* in lectures that are of different topics. For example, “today we” occurs at the beginning of a lecture and “thank you” usually appears towards the end (Figure 1) no matter whether the lecture is about history or computer science.

We define the RSI of a word w as:

$$\text{RSI}(w) = \frac{1}{\lambda \text{Var}(L_w) + (1 - \lambda) \text{idf}(w, D)} \quad (1)$$

where L_w is the random variable of “normalized positions” of a word w in a lecture. For each occurrence of w in a particular lecture d , we divide its position by the length of the lecture $|d|$ to estimate its “normalized position”. L_w takes a value between $[0, 1]$. A value close to 0 indicates this word occurs at the beginning and close to 1 means w is close to the end of the lecture. $\text{Var}(L_w)$ is the variance of the normalized position of a word w . A small $\text{Var}(L_w)$ indicates that w always occurs at certain positions of a typical lecture (e.g., “bye”) while a large value means w can occur at any position (e.g., function words “of” and “the”).

The second part of RSI is the *inverse document frequency* (idf), or effectively the document frequency since RSI is proportional to the $1/\text{idf}$ term. Lectures, such as different research talks, can vary in content but usually have a very similar structure and share some common structural cues. A good structural cue word should be common to many lectures. idf has been widely used in information retrieval research to assign higher weights to words that occur in just a few documents as compared to

Table 1: Examples of n -grams with high RSI values which are likely to be structural cues.

n -gram	$\text{Var}(L_w)$	idf	RSI
now	0.0004	0.60	1.04
here	0.0004	0.62	1.03
class	0.0001	2.12	0.90
week	0.0001	2.23	0.89
goodbye	0.0001	3.62	0.80
thank you	0.0003	1.53	0.95
talk about	0.0003	1.90	0.92
dealing with	0.0002	2.00	0.91
today we	0.0003	2.51	0.87
see how	0.0009	2.69	0.85
ladies and gentlemen	0.0008	1.35	0.96
last time we	0.0004	2.22	0.89
here we have	0.0005	2.35	0.88
next time we	0.0002	2.51	0.86

common words that occur in all documents. Define the idf of a word w given a collection of lectures D as:

$$\text{idf}(w, D) = \log \frac{|D|}{|\{d \in D | w \in d\}|} \quad (2)$$

$|D|$ is the number of all lectures in the collection and $|\{d \in D | w \in d\}|$ is the number of lectures where w appears. A low $\text{idf}(w, D)$ value indicates that word w occurs in many documents and thus is more likely to be a common structural cue.

Combining the variance of normalized position and idf by scaling factor λ , we define RSI as in equation 1. We found 0.9 as an optimal value of λ according our experiments over all data sets. A word w with high RSI value is more likely to be structurally important. Similarly, we can calculate the RSI values for phrases (n -grams) such as “I would like to talk about”, “I will switch gear to” and “thank you for your attention”.

Table 1 shows examples of n -grams and the calculated variance, idf-scores and RSI values from a collection of lectures.

3 Incorporating RSI in Lecture Segmentation

Several algorithms have been developed for text segmentation including the Naive Bayes classifier for keyword extraction (Balagopalan et al., 2012), the

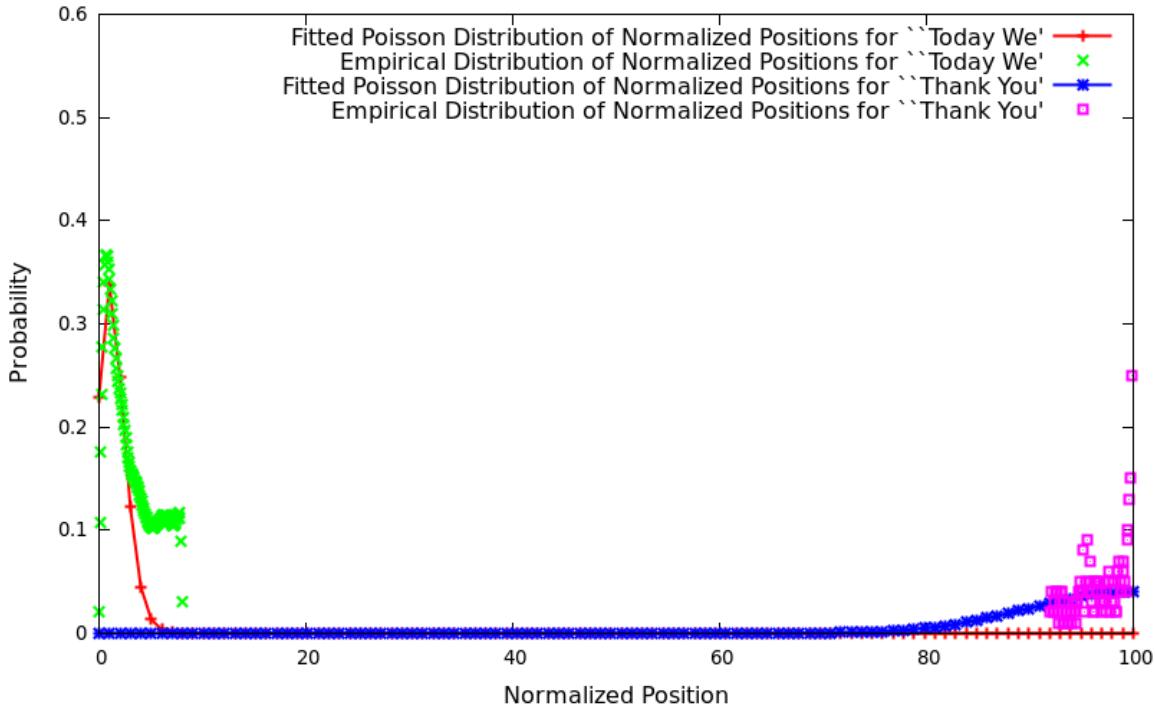

Figure 1: Fitted Poisson-distribution of normalized positions in lectures for the bigrams “today we” and “thank you”. “today we” appears more frequently at the beginning of a lecture, whereas “thank you” more in the concluding part of a lecture. The x-axis is the normalized word position in a lecture and y-axis is the probability of seeing the word at a position.

Hidden Markov Model (Gales and Young, 2007), the Maximum entropy Markov model (McCallum et al., 2000), the Conditional Random Field (Lafferty et al., 2001) and the Latent Content Analysis (Ponte and Croft, 1997). In this paper, we evaluate the effectiveness of the proposed RSI feature on lecture segmentation using an HMM.

We represent each segment in a lecture as a state in the Markov model and use the EM algorithm to learn HMM parameters from unlabeled lecture data. We use a fully connected HMM with five states. Typical state labels for lecture are: “Introduction”, “Background”, “Main Topic”, “Questions” and “Conclusion” as shown in Figure 2. HMM states emit word tokens. Instead of considering the full vocabulary as the possible emission alphabet, which usually leads to model over-fitting, we only consider terms with high RSI values and high TF-IDF* scores for comparison. For a word w , define its TF-IDF* score as:

$$\text{TF-IDF}^*(w) = \max_d \text{TF-IDF}(w, d), \quad (3)$$

which is the highest TF-IDF score of a word in any document in the collection. Our experiments try to answer the question that “if HMM is meant to capture the underlying structure of lectures no matter which topic the lecture is about, what kind of features should be emitted from each state to reflect such structural patterns among lectures?”

The learned HMM model is then applied to unseen lecture data to label each sentence to be “Introduction”, “Background”, “Main Topic”, “Questions” or “Conclusion” and, based on the label, we segment the lecture to different sections for evaluation. Segment boundaries are defined in the positions where sentence labels change.

3.0.1 Bootstrap HMM from K-Means Clustering Segmentation

Initial HMM parameters are bootstrapped using results from K-means clustering where we cluster a sequence of sentences to form a “segment”. K corresponds to the number of desired segments of a lecture. Similarities are computed based on the content similarity (using n-gram matches) and the relative

sentence position defined as:

$$Sim(S_i, C_j) = \alpha M(S_i, C_j) + (1 - \alpha)P(S_i, C_j), \quad (4)$$

where S_i is the i -th sentence, C_j is the centroid of the j -th cluster. $M(S_i, C_j)$ is the content similarity between sentence S_i and centroid C_j and $P(S_i, C_j)$ is the position similarity (distance). α is a scaling factor (set to optimal value 0.2 based on all data sets in our experiments).

Content similarity is based on the number of common words between two sentences, or between a sentence and the centroid vector of a cluster. Denote the binary word frequency vector (bag of words) in sentence S_i as \vec{S}_i and similarly \vec{C}_j for cluster centroid C_j , define:

$$M(S_i, C_j) = \frac{\vec{S}_i \cdot \vec{C}_j}{\|\vec{S}_i\| \|\vec{C}_j\|}. \quad (5)$$

$P(S_i, C_j)$ measures the position similarity of two sentences. Position similarity is based on the relative position distance between the sentence and the cluster: Define

$$P(S_i, C_j) = \frac{L}{|\text{Pos}(S_i) - \text{Pos}(C_j)| + \epsilon}, \quad (6)$$

where S_i is the i -th sentence, C_j is the j -th cluster. $\text{Pos}(S_i)$ is the position of sentence S_i . $\text{Pos}(C_j)$ is the average sentence position of all members belonging to cluster C_j and L is the total number of sentences in a lecture. ϵ is a small constant to avoid division by zeros.

4 Experiments and Evaluation

We evaluated segmentation on three different data sets: college lectures recorded by Karlsruhe Institute of Technology (KIT), Microsoft research (MSR) lectures² and scientific papers³. Both college and Microsoft research lectures are manually transcribed. The reason why we do not include experiments on ASR output is that current ASR quality of lecture data is still quite poor. Word-Error-Rates (WER) of ASR output range from 24.37 to 30.80 for KIT lectures. Roughly speaking, every one out of 3 or 4 words is mis-recognized.

²<http://research.microsoft.com/apps/catalog/>

³<http://aclweb.org/anthology-new/>

For evaluation, human annotators annotated a few lectures to create test/reference sets. The test data from KIT is annotated by one human annotator and MSR lectures are annotated by four annotators. The segmentation gold standard is created based on the agreed annotations. Since the number of annotated lectures is small and human annotation is subjective, we also used ACL papers as an additional data set. ACL papers are in a way “lectures in written form” and have titles for section and subsections which can be used to identify the segments and annotate the data set automatically. The statistics of each data set are listed in Table 2.

Table 2: Statistics of three data sets used in the experiments: our own lecture data (KIT), Microsoft research talks (MSR) and conference proceedings from ACL anthology archive. We removed equations, short titles such as “Abstract” and “Conclusion”, when extracting text from PDF files from the ACL anthology, which results in a relatively small number of words per paper. Words are simply tokenized without case normalization or stemming, which results in relatively large vocabulary sizes.

Properties	KIT	MSR	ACL
Num.	74	1,182	3,583
Avg. Num. of Sent.	484	655	212
Avg. Num. of Words	10,078	10,225	3,896
Avg. Duration (Min.)	43.57	39.15	-
Vocabulary Size	1.3K	22K	24K

First, we calculate the RSI and TF-IDF* scores for each word in the dataset and choose the top N words as the HMM emission vocabulary. To avoid over-fitting, we choose N that is much smaller than the full vocabulary size of the data set. In our experiments, we set N=300 for KIT, N=5000 for MSR and N=5400 for ACL. The top 5 words with the highest TF-IDF* scores from the MSR data set are: “RFID”, “Cherokee”, “tree-to-string”, “GPU”, and “data-triggered”, whereas the top 5 words selected by RSI are “today”, “work”, “question”, “now”, and “thank”, which are more structurally informative.

To estimate the accuracy of the segmentation module, we used Recall, Precision, F-Measure and P_k (Beeferman et al., 1999) as evaluation metric. We used an error window of length 6 to calculate Precision, Recall and F-Measure and a sliding window with a length equal to half of the average seg-

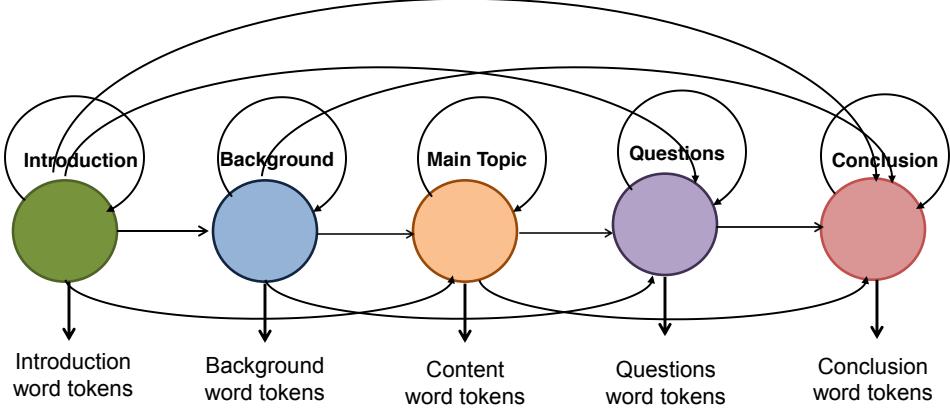

Figure 2: Fully connected 5-state HMM representing *Introduction*, *Background*, *Main Topic*, *Questions*, *Conclusion* in a typical lecture.

ment length to estimate the P_k score. With error window we mean that hypothesis boundaries do not have to be exactly the same as the reference segment boundaries. Hypothesis boundaries are acceptable if they are close enough to reference boundaries in that window. The P_k score indicates the probability of segmentation inconsistency. Therefore, the lower the P_k score the better the segmentation is.

Table 3: Segmentation results measured by P_k (the smaller the better), Precision, Recall and F-Measure scores (the higher the better) for three data sets comparing HMM using TF-IDF*-filtered word tokens as emission and RSI-filtered words as emissions.

Evaluation Score	KIT	MSR	ACL
P_k			
HMM + TF-IDF*	0.06	0.06	0.05
HMM + RSI	0.01	0.02	0.01
Precision			
HMM + TF-IDF*	32.01	30.47	32.85
HMM + RSI	41.10	41.01	42.70
Recall			
HMM + TF-IDF*	39.32	36.09	38.08
HMM + RSI	47.38	46.39	48.95
F-Measure			
HMM + TF-IDF*	35.29	33.04	35.27
HMM + RSI	44.01	43.53	45.61

The evaluation results on all data sets listed in Table 3 show that according F-Measure and P_k scores, considering words with high RSI values as

HMM emission significantly improve over the baseline method of choosing word tokens with high TF-IDF* scores.

5 Conclusions

In this work we propose the Rhetorical Structure Index (RSI), a method to identify structurally important terms in lectures. Experiments show that terms with high RSI values are better candidates than those with high TF-IDF values when used by an HMM-based segmenter as state emissions. In other words, terms with high RSI values are more likely to be structural cues in lectures independent of the lecture topic. In the future we will run experiments on ASR output and incorporate other prosodic features such as pitch, intensity, duration into the RSI to improve this metric for structural analysis of lectures and apply the RSI to other structure discovery applications such as dialogue segmentation.

Separating Fact from Fear: Tracking Flu Infections on Twitter

Alex Lamb, Michael J. Paul, Mark Dredze

Human Language Technology Center of Excellence

Department of Computer Science

Johns Hopkins University

Baltimore, MD 21218

{alamb3, mpaul19, mdredze}@jhu.edu

Abstract

Twitter has been shown to be a fast and reliable method for disease surveillance of common illnesses like influenza. However, previous work has relied on simple content analysis, which conflates flu tweets that report infection with those that express concerned awareness of the flu. By discriminating these categories, as well as tweets about the authors versus about others, we demonstrate significant improvements on influenza surveillance using Twitter.

1 Introduction

Twitter is a fantastic data resource for many tasks: measuring political (O’Connor et al., 2010; Tumasjan et al., 2010), and general sentiment (Bollen et al., 2011), studying linguistic variation (Eisenstein et al., 2010) and detecting earthquakes (Sakaki et al., 2010). Similarly, Twitter has proven useful for public health applications (Dredze, 2012), primarily disease surveillance (Collier, 2012; Signorini et al., 2011), whereby public health officials track infection rates of common diseases. Standard government data sources take weeks while Twitter provides an immediate population measure.

Strategies for Twitter influenza surveillance include supervised classification (Culotta, 2010b; Culotta, 2010a; Eiji Aramaki and Morita, 2011), unsupervised models for disease discovery (Paul and Dredze, 2011), keyword counting¹, tracking geographic illness propagation (Sadilek et al., 2012b), and combining tweet contents with the social network (Sadilek et al., 2012a) and location informa-

tion (Asta and Shalizi, 2012). All of these methods rely on a relatively simple NLP approach to analyzing the tweet content, i.e. n -gram models for classifying related or not related to the flu. Yet examining flu tweets yields a more complex picture:

- going over to a friends house to check on her son. he has the flu and i am worried about him
- Starting to get worried about swine flu...

Both are related to the flu and express worry, but tell a different story. The first reports an infection of another person, while the second expresses the author’s concerned awareness. While infection tweets indicate a rise in infection rate, awareness tweets may not. Automatically making these distinctions may improve influenza surveillance, yet requires more than keywords.

We present an approach for differentiating between flu infection and concerned awareness tweets, as well as self vs other, by relying on a deeper analysis of the tweet. We present our features and demonstrate improvements in influenza surveillance.

1.1 Related Work

Much of the early work on web-based influenza surveillance relied on query logs and click-through data from search engines (Eysenbach, 2006), most famously Google’s Flu Trends service (Ginsberg et al., 2008; Cook et al., 2011). Other sources of information include articles from the news media and online mailing lists (Brownstein et al., 2010).

2 Capturing Nuanced Trends

Previous work has classified messages as being related or not related to influenza, with promising surveillance results, but has ignored nuanced differences between flu tweets. Tweets that are related to

¹The DHHS competition relied solely on keyword counting.
<http://www.nowtrendingchallenge.com/>

flu but do not report an infection can corrupt infection tracking.

Concerned Awareness vs. Infection (A/I) Many flu tweets express a concerned awareness as opposed to infection, including fear of getting the flu, an awareness of increased infections, beliefs related to flu infection, and preventative flu measures (e.g. flu shots.) Critically, these people do not seem to have the flu, whereas infection tweets report having the flu. This distinction is similar to modality (Prabhakaran et al., 2012a). Conflating these tweets can hurt surveillance, as around half of our annotated flu messages were awareness. Identifying awareness tweets may be of use in-and-of itself, such as for characterizing fear of illness (Epstein et al., 2008; Epstein, 2009), public perception, and discerning sentiment (e.g. flu is negative, flu shots may be positive.) We focus on surveillance improvements.²

Self vs. Other (S/O) Tweets for both awareness and infection can describe the author (self) or others. It may be that self infection reporting is more informative. We test this hypothesis by classifying tweets as self vs. other.

Finding Flu Related Tweets (R/U) We must first identify messages that are flu related. We construct a classifier for flu related vs. unrelated.

3 Features

Token sequences (n -grams) are an insufficient feature set, since our classes share common vocabularies. Consider,

- A little worried about the swine flu epidemic!
- Robbie might have swine flu. I'm worried.

Both tweets mention flu and worried, which distinguish them as flu related but not specifically awareness or infection, nor self or other. Motivated by Bergsma et al. (2012), we complement 3-grams with additional features that capture longer spans of text and generalize using part of speech tags. We begin by processing each tweet using the ARK POS tagger (Gimpel et al., 2011) and find phrase segmentations using punctuation tags.³ Most phrases were two (31.2%) or three (26.6%) tokens long.

²While tweets can both show awareness and report an infection, we formulate a binary task for simplicity since only a small percentage of tweets were so labeled.

³We used whitespace for tokenization, which did about the same as Jerboa (Van Durme, 2012).

Class Name	Words in Class
Infection	getting, got, recovered, have, having, had, has, catching, catch, cured, infected
Possession	bird, the flu, flu, sick, epidemic
Concern	afraid, worried, scared, fear, worry, nervous, dread, dreaded, terrified
Vaccination	vaccine, vaccines, shot, shots, mist, tamiflu, jab, nasal spray
Past Tense	was, did, had, got, were, or verb with the suffix “ed”
Present Tense	is, am, are, have, has, or verb with the suffix “ing”
Self	I, I've, I'd, I'm, im, my
Others	your, everyone, you, it, its, u, her, he, she, he's, she's, she, they, you're, she'll, he'll, husband, wife, brother, sister, your, people, kid, kids, children, son, daughter

Table 1: Our manually created set of word class features.

Word Classes For our task, many word types can behave similarly with regard to the label. We create word lists for possessive words, flu related words, fear related words, “self” words, “other” words, and fear words (Table 1). A word’s presence triggers a count-based feature corresponding to each list.

Stylometry We include Twitter-specific style features. A feature is included for retweet, hashtags, and mentions of other users. We include a feature for emoticons (based on the emoticon part-of-speech tag). We include a more specific feature for positive emoticons (:) :D :)). We also include a feature for negative emoticons (:(:(:/). Additionally, we include a feature for links to URLs.

Part of Speech Templates We include features based on a number of templates matching specific sequences of words, word classes, and part of speech tags. Where any word included in the template matches a word in one of the word classes, an additional feature is included indicating that the word class was included in that template.

- Tuples of (subject,verb,object) and pairs of (subject, verb), (subject, object), and (verb, object). We use a simple rule to construct these tuples: the first noun or pronoun is taken as the subject, and the first verb appearing after the subject is taken as the verb. The object is taken as any noun or pronoun that appears before a verb or at the end of a phrase.

- A pairing of the first pronoun with last noun. These are useful for S/O, e.g. *I am worried that my son has the flu* to recognize the difference between the author (I) and someone else.
- Phrases that begin with a verb (pro-drop). This is helpful for S/O, e.g. *getting the flu!* which can indicate self even without a self-related pronoun. An additional feature is included if this verb is past-tense.
- Numeric references. These often indicate awareness (number of people with the flu) and are generally not detected by an n-gram model. We add a separate feature if the word following has the root “died”, e.g. *So many people dying from the flu, I'm scared!*
- Pair of first pronoun/noun with last verb in a phrase. Many phrases have multiple verbs, but the last verb is critical, e.g. *I had feared the flu*. Additional features are added if the noun/pronoun is in the “self” or “other” word class, and if the verb is in the “possessive” word class.
- Flu appears as a noun before first verb in a phrase. This indicates when flu is a subject, which is more likely to be about awareness.
- Pair of verb and following noun. This indicates the verbs object, which can change the focus of A/I, e.g., *I am getting a serious case of the flu* vs. *I am getting a flu shot*. Additional features are added if the verb is past tense (based on word list and suffix “-ed”).
- Whether a flu related word appears as a noun or an adjective. When flu is used as an adjective, it may indicate a more general discussion of the flu, as opposed to an actual infection *I hate this flu* vs. *I hate this flu hype*.
- If a proper noun is followed by a possessive verb. This may indicate others for the S/O task *Looks like Denmark has the flu*. An additional feature fires for any verb that follows a proper noun and any past tense verb that follows a proper noun.
- Pair each noun with “?”. While infection tweets are often statements and awareness questions, the subject matters, e.g. *Do you think that swine flu is coming to America?* as awareness. An equivalent feature is included for phrases ending with “!”.

While many of our features can be extracted using a syntactic parser (Foster et al., 2011), tweets are very short, so our simple rules and over-generating features captures the desired effects without parsing.

	Self	Other	Total
Awareness	23.15%	24.07%	47.22%
Infection	37.21%	15.57%	52.78%
Total	60.36%	39.64%	

Table 2: The distribution over labels of the data set. Infection tweets are more likely to be about the author (self) than those expressing awareness.

3.1 Learning

We used a log-linear model from Mallet (McCallum, 2002) with L_2 regularization. For each task, we first labeled tweets as related/not-related and then classified the related tweets as awareness/infection and self/others. We found this two phase approach worked better than multi-class.

4 Data Collection

We used two Twitter data sets: a collection of 2 billion tweets from May 2009 and October 2010 (O’Connor et al., 2010)⁴ and 1.8 billion tweets collected from August 2011 to November 2012. To obtain labeled data, we first filtered the data sets for messages containing words related to concern and influenza,⁵ and used Amazon Mechanical Turk (Callison-Burch and Dredze, 2010) to label tweets as concerned awareness, infection, media and unrelated. We allowed multiple categories per tweet. Annotators also labeled awareness/infection tweets as self, other or both. We included tweets we annotated to measure Turker quality and obtained three annotations per tweet. More details can be found in Lamb et al. (2012).

To construct a labeled data set we removed low quality annotators (below 80% accuracy on gold tweets.) This seemed like a difficult task for annotators as a fifth of the data had no annotations after this step. We used the majority label as truth and ties were broken using the remaining low quality annotators. We then hand-corrected all tweets, changing 13.5% of the labels. The resulting data set contained 11,990 tweets (Table 2), 5,990 from 2011-2012 for training and the remaining from 2009-2010 as test.⁶

⁴This coincided with the second and larger H1N1 (swine flu) outbreak of 2009; swine flu is mentioned in 39.6% of the annotated awareness or infection tweets.

⁵e.g. “flu”, “worried”, “worry”, “scared”, “scare”, etc.

⁶All development was done using cross-validation on training data, reserving test data for the final experiments.

Feature Removed	A/I	S/O
<i>n</i> -grams	0.6701	0.8440
Word Classes	0.7735	0.8549
Stylometry	0.8011	0.8522
Pronoun/Last Noun	0.7976	0.8534
Pro-Drop	0.7989	0.8523
Numeric Reference	0.7988	0.8530
Pronoun/Verb	0.7987	0.8530
Flu Noun Before Verb	0.7987	0.8526
Noun in Question	0.8004	0.8534
Subject, Object, Verb	0.8005	0.8541

Table 3: F1 scores after feature ablation.

5 Experiments

We begin by evaluating the accuracy on the binary classification tasks and then measure the results from the classifiers for influenza surveillance. We created precision recall curves on the test data (Figure 1), and measured the highest F1, for the three binary classifiers. For A/I and S/O, our additional features improved over the *n*-gram baselines. We performed feature ablation experiments (Table 3) and found that for A/I, the word class features helped the most by a large margin, while for S/O the stylometry and pro-drop features were the most important after *n*-grams. Interestingly, S/O does equally well removing just *n*-gram features, suggesting that the S/O task depends on a few words captured by our features.

Since live data will have classifiers run in stages – to filter out not-related tweets – we evaluated the performance of two-staged classification. F1 dropped to 0.7250 for A/I and S/O dropped to 0.8028.

5.1 Influenza surveillance using Twitter

We demonstrate how our classifiers can improve influenza surveillance using Twitter. Our hypothesis is that by isolating infection tweets we can improve correlations against government influenza data. We include several baseline methods:

Google Flu Trends: Trends from search queries.⁷

Keywords: Tweets that contained keywords from the DHHS Twitter surveillance competition.

ATAM: We obtained 1.6 million tweets that were automatically labeled as influenza/other by ATAM

Data	System	2009	2011
Twitter	Google Flu Trends	0.9929	0.8829
	ATAM	0.9698	0.5131
	Keywords	0.9771	0.6597
	All Flu	0.9833	0.7247
	Infection	0.9897	0.7987
	Infection+Self	0.9752	0.6662

Table 4: Correlations against CDC ILI data: Aug 2009-Aug 2010, Dec 2011 to Aug 2012.

(Paul and Dredze, 2011). We trained a binary classifier with *n*-grams and marked tweets as flu infection.

We evaluated three trends using our three binary classifiers trained with a reduced feature set close to the *n*-gram features:⁸

All Flu: Tweets marked as flu by Keywords or ATAM were then classified as related/unrelated.⁹ This trend used all flu-related tweets.

Infection: Related tweets were classified as either awareness or infection. This used infection tweets.

Infection+Self: Infection were then labeled as self or other. This trend used self tweets.

All five of these trends were correlated against data from the Centers for Disease Control and Prevention (CDC) weekly estimates of influenza-like illness (ILI) in the U.S., with Pearson correlations computed separately for 2009 and 2011 (Table 4).¹⁰ Previous work has shown high correlations for 2009 data, but since swine flu had so dominated social media, we expect weaker correlations for 2011.

Results are show in Table 4 and Figure 2 shows two classifiers against the CDC ILI data. We see that in 2009 the Infection curve fits the CDC curve very closely, while the All Flu curve appears to substantially overestimate the flu rate at the peak. While 2009 is clearly easier, and all trends have similar correlations, our Infection classifier beats the other Twitter methods. All trends do much worse in

⁸Classifiers trained on 2011 data and thresholds selected to maximize F1 on held out 2009 data.

⁹Since our data set to train related or unrelated focused on tweets that appeared to mention the flu, we first filtered out obvious non-flu tweets by running ATAM and Keywords.

¹⁰While the 2009 data is a 10% sample of Twitter, we used a different approach for 2011. To increase the amount of data, we collected Tweets mentioning health keywords and then normalized by the public stream counts. For our analysis, we excluded days that were missing data. Additionally, we used a geolocator based on user provided locations to exclude non-US messages. See (Dredze et al., 2013) for details and code for the geolocator.

⁷<http://www.google.org/flutrends/>

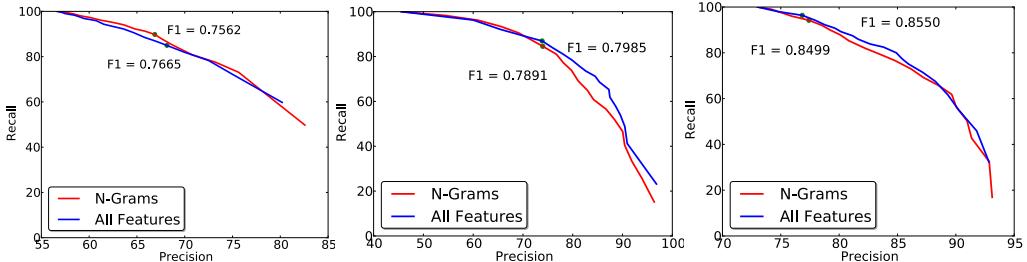

Figure 1: Left to right: Precision-recall curves for related vs. not related, awareness vs. infection and self vs. others.

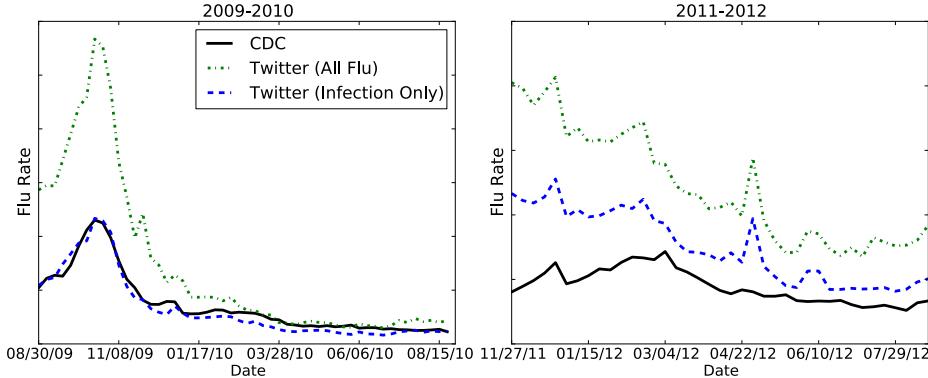

Figure 2: The Twitter flu rate for two years alongside the ILI rates provided by the CDC. The y-axes are not comparable between the two years due to differences in data collection, but we note that the 2011-12 season was much milder.

the 2011 season, which was much milder and thus harder to detect. Of the Twitter methods, those using our system were dramatically higher, with the Infection curve doing the best by a significant margin. Separating out infection from awareness (A/I) led to significant improvements, while the S/O classifier did not, for unknown reasons.

The best result using Twitter reported to date has been by Doan et al. (2012), whose best system had a correlation of 0.9846 during the weeks beginning 8/30/09–05/02/10. Our Infection system had a correlation of 0.9887 during the same period. While Google does better than any of the Twitter systems, we note that Google has access to much more (proprietary) data, and their system is trained to predict CDC trends, whereas our Twitter system is intrinsically trained only on the tweets themselves.

Finally, we are also interested in daily trends in addition to weekly, but there is no available evaluation data on this scale. Instead, we computed the stability of each curve, by measuring the day-to-day changes. In the 2009 season, the relative increase or decrease from the previous day had a variance of 3.0% under the Infection curve, compared to 4.1% under ATAM and 6.7% under Keywords.

6 Discussion

Previous papers have implicitly assumed that flu-related tweets mimick the infection rate. While this was plausible on 2009 data that focused on the swine flu epidemic, it is clearly false for more typical flu seasons. Our results show that by differentiating between types of flu tweets to isolate reports of infection, we can recover reasonable surveillance. This result delivers a promising message for the NLP community: deeper content analysis of tweets matters. We believe this conclusion is applicable to numerous Twitter trend tasks, and we encourage others to investigate richer content analyses for these tasks. In particular, the community interested in modeling author beliefs and influence (Diab et al., 2009; Prabhakaran et al., 2012b; Biran and Rambow, 2011) may find our task and data of interest. Finally, beyond surveillance, our methods can be used to study disease awareness and sentiment, which has implications for how public health officials respond to outbreaks. We conclude with an example of this distinction. On June 11th, 2009, the World Health Organization declared that the swine flu had become a global flu pandemic. On that day, flu awareness increased 282%, while infections increased only 53%.

Differences in User Responses to a Wizard-of-Oz versus Automated System

litman@cs.pitt.edu

Abstract

Wizard-of-Oz experimental setup in a dialogue system is commonly used to gather data for informing an automated version of that system. Previous work has exposed dependencies between user behavior towards systems and user belief about whether the system is automated or human-controlled. This work examines whether user behavior changes when user belief is held constant and the system’s operator is varied. We perform a post-hoc experiment using generalizable prosodic and lexical features of user responses to a dialogue system backed with and without a human wizard. Our results suggest that user responses are different when communicating with a wizarded and an automated system, indicating that wizard data may be less reliable for informing automated systems than generally assumed.

1 Introduction

In a Wizard-of-Oz (WOZ) experimental setup, some or all of the automated portions of a dialogue system are replaced with a hidden, human evaluator. This setup is often used to gather data from users who believe they are interacting with an automated system (Wolska et al., 2004; Andrews et al., 2008; Becker et al., 2011). This data can inform a downstream, real automated system. A WOZ experimental protocol calls for holding “all other input and output ... constant so that the only unknown variable is who does the internal processing” (Paek, 2001). Thus, hiding the human wizard’s input by layers of

system interface can render that system believably automated.

An assumption of this WOZ data-gathering strategy is that user behavior will not vary substantially between the WOZ and automated (AUT) experimental setups. However, it was shown in a dialogue system that training with a small set of data from an automated system gave rise to better performance than training with a large set of data from an analogous wizarded system (Drummond and Litman, 2011). There, it was suggested that differences in system automation may be responsible for the performance gap. It is possible that user responses to these dialogue systems differed substantially.

This paper aims to investigate this possibility by comparing data between a wizarded and automated version of a tutoring dialogue system. We hypothesize that what users say and how they say it will differ when the only change is whether the system’s speech recognition and correctness evaluation components are wizarded or automated.

2 Dialogue System

The data for this study is provided by the baseline conditions (one wizarded (WOZ) and one automated (AUT)) of two prior experiments with a spoken tutorial dialogue system. Users of this system were students recruited at our university, and each was a native speaker of American English. Users were novices and were tutored in basic Newtonian physics by the system. Each was engaged by a set of dialogues that illustrated one or more basic physics concepts. Those dialogues included remedial sub-dialogues that were accessed when the users pro-

Tutor: So what are the forces acting on the packet after it's dropped from the plane?
Student: um gravity then well air resistance is negligible just gravity
Tutor: Fine. So what's the direction of the force of gravity on the packet?
Student: vertically down

Figure 1: Tutor text is shown on a screen and read aloud via text-to-speech. The user responds verbally to the tutor’s queries.

vided incorrect or off-topic answers. These prior experiments were examining the effects of system adaptation in response to detected student uncertainty (Forbes-Riley and Litman(a), 2011; Forbes-Riley and Litman(b), 2011). However, in this study we consider only the baseline, non-adaptive conditions of those experiments. Figure 1 shows a sample dialogue excerpt between the student and tutor.

In the baseline conditions of the WOZ and AUT system past experiments, as shown in Figure 2, the setups varied only by the system component responsible for understanding and evaluating a user’s verbal response. Each student participated in only one of the two setups, and students were not informed when the system was wizarded. In the WOZ setup a human wizard marked student responses to prompts as correct or incorrect. In the AUT setup, automatic speech recognition was performed on student responses¹, and (in)correctness of answers was determined using natural language understanding models trained from the WOZ experiment’s data.

3 Post-Hoc Experiment

Using both lexical and prosodic features, we aimed to determine whether there exist significant differences in users’ turn-level responses to the WOZ and AUT systems.

It was suspected that the imperfect accuracy² (87%) of the AUT system’s evaluations of the (in)correctness of user responses may have led to remedial sub-dialogues being accessed by the AUT system more often, since false-negatives accounted

¹The average word-error rate for these AUT responses was 19%.

²Agreement of $\kappa = 0.7$ between the system and human.

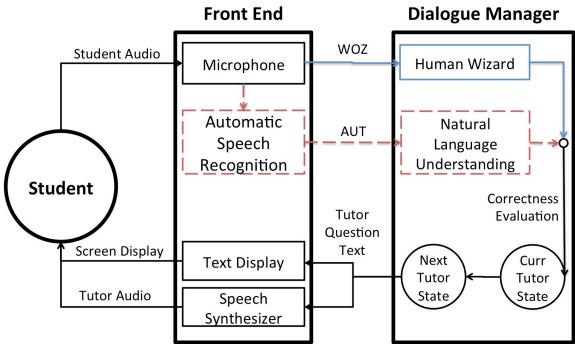

Figure 2: The workflow of the tutoring dialogue system with the WOZ setup component shown in solid, blue and the AUT setup component shown in dashed, red.

System	#Users	#Qu	#Turns
WOZ	21	111	1542
AUT	25	111	2034

Table 1: Counts for users, unique questions, and user turns in each data set.

for 72% of inaccurate evaluations. To correct for this imbalance, rather than comparing user responses to all questions, we compared the features of user responses (turns) to each question individually. We omitted questions which were presented in only one setup³ as well as turns for which a human transcriber found no user speech. Table 1 gives the numbers of users, number of unique questions asked, and total number of user responses contained in the remaining data and used in our investigations.

For prosodic features, we considered duration, pitch, and energy (RMS), each extracted using openSMILE (Eyben et al., 2010). From pitch and energy, which contain many samples during a single turn, we extracted features for maximum, minimum, mean, and standard deviation of these readings. We also considered speech duration and the length of the pause before speech began. This gave us a total of 10 prosodic features. To account for any differences in recording environment and users’ voices, we normalized each prosodic feature by dividing its value on each turn by its value in the first turn of the current problem dialogue for that user. This normal-

³There were 3 such questions containing 6 user responses; each question was a remedial sub-dialogue accessed in the AUT but not WOZ setup.

ization scheme was chosen for our analysis because it is used in the live system, though we note that alternative methods considering more user responses could be explored in the future.

For lexical features, we used the *Linguistic Inquiry and Word Count* (LIWC). LIWC (Pennebaker et al., 2001), a word-count dictionary, provides features representing the percentage of words in an utterance falling under particular categories. Though still a counting strategy, these categories capture higher-level concepts than would simple unigrams. For example, one category is *Tentative(T)*, which includes words such as “maybe”, “perhaps”, and “guess”. Less abstract categories, such as *Prepositions(P)*, with words such as “to”, “with”, and “above”, are also generated by LIWC. Using these example categories, the utterance “Maybe above” would receive feature vector:

$$\langle 0, \dots, 0, T = 50, 0, \dots, 0, P = 50, 0, \dots, 0 \rangle \quad (1)$$

Human transcriptions of users’ speech were made available post-hoc for both system versions. We extracted 69 LIWC categories as lexical features from these human transcriptions of each user turn.

Between the WOZ and AUT setups, we looked for user response feature differences in two ways. First, a Welch’s two-tailed t-test was used to compare the distributions of each feature’s values between WOZ and AUT user responses per question. We noted the features found to be significantly different. Second, we built classification models to distinguish between user responses per question from the WOZ and AUT experiments. For each question, a J48⁴ decision tree model was trained and tested using 10-fold cross validation via the Weka⁵ toolkit. Only questions with at least 10 responses between both setups were considered. Each model was compared against majority-class baseline for its respective question by checking for statistically significant differences in the model’s accuracy.

⁴We tried Logistic Regression and Support Vector classifiers but these were consistently outperformed by J48.

4.1 Statistical Comparison of Features

The number of questions for which at least one feature differed statistically significantly was calculated. Since distinct sets of students were involved in the WOZ and AUT setups, it is possible that some of these differences are inherent between the students and not resulting from the presence or absence of a human wizard. To control for this possibility, we assigned students randomly into two new groups (preserving the original class distribution in each new group) and tested for feature differences between these new groups. Table 2 summarizes the differences found by each feature set. We report only questions for which at least one feature differed between WOZ and AUT but not between these two random groups⁶. Table 2 also shows the percentage of turns that those questions comprised in the corpus. Prosodic and lexical features each differ for a substantial portion of the corpus of turns, and when both sets are considered about 67% of the corpus is captured.

Feature set	#Qu	% Corpus by Turns
Prosodic	42	46.22%
Lexical	33	35.46%
Either	61	66.86%

Table 2: Number of questions for which at least one feature from the feature set was found to differ with significance $p < 0.05$ between WOZ and AUT responses and the percentage the corpus represented by those questions, weighted by the speech turns they comprise.

After controlling for possible between-student differences, all 10 prosodic features and 29 out of 69 lexical features differed significantly ($p < 0.05$) for at least one question. Table 3 gives the features which were able to differentiate at least 10% of the corpus by turns.

These t-tests show there exist features which differ for a substantial number of questions between the two experimental setups. Examination of Table

⁶We repeated this random split procedure 10 times and found, after omitting features found significant in any of the 10 splits, that 58.08% of the corpus was still captured. Less than 2% of the turns belonged to questions with at least one feature different through all 10 splits.

Feature	% CbT	#Qu	#W>A
Duration	22.15%	19	1
RMS Min	16.86%	15	14
Dictionary Words	15.13%	13	11
pronoun	12.56%	10	10
social	11.35%	9	8
funct	10.99%	9	9
Six Letter Words	10.91%	9	0

Table 3: Features shown to differ with significance $p < 0.05$ between WOZ and AUT responses in questions comprising at least 10% of the corpus by turns (CbT). The numbers of questions these turns comprised and of questions with greater (W)OZ than (A)UT mean are also given.

Tutor: So how do these two forces' directions compare?
<i>Top two most common responses:</i>
WOZ(9),AUT(2): they are opposite
WOZ(3),AUT(8): opposite
<i>Longest responses per tutor setup:</i>
WOZ Student: the relationship between the two forces' directions are towards each other since the sun is pulling the gravitational force of the earth
AUT Student: they are opposite directions

Figure 3: The tutor question and select user responses to a question for which the *Dictionary Words* feature was greater for WOZ responses.

3 in addition suggests that users used more words with the wizarded system. For example, the fourth row shows that all of the questions showing differences for the LIWC category *pronoun* (the words “they”, “he”, and “it” are popular in this corpus) exposed higher percentage of pronouns in the WOZ utterances. The usual dominance of the third row, *Dictionary Words*, by the WOZ utterances also reflects this trend. Figure 3 gives common and characteristic student responses for each setup on a question for which *Dictionary Words* differed significantly. We next applied machine learning to classify the experiment-of-origin of responses based on these features.

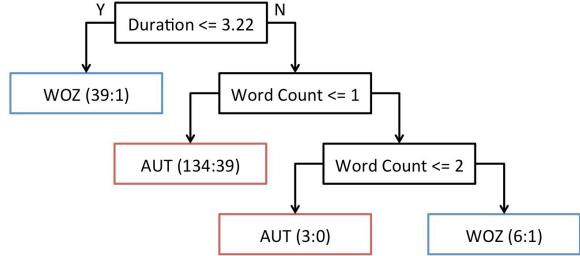

Figure 4: The J48 tree for the question “Would you like to do another problem?”. Classification nodes are marked in blue and red for WOZ and AUT, respectively, and specify (#Instances:#Incorrect).

4.2 Response Classification Experiments

After removing questions with less than 10 responses between the two setups, there remained 97 questions totaling 2980 turns. Of the J48 models built and tested on each question, 21 of 97 outperformed the majority-class baseline accuracies for those questions with significance $p < 0.05$. These 21 questions represented 32.79% of the corpus by turns. We present in detail the two of these 21 questions with the most turns.

The question “Would you like to do another problem?” represented 6.11% of the corpus by turns and the J48 model built for it, shown in Figure 4, outperformed the baseline accuracy with $p < 0.001$. While the *Duration* feature was the root node, a bigger decision was made by *Word Count* ≤ 1 , for which most responses were from AUT data. This result is consistent with literature (Schechtman and Horowitz, 2003; Rosé and Torrey, 2005) that suggests that users interacting with automated systems will be more curt.

The question “Now let’s find the forces exerted on the car in the vertical direction during the collision. First, what vertical force is always exerted on an object near the surface of the earth?” represented 1.54% of the corpus by turns and the J48 model built for it, shown in Figure 5, outperformed the baseline accuracy with $p < 0.01$. Again, *Duration* emerged as the tree root, but here the biggest decision fell to *RMS mean*. Student responses approximately louder than the initial response to the tutor in this question dialogue were marked, almost entirely accurately, as AUT.

Since both trees were rooted at *Duration*, we sam-

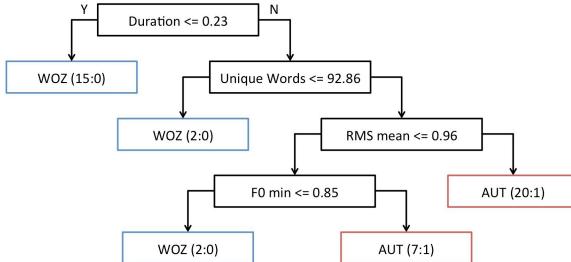

Figure 5: The J48 tree for the question “Now let’s find the forces exerted on the car in the vertical direction during the collision. First, what vertical force is always exerted on an object near the surface of the earth?”. Classification nodes are marked in blue and red for WOZ and AUT, respectively, and specify (#Instances:#Incorrect).

pled common responses from each experiment for both problems. We noticed that hyper-articulation (speaking slowly, loudly, and enunciating each syllable) was more common in the AUT responses. For example, one user answering “Would you like to do another problem?” took almost 4 seconds to clearly and slowly pronounce the word “yes”. We suspect that these hyper-articulations may have contributed to the classifiers’ ability to detect WOZ responses based on their brevity.

The performance of the per-question J48 models shows, for a non-trivial portion of the turns, that the experiment-of-origin can be classified based on generalizable prosodic and lexical features alone. The two trees discussed above demonstrate the simplicity of the models needed to perform this separation.

5 Discussion and Future Work

We demonstrate that there exist significant differences between user responses to a wizarded and an automatic dialogue system’s questions, even when the contribution of the wizard is as atomic as speech recognition and correctness evaluation. Our generalizable features are derived exclusively from the recordings of the users’ responses and human transcriptions of their speech.

Because the role of the wizard in the WOZ setup was limited to evaluating users’ spoken response to a prompt, our results suggest that user speech changes as a result of user confidence in the system’s accuracy. For example, Figure 3 demonstrates that users in the WOZ setup used complete sentences

and gave long responses, where AUT users, possibly anticipating system error, used shorter (sometimes one word) responses. This relationship between user confidence and user speech may be analogous to observed differences like users’ longer speech and typed responses to systems when told those systems are human-operated (Schechtman and Horowitz, 2003; Rosé and Torrey, 2005). Our results suggest ways in which raw wizarded data may fall short of ideal for training an automated system.

Having established that differences exist, our future work will focus on deeper exploration of the nature of these differences in users’ responses. We suspect users become less confident in the automated system over time, so one direction of study will be to measure how the observed differences change over the course of the dialogue. We expect that they are minimal early on and become more pronounced in the automated setup as users’ confidence is shaken. Additionally, some technical aspects of our methodology may impact these and future results: using different methods of normalization for user speech values than the one from this paper may affect visibility of observed differences between the setups.

Future work may also attempt to address these differences directly. Intentional wizard error could be introduced to frustrate the user into responding as she would to a less accurate system, analogous to intentional errors produced in user simulation in spoken dialogue systems (Lee and Eskenazi, 2012). This strategy would be further informed by studies of the relationship between the system’s evaluation accuracy and student responses’ deviation from wizarded responses. Alternatively, post-hoc domain adaptation could be used to adjust the WOZ data. Generalizable statistical classification domain adaptation (Daumé and Marcu, 2006) and adaptation demonstrated to work well in NLP-specific domains (Jiang and Zhai, 2007) both have the potential to adjust WOZ data to better match that seen by automated systems.

Abstract

We present a method of improving the performance of dialog act tagging in identifying minority classes by using per-class feature optimization and a method of choosing the class based not on confidence, but on a cascade of classifiers. We show that it gives a minority class F-measure error reduction of 22.8%, while also reducing the error for other classes and the overall error by about 10%.

1 Introduction

In this paper, we discuss **dialog act tagging**, the task of assigning a dialog act to an utterance, where a **dialog act** (DA) is a high-level categorization of the pragmatic meaning of the utterance. Our data is email. Our starting point is the tagger described in (Hu et al., 2009), which uses a standard multi-class classifier based on support vector machines (SVMs). While the performance of this system is pretty good as measured by accuracy, it performs badly on the DA REQUEST-ACTION, which is a rare class. Multi-class SVMs are typically implemented as a set of SVMs, one per class, with the overall choice of class being determined by the SVM with the highest confidence (“one-against-all”). Multi-class SVMs are typically packaged as a single system, whose inner workings are ignored by the NLP researcher. In this paper we show that, for our problem of DA classification, we can boost the performance of the rare classes (while maintaining the overall performance) by performing feature optimization separately for each individual classifier. But we also show that we

can achieve an all-around error reduction by altering the method by which the multi-class classifier combines the individual SVMs. This new method of combination is a simple cascade: we run the individual classifiers in ascending order of frequency of the classes in the training corpus; the first classifier to classify the data point positively determines the choice of the overall classifier. If no classifier classifies the data point positively, we use the usual confidence-based method. This new method obtains a 22.8% error reduction for the minority class, and around 10% error reduction for the other classes and for the overall classifier.

This paper is structured as follows. We start out by discussing related work (Section 2). We then present our data in Section 3, and in Section 4 we present the experiments with our systems and the results. We report the results of an extrinsic evaluation in Section 5, and conclude.

2 Related Work

Dialog act (DA) annotations and tagging, inspired by the speech act theory of Austin (1975) and Searle (1976), have been used in the NLP community to understand and model dialog. Initial work was done on spoken interactions (see for example (Stolcke et al., 2000)). Recently, studies have explored dialog act tagging in written interactions such as emails (Cohen et al., 2004), forums (Kim et al., 2006; Kim et al., 2010b), instant messaging (Kim et al., 2010a) and Twitter (Zhang et al., 2012). Most DA tagging systems for written interactions use a message/post level tagging scheme, and allow multiple tags for each message/post. In such a tagging scheme, indi-

vidual binary classifiers for each tag are independent of one another. However, recent studies have found merit in segmenting each message into functional units and assigning a single DA to each segment (Hu et al., 2009). Our work falls in this paradigm (we choose a single DA for smaller textual units). We build on the work by (Hu et al., 2009); we improve their dialog act predicting performance on minority classes using per-class feature optimization.

3 Data

In this study, we use the email corpus presented in (Hu et al., 2009), which is manually annotated for DA tags. The corpus contains 122 email threads with a total of 360 messages and 20,740 word tokens. This set of email threads is chosen from a version of the Enron email corpus with some missing messages restored from other emails in which they were quoted (Yeh and Harnly, 2006; Agarwal et al., 2012). Most emails are concerned with exchanging information, scheduling meetings, or solving problems, but there are also purely social emails.

Dialog Act Tag	Count (%)
REQUEST-ACTION (R-A)	35 (2.5%)
REQUEST-INFORMATION (R-I)	151 (10.7%)
CONVENTIONAL (CONV)	357 (25.4%)
INFORM (INF)	853 (60.7%)
Total # of DFUs	1406

Table 1: Annotation statistics

Each message in the thread is segmented into Dialog Functional Units (DFUs). A DFU is a contiguous span within an email message which has a coherent communicative intention. Each DFU is assigned a single DA label which is one of the following: REQUEST-ACTION (R-A), REQUEST-INFORMATION (R-I), CONVENTIONAL (CONV) and INFORM (INF). There are three other DA labels — INFORM-OFFLINE, COMMIT, and NODA for no dialog act — which occurred 5 or fewer times in the corpus. We ignore these DA labels in this paper. The corpus also contains links between the DFUs, but we do not use those annotations in this study. Table 1 presents the distribution of DA labels in our corpus. We now describe each of the DAs we consider in our experiments.

In a REQUEST-ACTION, the writer signals her desire that the reader perform some non-communicative act, i.e., an act that cannot in itself be part of the dialogue. For example, a writer can ask the reader to write a report or make coffee.

In a REQUEST-INFORMATION, the writer signals her desire that the reader perform a specific communicative act, namely that he provide information (either facts or opinion).

In an INFORM, the writer conveys information, or more precisely, the writer signals that her desire that the reader adopt a certain belief. It covers many different types of information that can be conveyed including answers to questions, beliefs (committed or not), attitudes, and elaborations on prior DAs.

A CONVENTIONAL dialog act does not signal any specific communicative intention on the part of the writer, but rather it helps structure and thus facilitate the communication. Examples include greetings, introductions, expressions of gratitude, etc.

4 System

We developed four systems for our experiments: a baseline (BAS) system which is close to the system described in (Hu et al., 2009), and three variants of our novel divide and conquer (DAC) system. Features used in both systems are extracted as explained in Section 4.2. Section 4.3 describes the baseline system, the basic DAC system, and two variations of the DAC system.

4.1 Experimental Framework

In all our experiments, we use linear kernel Support Vector Machines (SVM). However, across the systems, there are differences in how we use them. Our framework was built with the ClearTK toolkit (Ogren et al., 2008) with its wrapper for SVMLight (Joachims, 1999). The ClearTK wrapper internally shifts the prediction threshold based on posterior probabilistic scores calculated using the algorithm of Lin et al. (2007). We report results from 5-fold cross validation performed on the entire corpus.

4.2 Feature Engineering

In developing our system, we classified our features into three categories: lexical, verbal and message-

level. Lexical features consists of n-grams of words, n-grams of POS tags, mixed n-grams of closed class words and POS tags (Prabhakaran et al., 2012), as well as a small set of specialized features — Start-POS/Lemma (POS tag and lemma of the first word), LastPOS/Lemma (POS tag and lemma of the last word), MDCount (number of modal verbs in the DFU) and QuestionMark (is there a question mark in the DFU). We used the POS tags produced by the OpenNLP POS tagger. Verbal features capture the position and identity of the first verb in the DFU. Finally, message-level features capture aspects of the location of the DFU in the message and of the message in the thread (relative position and size). In optimizing each system, we first performed an exhaustive search across all combinations of features within each category. For the lexical n-gram features we varied the n-gram window from 1 to 5. This step gave us the best performing feature combination within each category. In a second step, we found the best combination of categories, using the previously determined features for each category. In this paper, we do not report best performing feature sets for each configuration, due to lack of space.

4.3 Experiments

Baseline (BAS) System This system uses the ClearTK built-in one-versus-all multiclass SVM in prediction. Internally, the multi-class SVM builds a set of binary classifiers, one for each dialog act. For a given test instance, the classifier that obtains the highest probability score determines the overall prediction. We performed feature optimization on the whole multiclass classifier (as described in Section 4.2), i.e., the same set of features was available to all component classifiers. We optimized for system accuracy. Table 2 shows results using this system. In this and all tables, we give the performance of the system on the four DAs, using precision, recall, and F-measure. The DAs are listed in ascending order of frequency in the corpus (least frequent DA first). We also give an overall accuracy evaluation. As we can see, detecting REQUEST-ACTION is much harder than detecting the other DAs.

Basic Divide and Conquer (DAC) System Like the BAS system, the DAC system also builds a binary classifier for each dialog act separately, and the

Table 2: Results for baseline (BAS) system (standard multiclass SVM)

component classifier with highest probability score determines the overall prediction. The crucial difference in the DAC system is that the feature optimization is performed for each component classifier separately. Each component classifier is optimized for F-measure. Table 3 shows results using this system.

	Prec.	Recall	F-meas.	ER
R-A	66.7	40.0	50.0	15.6
R-I	91.5	78.2	84.3	0.0

<i>Accuracy</i>			91.7	4.9

Table 3: Results for basic DAC system (per-class feature optimization followed by maximum confidence based choice); “ER” refers to error reduction in percent over standard multiclass SVM (Table 2)

Minority Preference (DAC_{MP}) System This system is exactly the same as the basic DAC system except for one crucial difference: overall classification is biased towards a specified minority class. If the minority class binary classifier predicts true, this system chooses the minority class as the predicted class. In cases where the minority class classifier predicts false, it backs off to the basic DAC system after removing the minority class classifier from the confidence tally. Table 4 shows our results using REQUEST-ACTION as the minority class.

Cascading Minority Preference (DAC_{CMP}) System This system is similar to the Minority Preference System; however, instead of a single supplied minority class, the system accepts an ordered list of classes. The classifier then works, in order, through this list; whenever any classifier in the list predicts

	Prec.	Recall	F-meas.	ER
R-A	66.7	45.7	54.2	22.8
R-I	91.5	78.2	84.3	0.0

INF	91.6	96.0	93.8	6.5
<i>Accuracy</i>		91.8		5.7

Table 4: Results for minority-preference DAC system — DAC_{MP} (first consult REQUEST-ACTION tagger, then default to choice by maximum confidence); “ER” refers to error reduction in percent over standard multiclass SVM (Table 2)

true, for a given instance, it then assigns this class as the predicted class. The subsequent classifiers in the list are not run. If all classifiers predict false, we back off to the basic DAC system, i.e., the component classifier with highest probability score determines the overall prediction. We ordered the list of classes in the ascending order of their frequencies in the training data. This ordering is driven by the observation that the less frequent classes are also hard to predict correctly. Table 5 shows our results using the ordered list: (REQUEST-ACTION, REQUEST-INFORMATION, CONVENTIONAL, INFORM).

	Prec.	Recall	F-meas.	ER
R-A	66.7	45.7	54.2	22.8
R-I	91.0	80.8	85.6	8.4

<i>Accuracy</i>		92.2		10.6

Table 5: Results for cascading minority-preference DAC system — DAC_{CMP} (consult classifiers in reverse order of frequency of class); “ER” refers to error reduction in percent over standard multiclass SVM (Table 2)

4.4 Discussion

As shown in Table 3, the basic DAC system obtained a 15.6% F-measure error reduction for the minority class REQUEST-ACTION over the BAS system. It also improves performance of two other classes — CONVENTIONAL and INFORM, and obtains a 4.9% error reduction on overall accuracy. Recall here that the only difference between the DAC system and the BAS system is the per-class feature optimization and therefore this must be the reason for

this boost in performance. When we turn to DAC_{MP} , we see that the performance on the minority class REQUEST-ACTION is further enhanced, with an F-measure error reduction of 22.8%; the overall accuracy improves slightly with an error reduction of 5.7%. Finally, DAC_{CMP} further improves the performance. Since the method of choosing the minority class REQUEST-ACTION does not change over DAC_{MP} , the F-measure error reduction remains the same. However, now all three other classes also improve their performance, and we obtain a 10.6% error reduction on overall accuracy over the baseline system.

Following (Guyon et al., 2002), we performed a post-hoc analysis by inspecting the feature weights of the best performing models created for each individual classifier in the DAC system. Table 6 lists some interesting features chosen during feature optimization for the individual SVMs. We selected them from the top 25 features in terms of absolute value of feature weights.

Some features help distinguish different DA categories. For example, the feature *QuestionMark* is the feature with the highest negative weight for INFORM, but has the highest positive weight for REQUEST-INFORMATION. Features like *fyi* and *period(.)* have high positive weights for INFORM and high negative weights for CONVENTIONAL. Some other features are important only for certain classes. For e.g., *please* and *VB_NN* are important for REQUEST-ACTION, but not so for other classes. Overall, the most discriminating features for both INFORM and CONVENTIONAL are mostly word ngrams, while those for REQUEST-ACTION and REQUEST-INFORMATION are mostly POS ngrams. This shows why our approach of per-class feature optimization is important to boost the classification performance.

Another interesting observation is that the least frequent category, REQUEST-ACTION, has the least strong indicators (as measured by feature weights). Presumably this is because there is much less training data for this class. This explains why our cascading classifiers approach giving priority to the least frequent categories worked better than a simple confidence based approach, since the simple approach drowns out the less confident classifiers.

REQUEST-ACTION	REQUEST- INFORMATION	CONVENTIONAL	INFORM
please (0.9)	QuestionMark (6.6)	StartPOS_NNP (2.7)	QuestionMark (-3.0)
VB_NN (0.7)	_BOS_PRP (-1.2)	thanks (2.3)	thanks (-2.2)

will (-0.2)	_BOS_DT (-0.7)	QuestionMark (-0.8)	can_you (-0.9)

Table 6: Post-hoc analysis on the models built by the DAC system: some of the top features with corresponding feature weights in parentheses, for each individual tagger. (POS tags are capitalized; _BOS_ stands for Beginning Of Sentence)

5 Extrinsic Evaluation

In this section, we perform an extrinsic evaluation for the dialog act tagger presented in Section 4 by applying it to the task of identifying Overt Displays of Power (ODP) in emails, proposed by Prabhakaran et al. (2012). The task is to identify utterances where the linguistic form introduces additional constraints on its responses, beyond those introduced by the general dialog act. The dialog act features were found to be useful and the best performing system obtained an F-measure of 65.8 using gold dialog act tags. For our extrinsic evaluation, we retrained the ODP tagger using dialog act tags predicted by our BAS and DAC_{CMP} systems instead of gold dialog acts. ODP tagger uses the same dataset as ours for training. In the cross validation step, we made sure that the test folds for ODP were excluded from training the taggers to obtain DA tags. At each ODP cross validation step, we trained a BAS or DAC_{CMP} tagger using ODP’s training folds for that step and used tags produced by that tagger for both training and testing the ODP tagger for that step. Table 7 lists the results obtained.

	Prec.	Rec.	F-meas.
No-DA	55.7	45.4	50.0
Gold-DA	75.8	58.1	65.8
BAS-DA	60.6	46.5	52.6
DAC_{CMP} -DA	67.2	45.4	54.2

Table 7: Results for ODP system using various sources of DA tags

Using BAS tagged DA, the F-measure of ODP system reduced by 13.2 points to 52.6 from using gold dialog acts ($F=65.8$). Using DAC_{CMP} , the F-

measure improved over BAS by 1.6 points to 54.2. This constitutes an error reduction of 12.1%, taking the system using gold DA tags as the reference. This improvement is noteworthy, given the fact that the overall error reduction obtained by DAC_{CMP} over BAS in the DA tagging was around 10.6%. Also, the DAC_{CMP} -based ODP system obtained an error reduction of about 26.6% over a system that does not use the DA features at all ($F=50.0$).

6 Conclusion

We presented a method of improving the performance of dialog act tagging in identifying minority classes by using per-class feature optimization and choosing the class based on a cascade of classifiers. We showed that it gives a minority class F-measure error reduction of 22.8% while also reducing the error on other classes and the overall error by around 10%. We also presented an extrinsic evaluation of this technique on detecting Overt Displays of Power in dialog, where we achieve an error reduction of 12.1% over using the standard multiclass SVM to generate dialog act tags.

Abstract

Document-level sentiment analysis can benefit from fine-grained subjectivity, so that sentiment polarity judgments are based on the relevant parts of the document. While fine-grained subjectivity annotations are rarely available, encouraging results have been obtained by modeling subjectivity as a latent variable. However, latent variable models fail to capitalize on our linguistic knowledge about discourse structure. We present a new method for injecting linguistic knowledge into latent variable subjectivity modeling, using discourse connectors. *Connector-augmented transition features* allow the latent variable model to learn the relevance of discourse connectors for subjectivity transitions, without subjectivity annotations. This yields significantly improved performance on document-level sentiment analysis in English and Spanish. We also describe a simple heuristic for automatically identifying connectors when no predefined list is available.

1 Introduction

Document-level sentiment analysis can benefit from consideration of discourse structure. Voll and Taboada (2007) show that adjective-based sentiment classification is improved by examining topicality (whether each sentence is central to the overall point); Yessenalina et al. (2010b) show that bag-of-ngrams sentiment classification is improved by examining subjectivity (whether a sentence expresses a subjective opinion or objective fact). However, it is unclear how best to obtain the appropriate discourse analyses. Voll and Taboada (2007) find that

domain-independent discourse parsing (Soricut and Marcu, 2003) offers little improvement for sentiment analysis, so they resort to training a domain-specific model for identifying topic sentences in reviews. But this requires a labeled dataset of topic sentences, imposing a substantial additional cost.

Yessenalina et al. (2010b) treat sentence level subjectivity as a *latent variable*, automatically inducing the “annotator rationale” (Zaidan et al., 2007; Yessenalina et al., 2010a) for each training sentence so as to focus sentiment learning on the subjective parts of the document. This yields significant improvements over bag-of-ngrams supervised sentiment classification. Latent variable subjectivity analysis is attractive because it requires neither subjectivity annotations nor an accurate domain-independent discourse parser. But while the “knowledge-free” nature of this approach is appealing, it is unsatisfying that it fails to exploit decades of research on discourse structure.

In this paper, we explore a lightweight approach to injecting linguistic knowledge into latent variable models of subjectivity. The entry point is a set of *discourse connectors*: words and phrases that signal a shift or continuation in the discourse structure. Such connectors have been the subject of extensive study in the creation of the Penn Discourse Treebank (PDTB: Prasad et al. 2008). The role of discourse connectors in sentiment analysis can be clearly seen in examples, such as “*It’s hard to imagine the studios hiring another manic German maverick to helm a cop thriller. But that’s exactly why the movie is unmissable.*” (Huddleston, 2010)

We present a new approach to incorporate discourse connectors in a latent subjectivity model (Yessenalina et al., 2010b). This approach requires no manually-specified information about the meaning of the connectors, just the connectors themselves. Our approach builds on proximity features, which give the latent variable model a way to prefer or disprefer subjectivity and sentiment transitions, usually with the goal of encouraging smoothness across the document. By taking the cross-product of these features with a set of discourse connectors, we obtain a new set of *connector-augmented transition features*, which capture the way discourse connectors are used to indicate subjectivity and sentiment transitions. The model is thus able to learn that subjectivity shifts are likely to be accompanied by connectors such as *however* or *nonetheless*.

We present experiments in both English and Spanish showing that this method of incorporating discourse connectors yields significant improvements in document-level sentiment analysis. In case no list of connectors is available, we describe a simple heuristic for automatically identifying candidate connector words. The automatically identified connectors do not perform as well as the expert-defined lists, but they still outperform a baseline method that ignores discourse connectors (in English). This demonstrates both the robustness of the approach and the value of linguistic knowledge.

2 Model

Given accurate labels of the subjectivity of each sentence, a document-level sentiment analyzer could safely ignore the sentences marked as non-subjective.¹ This would be beneficial for training as well as prediction, because the learning algorithm would not be confused by sentences that contradict the document label. But in general we cannot rely on having access to sentence-level subjectivity annotations. Instead, we treat subjectivity as a *latent variable*, and ask the learner to impute its value. Given document-level sentiment annotations and an initial

¹Discourse parsing often focuses on sub-sentence *elementary discourse units* (Mann and Thompson, 1988). For simplicity, we consider units at the sentence level only, and leave finer-grained analysis for future work.

model, the learner can mark as non-subjective those sentences whose analysis disagrees with the document label.

More formally, each document has a label $y \in \{-1, 1\}$, a set of sentences \mathbf{x} , and a set of sentence subjectivity judgments $\mathbf{h} \in \{0, 1\}^S$, where S is the number of sentences. We compute a set of features on these variables, and score each instance by a weighted combination of the features, $\mathbf{w}^\top \mathbf{f}(y, \mathbf{x}, \mathbf{h})$. At prediction time, we seek a label y which achieves a high score given the observed \mathbf{x} and the ideal \mathbf{h} .

$$\hat{y} = \arg \max_y \left(\max_{\mathbf{h}} \mathbf{w}^\top \mathbf{f}(y, \mathbf{x}, \mathbf{h}) \right). \quad (1)$$

At training time, we seek weights w which achieve a high score given all training examples $\{\mathbf{x}_t, y_t\}_t$,

$$\hat{w} = \arg \max_w \sum_t \max_{\mathbf{h}} \mathbf{w}^\top \mathbf{f}(y_t, \mathbf{x}_t, \mathbf{h}). \quad (2)$$

We can decompose the feature vector into two parts: polarity features $\mathbf{f}_{\text{pol}}(y, \mathbf{x}, \mathbf{h})$, and subjectivity features $\mathbf{f}_{\text{subj}}(\mathbf{x}, \mathbf{h})$. The basic feature set decomposes across sentences, though the polarity features involve the document-level polarity. For sentence i , we have $\mathbf{f}_{\text{pol}}(y, \mathbf{x}_i, h_i) = y h_i \mathbf{x}_i$: the bag-of-words features for sentence i are multiplied by the document polarity $y \in \{-1, 1\}$ and the sentence subjectivity $h_i \in \{0, 1\}$. The weights \mathbf{w}_{pol} capture the sentiment polarity of each possible word. As for the subjectivity features, we simply have $\mathbf{f}_{\text{subj}}(\mathbf{x}_i, h_i) = h_i \mathbf{x}_i$. The weights \mathbf{w}_{subj} capture the subjectivity of each word, with large values indicate positive subjectivity.

However, these features do not capture transitions between the subjectivity and sentiment of adjacent sentences. For this reason, Yessenalina et al. (2010b) introduce an additional set of *proximity* features, $\mathbf{f}_{\text{prox}}(h_i, h_{i-1})$, which are parametrized by the subjectivity of both the current sentence i and the previous sentence $i - 1$. The effect of these features will be to learn a preference for consistency in the subjectivity of adjacent sentences.

By augmenting the transition features with the text \mathbf{x}_i , we allow this preference for consistency to be modulated by discourse connectors. We design the *transition* feature vector $\mathbf{f}_{\text{trans}}(\mathbf{x}_i, h_i, h_{i-1})$

to contain two elements for every discourse connector, one for $h_i = h_{i-1}$, and one for $h_i \neq h_{i-1}$. For example, the feature $\langle \text{moreover}, \text{CONTINUE} \rangle$ fires when sentence i starts with *moreover* and $h_{i-1} = h_{i,i}$. We would expect to learn a positive weight for this feature, and negative weights for features such as $\langle \text{moreover}, \text{SHIFT} \rangle$ and $\langle \text{however}, \text{CONTINUE} \rangle$.

3 Experiments

To evaluate the utility of adding discourse connectors to latent subjectivity sentiment analysis, we compare several models on movie review datasets in English and Spanish.

3.1 Data

We use two movie review datasets:

- 50,000 English-language movie reviews (Maas et al., 2011). Each review has a rating from 1-10; we marked ratings of 5 or greater as positive. Half the dataset is used for test and half for training. Parameter tuning is performed by cross-validation.
- 5,000 Spanish-language movie reviews (Cruz et al., 2008). Each review has a rating from 1-5; we marked 3-5 as positive. We randomly created a 60/20/20 split for training, validation, and test.

3.2 Connectors

We first consider single-word discourse connectors: in English, we use a list of all 57 one-word connectors from the Penn Discourse Tree Bank (Prasad et al., 2008); in Spanish, we selected 25 one-word connectors from a Spanish language education website.² We also consider multi-word connectors. Using the same sources, this expands the English set to 93 connectors, and Spanish set to 80 connectors.

In case no list of discourse connectors is available, we propose a simple technique for automatically identifying potential connectors. We use a χ^2 test to select words which are especially likely to initiate sentences. The top K words (with the lowest p values) were added as potential connectors, where K is equal to the number of “true” connectors provided by the gold-standard resource.

²russell.famaf.unc.edu.ar/~laura/shallowdisc4summ/discmar/

Finally, we consider a model with connector-augmented transition features for all words in the vocabulary. Thus, there are four connector sets:

- **true-unigram-connectors:** unigram connectors from the Penn Discourse Treebank and the Spanish language education website
- **true-multiword-connectors:** unigram and multiword connectors from these same resources
- **auto-unigram-connectors:** automatically-selected connectors using the χ^2 test
- **all-unigram-connectors:** all words are potential connectors

3.3 Systems

The connector-augmented transition features are incorporated into a latent variable support vector machine (SVM). We also consider two baselines:

- **no-connectors:** the same latent variable SVM, but without the connector features. This is identical to the prior work of Yessenalina et al. (2010b).
- **SVM:** a standard SVM binary classifier

The latent variable models require an initial guess for the subjectivity of each sentence. Yessenalina et al. (2010b) compare several initializations and find the best results using OpinionFinder (Wilson et al., 2005). For the Spanish data, we performed initial subjectivity analysis by matching against a publicly-available full-strength Spanish lexicon set (Rosas et al., 2012).

3.4 Implementation details

Both our implementation and the baselines are built on the latent structural SVM (Yu and Joachims, 2009; <http://www.cs.cornell.edu/~cnyu/latentssvm/>), which is in turn built on the SVM-Light distribution (<http://svmlight.joachims.org/>). The regularization parameter C was chosen by cross-validation.

4 Results

Table 1 shows the sentiment analysis accuracy with each system and feature set. The best overall results in both language are given by the models with

system	English	Spanish
true-multiword-connectors	91.25	79.80
true-unigram-connectors	91.36	77.50
auto-connectors	90.22	76.90
all-unigram-connectors	87.60	74.30
No-connectors	88.21	76.42
SVM	84.79	69.44

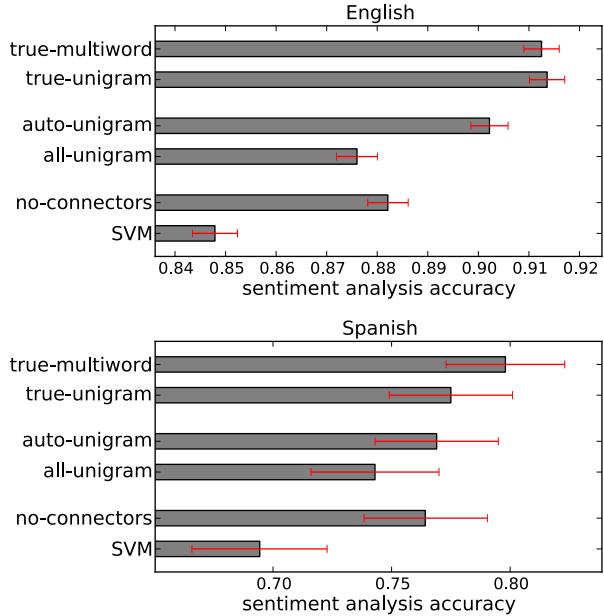

Figure 1: Document-level sentiment analysis accuracy. The 95% confidence intervals are estimated from the cumulative density function of the binomial distribution.

connector-augmented transition features. In English, the multiword and unigram connectors perform equally well, and significantly outperform all alternatives at $p < .05$. The connector-based features reduce the error rate of the latent subjectivity SVM by 25%. In Spanish, the picture is less clear because the smaller test set yields larger confidence intervals, so that only the comparison with the SVM classifier is significant at $p < .05$. Nonetheless, the connector-augmented transition features give the best accuracy, with an especially large improvement obtained by the multiword connectors.

Next, we investigated the quality of the automatically-induced discourse connectors. The χ^2 heuristic for selecting candidate connectors gave results that were significantly better than the no-connector baseline in English, though the

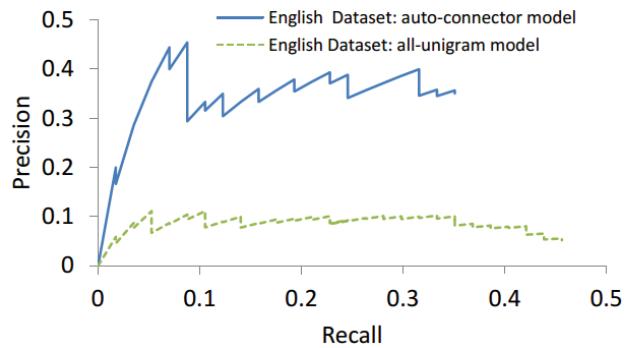

Figure 2: Precision-Recall curve for top-K discovered connectors when compared with PDTB connector set

difference in Spanish was minimal. However, when every word is included as a potential connectors, the performance suffers, dropping below the accuracy of the no-connector baseline. This shows that the improvement in accuracy offered by the connector features is not simply due to the increased flexibility of the model, but depends on identifying a small set of likely discourse connectors.

For a qualitative evaluation, we ranked all English-language unigram connectors by their feature weights, and list the top ten for each subjectivity transition:

- SHIFT: *however; though; but; if; unlike; although; while; overall; nevertheless; still*
- CONTINUATION: *as; there; now; even; in; after; once; almost; because; so*

Overall these word lists cohere with our intuitions, particularly the words associated with SHIFT transitions: *however, but, and nevertheless*. As one of the reviewers noted, some of the words associated with CONTINUATION transitions are better seen as discourse **cues** rather than connectors, such as *now*. Other words seem to connect two **subsequent** clauses, e.g., *if Nicholas Cage had played every role, the film might have reached its potential*. Incorporating such connectors must be left for future work.

Finally, in learning weights for each connector feature, our model can be seen as *discovering* discourse connectors. We compare the highly weighted discovered connectors from the all-unigram and auto-unigram settings with the one-word connectors from the Penn Discourse Tree Bank. The results

of this comparison are shown in Figure 2, which traces a precision-recall curve by taking the top K connectors for various values of K . The **auto-unigram** model is able to identify many true connectors from the Penn Discourse Treebank, while the **all-unigram** model achieves low precision. This graph helps to explain the large performance gap between the **auto-unigram** and **all-unigram** feature sets; the **all-unigram** set includes too many weak features, and the learning algorithm is not able to distinguish the true discourse connectors. The Spanish discourse connectors identified by this approach were extremely poor, possibly because so many more of the Spanish connectors include multiple words.

5 Related Work

Polanyi and Zaenen (2006) noted the importance of accounting for *valence shifters* in sentiment analysis, identifying relevant connectors at the sentence and discourse levels. They propose a heuristic approach to use shifters to modify the contributions of sentiment words. There have been several subsequent efforts to model within-sentence valence shifts, including compositional grammar (Moilanen and Pulman, 2007), matrix-vector products across the sentence (Yessenalina and Cardie, 2011), and methods that reason about polarity shifters within the parse tree (Socher et al., 2012; Sayeed et al., 2012). The value of discourse structure towards predicting opinion polarity has also demonstrated in the context of multi-party dialogues (Somasundaran et al., 2009). Our approach functions at the discourse level within single-author documents, so it is complementary to this prior work.

Voll and Taboada (2007) investigate various techniques for focusing sentiment analysis on sentences that are central to the main topic. They obtain negative results with the general-purpose SPADE discourse parser (Soricut and Marcu, 2003), but find that training a decision tree classifier to identify topic-central sentences yields positive results. Wiebe (1994) argues that in coherent narratives, objectivity and subjectivity are usually consistent between adjacent sentences, an insight exploited by Pang and Lee (2004) in a supervised system for subjectivity analysis. Later work employed struc-

tured graphical models to model the flow of subjectivity and sentiment over the course of the document (Mao and Lebanon, 2006; McDonald et al., 2007). All of these approaches depend on labeled training examples of subjective and objective sentences, but Yessenalina et al. (2010b) show that subjectivity can be modeled as a *latent variable*, using a latent variable version of the structured support vector machine (Yu and Joachims, 2009).

Our work can be seen as a combination of the machine learning approach of Yessenalina et al. (2010b) with the insight of Polanyi and Zaenen (2006) that connectors play a key role in transitions between subjectivity and sentiment. Eisenstein and Barzilay (2008) incorporated discourse connectors into an unsupervised model of topic segmentation, but this work only considered the role of such markers to differentiate adjoining segments of text, and not to identify their roles with respect to one another. That work was also not capable of learning from supervised annotations in a downstream task. In contrast, our approach uses document-level sentiment annotations to learn about the role of discourse connectors in sentence-level subjectivity.

6 Conclusion

Latent variable machine learning is a powerful tool for inducing linguistic structure directly from data. However, adding a small amount of linguistic knowledge can substantially improve performance. We have presented a simple technique for combining a latent variable support vector machine with a list of discourse connectors, by creating an augmented feature set that combines the connectors with pairwise subjectivity transition features. This improves accuracy, even with a noisy list of connectors that has been identified automatically. Possible directions for future work include richer representations of discourse structure, and the combination of discourse-level and sentence-level valence and subjectivity shifters.

Coherence Modeling for the Automated Assessment of Spontaneous Spoken Responses

Xinhao Wang, Keelan Evanini, Klaus Zechner

Educational Testing Service

660 Rosedale Road

Princeton, NJ 08541, USA

xwang002,kevanini,kzechner@ets.org

Abstract

This study focuses on modeling discourse coherence in the context of automated assessment of spontaneous speech from non-native speakers. Discourse coherence has always been used as a key metric in human scoring rubrics for various assessments of spoken language. However, very little research has been done to assess a speaker's coherence in automated speech scoring systems. To address this, we present a corpus of spoken responses that has been annotated for discourse coherence quality. Then, we investigate the use of several features originally developed for essays to model coherence in spoken responses. An analysis on the annotated corpus shows that the prediction accuracy for human holistic scores of an automated speech scoring system can be improved by around 10% relative after the addition of the coherence features. Further experiments indicate that a weighted F-Measure of 73% can be achieved for the automated prediction of the coherence scores.

1 Introduction

In recent years, much research has been conducted into developing automated assessment systems to automatically score spontaneous speech from non-native speakers with the goals of reducing the burden on human raters, improving reliability, and generating feedback that can be used by language learners. Various features related to different aspects of speaking proficiency have been exploited, such as delivery features for pronunciation, prosody, and fluency (Strik and Cucchiarini, 1999; Chen et al., 2009; Cheng, 2011; Higgins et al., 2011), as

well as language use features for vocabulary and grammar, and content features (Chen and Zechner, 2011; Xie et al., 2012). However, discourse-level features related to topic development have rarely been investigated in the context of automated speech scoring. This is despite the fact that an important criterion in the human scoring rubrics for speaking assessments is the evaluation of coherence, which refers to the conceptual relations between different units within a response.

Methods for automatically assessing discourse coherence in text documents have been widely studied in the context of applications such as natural language generation, document summarization, and assessment of text readability. For example, Foltz et al. (1998) measured the overall coherence of a text by utilizing Latent Semantic Analysis (LSA) to calculate the semantic relatedness between adjacent sentences. Barzilay and Lee (2004) introduced an HMM-based model for the document-level analysis of topics and topic transitions. Barzilay and Lapata (2005; 2008) presented an approach to coherence modeling which focused on the entities in the text and their grammatical transitions between adjacent sentences, and calculated the entity transition probabilities on the document level. Pitler et al. (2010) provided a summary of the performance of several different types of features for automated coherence evaluation, such as cohesive devices, adjacent sentence similarity, Coh-Metrix (Graesser et al., 2004), word co-occurrence patterns, and entity-grid.

In addition to studies on well-formed text, researchers have also addressed coherence modeling on text produced by language learners, which may contain many spelling and grammar errors. Utilizing LSA and Random Indexing methods, Higgins et al. (2004) measured the global

coherence of students' essays by calculating the semantic relatedness between sentences and the corresponding prompts. In addition, Burstein et. al (2010) combined entity-grid features with writing quality features produced by an automated assessment system of essays to predict the coherence scores of student essays. Recently, Yannakoudakis and Briscoe (2012) systematically analyzed a variety of coherence modeling methods within the framework of an automated assessment system for non-native free text responses and indicated that features based on Incremental Semantic Analysis (ISA), local histograms of words, the part-of-speech IBM model, and word length were the most effective.

In contrast to these previous studies involving well-formed text or learner text containing errors, this paper focuses on modeling coherence in spontaneous spoken responses as well as investigating discourse features in an attempt to extend the construct coverage of an automated speech scoring system. In a related study, Hassanali et al. (2012) investigated coherence modeling for spoken language in the context of a story retelling task for the automated diagnosis of children with language impairment. They annotated transcriptions of children's narratives with coherence scores as well as markers of narrative structure and narrative quality; furthermore they built models to predict the coherence scores based on Coh-Metrix features and the manually annotated narrative features. The current study differs from this one in that it deals with free spontaneous spoken responses provided by students at a university level; these responses therefore contain more varied and more complicated information than the child narratives.

The main contributions of this paper can be summarized as follows: First, we obtained coherence annotations on a corpus of spontaneous spoken responses drawn from a university-level English language proficiency assessment, and demonstrated an improvement of around 10% relative in the accuracy of the automated prediction of human holistic scores with the addition of the coherence annotations. Second, we applied the entity-grid features and writing quality features from an automated essay scoring system to predict the coherence scores; the experimental results have shown promising correlations between some of these features and the coherence scores.

2 Data and Annotation

2.1 Data

For this study, we collected 600 spoken responses from the international TOEFL® iBT assessment of English proficiency for non-native speakers. 100 responses were drawn from each of 6 different test questions comprising two different speaking tasks: 1) providing an opinion based on personal experience ($N = 200$) and 2) summarizing or discussing material provided in a reading and/or listening passage ($N = 400$). The spoken responses were all transcribed by humans with punctuation and capitalization. The average number of words contained in the responses was 104.4 (st. dev. = 34.4) and the average number of sentences was 5.5 (st. dev. = 2.1).

The spoken responses were all provided with holistic English proficiency scores on a scale of 1 - 4 by expert human raters in the context of operational, high-stakes scoring for the spoken language assessment. The scoring rubrics address the following three main aspects of speaking proficiency: delivery (pronunciation, fluency, prosody), language use (grammar and lexical choice), and topic development (content and coherence). In order to ensure a sufficient quantity of responses from each proficiency level for training and evaluating the coherence prediction features, the spoken responses selected for this study were balanced based on the human scores as follows: 25 responses were selected randomly from each of the 4 score points (1 - 4) for each of the 6 test questions. In some cases, more than one response was selected from a given test-taker; in total, 471 distinct test-takers are represented in the data set.

2.2 Annotation and Analysis

The coherence annotation guidelines used for the spoken responses in this study were modified based on the annotation guidelines developed for written essays described in Burstein et al. (2010). According to these guidelines, expert annotators provided each response with a score on a scale of 1 - 3. The three score points were defined as follows: 3 = highly coherent (contains no instances of confusing arguments or examples), 2 = somewhat coherent (contains some awkward points in which the speaker's line of argument is unclear), 1 = barely

coherent (the entire response was confusing and hard to follow; it was intuitively incoherent as a whole and the annotators had difficulties in identifying specific weak points). For responses receiving a coherence score of 2, the annotators were required to highlight the specific awkward points in the response. In addition, the annotators were specifically required to ignore disfluencies and grammatical errors as much as possible; thus, they were instructed to not label sentences or clauses as awkward points solely because of the presence of disfluent or ungrammatical speech.

Two annotators (not drawn from the pool of expert human raters who provided the holistic scores) made independent coherence annotations for all 600 spoken responses. The distribution of annotations across the three score points is presented in Table 1. The two annotators achieved a moderate inter-annotator agreement (Landis and Koch, 1977) of $\kappa = 0.68$ on the 3-point scale. The average of the two coherence scores provided by the two annotators correlates with the holistic speaking proficiency scores at $r = 0.66$, indicating that the overall proficiency scores of spoken responses can benefit from the discourse coherence annotations.

	1	2	3
# 1	160 (27%)	278 (46%)	162 (27%)
# 2	125 (21%)	251 (42%)	224 (37%)

Table 1. Distribution of coherence annotations from two annotators

Furthermore, coherence features based on the human annotations were examined within the context of an automated spoken language assessment system, SpeechRaterSM (Zechner et al., 2007; 2009). We extracted 96 features related to pronunciation, prosody, fluency, language use, and content development using SpeechRater. These features were either extracted directly from the speech signal or were based on the output of an automatic speech recognition system (with a word error rate of around 28%¹). By utilizing a decision tree classifier (the J48 implementation from Weka (Hall et al., 2009)), 4-fold cross validation was

conducted on the 600 responses to train and evaluate a scoring model for predicting the holistic proficiency scores. The resulting correlation between the predicted scores (based on the 96 baseline SpeechRater features) and the human holistic proficiency scores was $r = 0.667$.

In order to model a spoken response's coherence, three different features were extracted from the human annotations. Firstly, the average of the two annotators' coherence scores was directly used as a feature with a 5-point scale (henceforth Coh_5). Secondly, following the work in Burstein et al. (2010), we collapsed the average coherence scores into a 2-point scale to deal with the difficulty in distinguishing somewhat and highly coherent responses. For this second feature (henceforth Coh_2), scores 1 and 1.5 were mapped to score 1, and scores 2, 2.5, and 3 were mapped to score 2. Finally, the number of awkward points was also counted as a feature (henceforth Awk). As shown in Table 2, when these three coherence features were combined separately with the SpeechRater features, the correlations could be improved from $r = 0.667$ to $r > 0.7$. Meanwhile, the accuracy (i.e., the percentage of correctly predicted holistic scores) could be improved from 0.487 to a range between 0.535 and 0.543.

Features	<i>r</i>	Accuracy
SpeechRater	0.667	0.487
SpeechRater+Coh_5	0.714	0.540
SpeechRater+Coh_2	0.705	0.543
SpeechRater+Awk	0.702	0.535
SpeechRater+Coh_5+Awk	0.703	0.537
SpeechRater+Coh_2+Awk	0.701	0.542

Table 2. Improvement to an automated speech scoring system after the addition of human-assigned coherence scores and measures, showing both Pearson *r* correlations and the ratio of correctly matched holistic scores between the system and human experts

These experimental results demonstrate that the automatic scoring system can benefit from coherence modeling either by directly using a human-assigned coherence score or the identified awkward points. However, the use of both kinds of annotations does not provide further improvement. When collapsing the average scores into a 2-point scale, there was a 0.009 correlation drop (not statistically significant), but the accuracy was slightly improved. In addition, due to the relatively small

¹ Both the training and evaluation sets used to develop the speech recognizer consist of similar spoken responses drawn from the same assessment. However, there is no response overlap between these sets and the corpus used for discourse coherence annotation in this study.

size of the set of available coherence annotations, we adopted the collapsed 2-point scale instead of the 5-point scale for the coherence prediction experiments in the next section.

2.3 Experimental Design

As demonstrated in Section 2.2, the collapsed average coherence score can be used to improve the performance of an automated speech scoring system. Therefore, this study treats coherence prediction as a binary classification task: low-coherent vs. high-coherent, where the low-coherent responses are those with average scores 1 and 1.5, and the high-coherent responses are those with average scores 2, 2.5, and 3.

For coherence modeling, we again use the J48 decision tree from the Weka machine learning toolkit (Hall et al., 2009) and run 4-fold cross-validation on the 600 annotated responses. The correlation coefficient (r) and the weighted average F-Measure² are used as evaluation metrics.

In this experiment, we examine the performance of the entity-grid features and a set of features produced by the e-rater® system (an automated writing assessment system for learner essays) (Attali and Burstein, 2006) to predict the coherence scores of the spontaneous spoken responses, where all the features are extracted from human transcriptions of the responses.

2.4 Entity Grid and e-rater Features

First, we applied the algorithm from Barzilay and Lapata (2008) to extract entity-grid features, which calculated the vector of entity transition probabilities across adjacent sentences. Several different methods of representing the entities can be used before generating the entity-grid. First, all the entities can be described by their syntactic roles including S (Subject), O (Object), and X (Other). Alternatively, these roles can also be reduced to P (Present) or N (Absent). Furthermore, entities can be defined as salient, when they appear two or more times, otherwise as non-salient. In this study,

² The data distribution in the experimental corpus is unbalanced: 71% of the responses are high-coherent and 29% are low-coherent. Therefore, we adopt the weighted average F-Measure to evaluate the performance of coherence prediction: first, the F1-Measure of each category is calculated, and then the percentages of responses in each category are used as weights to obtain the final weighted average F-Measure.

we generated three basic entity grids: EG_SOX (entity grid with the syntactic roles S, O, and X), EG_REDUCED (entity grid with the reduced representations P and N), and EG_SALIENT (entity grid with salient and non-salient entities). In addition to these entity-grid features, we also used 130 writing quality features related to grammar, usage, mechanics, and style from e-rater to model the coherence.

A baseline system for this task would simply assign the majority class (high-coherent) to all of the responses; this baseline achieves an F-Measure of 0.587. Table 3 shows that the EG_REDUCED and e-rater features can obtain F-Measures of 0.677 and 0.726 as well as correlations with human scores of 0.20 and 0.33, respectively. However, the combination of the two sets of features only brings a very small improvement (from 0.33 to 0.34). In addition, our experiments show that by introducing the component of co-reference resolution for entity grid building, we can only get a very slight improvement on EG_SALIENT, but no improvement on EG_SOX and EG_REDUCED. That may be because it is generally more difficult to parse the transcriptions of spoken language than well-formed text, and more errors are introduced during the process of co-reference resolution.

	r	F-Measure
Baseline	0.0	0.587
EG_SOX	0.16	0.664
EG_REDUCED	0.2	0.677
EG_SALIENT	0.2	0.678
e-rater	0.33	0.726
EG_SOX +e-rater	0.30	0.714
EG_REDUCED +e-rater	0.34	0.73
EG_SALIENT + e-rater	0.26	0.695

Table 3. Performance of entity grid and e-rater features on the coherence modeling task

2.5 Discussion and Future Work

In order to further analyze these features, the correlation coefficients between various features and the average coherence scores (on a five-point scale) were calculated; Figure 1 shows the histogram of these correlation values. As the figure shows, there are a total of approximately 50 features with correlations larger than 0.1. Four of the entity-grid features have correlations between 0.15 and 0.29. As for the writing quality features, some

of them show high correlations with the average coherence scores, despite the fact that they are not explicitly related to discourse coherence, such as the number of good lexical collocations.

Based on the above analysis, we plan to investigate additional superficial features explicitly related to discourse coherence, such as the distribution of conjunctions, pronouns, and discourse connectives. Moreover, based on the research on well-formed texts and learner essays, we will attempt to examine more effective features and models to better cover the discourse aspects of spontaneous speech. For example, local semantic features related to inter-sentential coherence and the ISA feature will be investigated on spoken responses. In addition, we will apply the features and build coherence models using the output of automatic speech recognition in addition to human transcriptions. Finally, various coherence features or models will be integrated into a practical automated scoring system, and further experiments will be performed to measure their effect on the performance of automated assessment of spontaneous spoken responses.

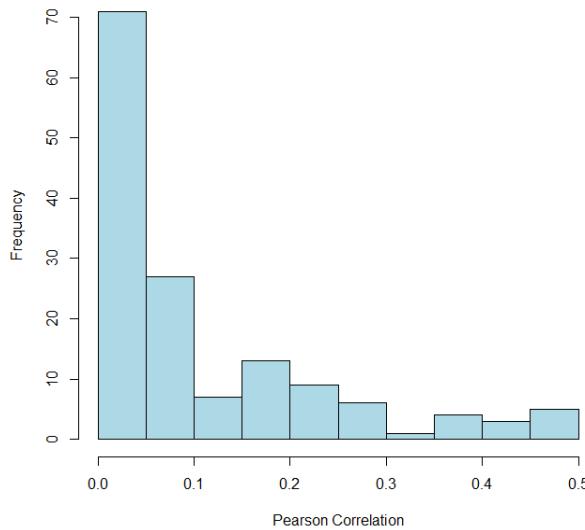

Figure1. Histogram of entity-grid and writing quality features based on their correlations with coherence scores

3 Conclusion

In this paper, we present a corpus of coherence annotations for spontaneous spoken responses provided in the context of an English speaking profi-

ciency assessment. Entity-grid features and features from an automated essay scoring system were examined for coherence modeling of spoken responses. The analysis on the annotated corpus showed promising results for improving the performance of an automated scoring system by means of modeling the coherence of spoken responses.

Acknowledgments

The authors wish to express our thanks to the discourse annotators Melissa Lopez and Matt Mulholand for their dedicated work and our colleagues Jill Burstein and Slava Andreyev for their support in generating entity-grid features.

Disfluency Detection Using Multi-step Stacked Learning

Xian Qian and Yang Liu
Computer Science Department
The University of Texas at Dallas
`{qx, yangl}@hlt.utdallas.edu`

Abstract

In this paper, we propose a multi-step stacked learning model for disfluency detection. Our method incorporates refined n-gram features step by step from different word sequences. First, we detect filler words. Second, edited words are detected using n-gram features extracted from both the original text and filler filtered text. In the third step, additional n-gram features are extracted from edit removed texts together with our newly induced in-between features to improve edited word detection. We use Max-Margin Markov Networks (M^3Ns) as the classifier with the weighted hamming loss to balance precision and recall. Experiments on the Switchboard corpus show that the refined n-gram features from multiple steps and M^3Ns with weighted hamming loss can significantly improve the performance. Our method for disfluency detection achieves the best reported F-score 0.841 without the use of additional resources.¹

1 Introduction

Detecting disfluencies in spontaneous speech can be used to clean up speech transcripts, which helps improve readability of the transcripts and make it easy for downstream language processing modules. There are two types of disfluencies: filler words including filled pauses (e.g., ‘uh’, ‘um’) and discourse markers (e.g., ‘I mean’, ‘you know’), and edited words that are repeated, discarded, or corrected by

¹Our source code is available at <http://code.google.com/p/disfluency-detection/downloads/list>

the following words. An example is shown below that includes edited words and filler words.

I want a flight to Boston uh I mean to Denver
 edited filler

Automatic filler word detection is much more accurate than edit detection as they are often fixed phrases (e.g., “uh”, “you know”, “I mean”), hence our work focuses on edited word detection.

Many models have been evaluated for this task. Liu et al. (2006) used Conditional Random Fields (CRFs) for sentence boundary and edited word detection. They showed that CRFs significantly outperformed Maximum Entropy models and HMMs. Johnson and Charniak (2004) proposed a TAG-based noisy channel model which showed great improvement over boosting based classifier (Charniak and Johnson, 2001). Zwarts and Johnson (2011) extended this model using minimal expected F-loss oriented n-best reranking. They obtained the best reported F-score of 83.8% on the Switchboard corpus. Georgila (2009) presented a post-processing method during testing based on Integer Linear Programming (ILP) to incorporate local and global constraints.

From the view of features, in addition to textual information, prosodic features extracted from speech have been incorporated to detect edited words in some previous work (Kahn et al., 2005; Zhang et al., 2006; Liu et al., 2006). Zwarts and Johnson (2011) trained an extra language model on additional corpora, and used output log probabilities of language models as features in the reranking stage. They reported that the language model gained about absolute 3% F-score for edited word detection on the Switchboard development dataset.

In this paper, we propose a multi-step stacked learning approach for disfluency detection. In our method, we first perform filler word detection, then edited word detection. In every step, we generate new refined n-gram features based on the processed text (remove the detected filler or edited words from the previous step), and use these in the next step. We also include a new type of features, called in-between features, and incorporate them into the last step. For edited word detection, we use Max-Margin Markov Networks (M^3Ns) with weighted hamming loss as the classifier, as it can well balance the precision and recall to achieve high performance. On the commonly used Switchboard corpus, we demonstrate that our proposed method outperforms other state-of-the-art systems for edit disfluency detection.

2 Balancing Precision and Recall Using Weighted M^3Ns

We use a sequence labeling model for edit detection. Each word is assigned one of the five labels: *BE* (beginning of the multi-word edited region), *IE* (in the edited region), *EE* (end of the edited region), *SE* (single word edited region), *O* (other). For example, the previous sentence is represented as:

I/O want/O a/O flight/O to/BE Boston/EE uh/O I/O mean/O to/O Denver/O

We use the F-score as the evaluation metrics (Zwarts and Johnson, 2011; Johnson and Charniak, 2004), which is defined as the harmonic mean of the precision and recall of the edited words:

$$\begin{aligned} P &= \frac{\text{\#correctly predicted edited words}}{\text{\#predicted edited words}} \\ R &= \frac{\text{\#correctly predicted edited words}}{\text{\#gold standard edited words}} \\ F &= \frac{2 \times P \times R}{P + R} \end{aligned}$$

There are many methods to train the sequence model, such as CRFs (Lafferty et al., 2001), averaged structured perceptrons (Collins, 2002), structured SVM (Altun et al., 2003), online passive aggressive learning (Crammer et al., 2006). Previous work has shown that minimizing F-loss is more effective than minimizing log-loss (Zwarts and Johnson, 2011), because edited words are much fewer than normal words.

In this paper, we use Max-margin Markov Networks (Taskar et al., 2004) because our preliminary

results showed that they outperform other classifiers, and using weighted hamming loss is simple in this approach (whereas for perceptron or CRFs, the modification of the objective function is not straightforward).

The learning task for M^3Ns can be represented as follows:

$$\begin{aligned} \min_{\alpha} \quad & \frac{1}{2} C \left\| \sum_{x,y} \alpha_{x,y} \Delta f(x, y) \right\|_2^2 + \sum_{x,y} \alpha_{x,y} L(x, y) \\ \text{s.t.} \quad & \sum_y \alpha_{x,y} = 1 \quad \forall x \\ & \alpha_{x,y} \geq 0, \quad \forall x, y \end{aligned}$$

The above shows the dual form for training M^3Ns , where x is the observation of a training sample, $y \in \mathcal{Y}$ is a label. α is the parameter needed to be optimized, $C > 0$ is the regularization parameter. $\Delta f(x, y)$ is the residual feature vector: $f(x, \tilde{y}) - f(x, y)$, where \tilde{y} is the true label of x . $L(x, y)$ is the loss function. Taskar et al. (2004) used un-weighted hamming loss, which is the number of incorrect components: $L(x, y) = \sum_t \delta(y_t, \tilde{y}_t)$, where $\delta(a, b)$ is the binary indicator function (it is 0 if $a = b$). In our work, we use the weighted hamming loss:

$$L(x, y) = \sum_t v(y_t, \tilde{y}_t) \delta(y_t, \tilde{y}_t)$$

where $v(y_t, \tilde{y}_t)$ is the weighted loss for the error when \tilde{y}_t is mislabeled as y_t . Such a weighted loss function allows us to balance the model's precision and recall rates. For example, if we assign a large value to $v(O, \cdot E)$ ($\cdot E$ denotes SE, BE, IE, EE), then the classifier is more sensitive to false negative errors (edited word misclassified as non-edited word), thus we can improve the recall rate. In our work, we tune the weight matrix v using the development dataset.

3 Multi-step Stacked Learning for Edit Disfluency Detection

Rather than just using the above M^3Ns with some features, in this paper we propose to use stacked learning to incorporate gradually refined n-gram features. Stacked learning is a meta-learning approach (Cohen and de Carvalho, 2005). Its idea is to use two

(or more) levels of predictors, where the outputs of the low level predictors are incorporated as features into the next level predictors. It has the advantage of incorporating non-local features as well as non-linear classifiers. In our task, we do not just use the classifier’s output (a word is an edited word or not) as a feature, rather we use such output to remove the disfluencies and extract new n-gram features for the subsequent stacked classifiers. We use 10 fold cross validation to train the low level predictors. The following describes the three steps in our approach.

3.1 Step 1: Filler Word Detection

In the first step, we automatically detect filler words. Since filler words often occur immediately after edited words (before the corrected words), we expect that removing them will make rough copy detection easy. For example, in the previous example shown in Section 1, if “uh I mean” is removed, then the reparandum “to Boston” and repair “to Denver” will be adjacent and we can use word/POS based n-gram features to detect that disfluency. Otherwise, the classifier needs to skip possible filler words to find the rough copy of the reparandum.

For filler word detection, similar to edited word detection, we define 5 labels: BP , IP , EP , SP , O . We use un-weighted hamming loss to learn M^3Ns for this task. Since for filler word detection, our performance metric is not F-measure, but just the overall accuracy in order to generate cleaned text for subsequent n-gram features, we did not use the weighted hamming loss for this. The features we used are listed in Table 1. All n-grams are extracted from the original text.

3.2 Step 2: Edited Word Detection

In the second step, edited words are detected using M^3Ns with the weighted-hamming loss. The features we used are listed in Table 2. All n-grams in the first step are also used here. Besides that, word n-grams, POS n-grams and logic n-grams extracted from filler word removed text are included. Feature templates $I(w_0, w'_i)$ is to generate features detecting rough copies separated by filler words.

3.3 Step 3: Refined Edited Word Detection

In this step, we use n-gram features extracted from the text after removing edit disfluencies based on

unigrams	$w_0, w_{-1}, w_1, w_{-2}, w_2$ $p_0, p_{-1}, p_1, p_{-2}, p_2, w_0 p_0$
bigrams	$w_{-1}w_0, w_0w_1, p_{-1}p_0, p_0p_1$
trigrams	$p_{-2}p_{-1}p_0, p_{-1}p_0p_1, p_0p_1p_2$
logic unigrams	$I(w_i, w_0), I(p_i, p_0), -4 \leq i \leq 4$
logic bigrams	$I(w_{i-1}w_i, w_{-1}, w_0)$ $I(p_{i-1}p_i, p_{-1}p_0)$ $I(w_iw_{i+1}, w_0w_1)$ $I(p_ip_{i+1}, p_0p_1), -4 \leq i \leq 4$
transitions	$y_{-1}y_0$

Table 1: Feature templates for filler word detection. w_0, p_0 denote the current word and POS tag respectively. w_{-i} denotes the i^{th} word to the left, w_i denotes the i^{th} word to the right. The logic function $I(a, b)$ indicates whether a and b are identical (either unigrams or bigrams).

All templates in Table 1	
unigrams	w'_1, w'_2, w'_3, w'_4
bigrams	$p_0p'_1, p_0p'_2, p_0p'_3, p_0p'_4$ $w_0p'_1, w_0p'_2, w_0p'_3, w_0p'_4$ $w_0p_1, w_0p_2, w_0p_3, w_0p_4$
logic unigrams	$I(w_0, w'_i), 1 \leq i \leq 4$
transitions	$p_0y_{-1}y_0$

Table 2: Feature templates for edit detection (step 2). w'_i, p'_i denote the i^{th} word/POS tag to the right in the filler words removed text. If current word w_0 is removed in step 1, we use its original n-gram features rather than the refined n-gram features.

the previous step. According to our analysis of the errors produced by step 2, we observed that many errors occurred at the boundaries of the disfluencies, and the word bigrams after removing the edited words are unnatural. The following is an example:

- **Ref:** *The new type is prettier than what their/SE they used to look like.*
- **Sys:** *The new type is prettier than what/BE their/EE they used to look like.*

Using the system’s prediction, we would have bi-gram *than they*, which is odd. Usually, the pronoun following *than* is accusative case. We expect adding n-gram features derived from the cleaned-up sentences would allow the new classifier to fix such hypothesis. This kind of n-gram features is similar to the language models used in (Zwarts and Johnson,

2011). They have the benefit of measuring the fluency of the cleaned text.

Another common error we noticed is caused by the ambiguities of coordinates, because the coordinates have similar patterns as rough copies. For example,

- **Coordinates:** *they ca n't decide which are the good aspects and which are the bad aspects*
- **Rough Copies:** *it/BE 's/IE a/IE pleasure/IE to/EE it s good to get outside*

To distinguish the rough copies and the coordinate examples shown above, we analyze the training data statistically. We extract all the pieces lying between identical word bigrams $AB \dots AB$. The observation is that coordinates are often longer than edited sequences. Hence we introduce the in-between features for each word. If a word lies between identical word bigrams, then its in-between feature is the log length of the subsequence lying between the two bigrams; otherwise, it is zero (we use log length to avoid sparsity). We also used other patterns such as $A \dots A$ and $ABC \dots ABC$, but they are too noisy or infrequent and do not yield much performance gain.

Table 3 lists the feature templates used in this last step.

All templates in Table 1, Table 2	
word n-grams	$w''_1, w_0w''_1$
in-between	$L_{AB}, w_0b_{AB}, b_{AB}$

Table 3: Feature templates for refined edit detection (step 3). w''_i denotes the i^{th} word tag to the right in the edited word removed text. L_{AB} denotes the log length of the sub-sequence in the pattern $AB\dots AB$, b_{AB} indicates whether the current word lies between two identical bigrams.

4 Experiments

4.1 Experimental Setup

We use the Switchboard corpus in our experiment, with the same train/develop/test split as the previous work (Johnson and Charniak, 2004). We also remove the partial words and punctuation from the training and test data for the reason to simulate the situation when speech recognizers are used and

such kind of information is not available (Johnson and Charniak, 2004).

We tuned the weight matrix for hamming loss on the development dataset using simple grid search. The diagonal elements are fixed at 0; for false positive errors, $O \rightarrow \cdot E$ (non-edited word mis-labeled as edited word), their weights are fixed at 1; for false negative errors, $\cdot E \rightarrow O$, we tried the weight from 1 to 3, and increased the weight 0.5 each time. The optimal weight matrix is shown in Table 4. Note that we use five labels in the sequence labeling task; however, for edited word detection evaluation, it is only a binary task, that is, all of the words labeled with $\cdot E$ will be mapped to the class of edited words.

truth \ predict	BE	IE	EE	SE	O
BE	0	1	1	1	2
IE	1	0	1	1	2
EE	1	1	0	1	2
SE	1	1	1	0	2
O	1	1	1	1	0

Table 4: Weighted hamming loss for M^3Ns .

4.2 Results

We compare several sequence labeling models: CRFs, structured averaged perceptron (AP), M^3Ns with un-weighted/weighted loss, and online passive-aggressive (PA) learning. For each model, we tuned the parameters on the development data: Gaussian prior for CRFs is 1.0, iteration number for AP is 10, iteration number and regularization penalty for PA are 10 and 1. For M^3Ns , we use Structured Sequential Minimal Optimization (Taskar, 2004) for model training. Regularization penalty is $C = 0.1$ and iteration number is 30.

Table 5 shows the results using different models and features. The baseline models use only the n-grams features extracted from the original text. We can see that M^3Ns with the weighted hamming loss achieve the best performance, outperforming all the other models. Regarding the features, the gradually added n-gram features have consistent improvement for all models. Using the weighted hamming loss in M^3Ns , we observe a gain of 2.2% after deleting filler words, and 1.8% after deleting edited words. In our analysis, we also noticed that the in-between fea-

Baseline	78.8	79.0	78.9	79.4	80.1
Step 2	81.0	81.1	81.1	81.5	82.3
Step 3	82.9	83.0	82.8	83.3	84.1

Table 5: Effect of training strategy and recovered features for stacked learning. F scores are reported. AP = Averaged Perceptron, PA = online Passive Aggressive, M^3N = un-weighted M^3Ns , w. M^3N = weighted M^3Ns .

tures yield about 1% improvement in F-score for all models (the gain of step 3 over step 2 is because of the in-between features and the new n-gram features extracted from the text after removing previously detected edited words). We performed McNemar’s test to evaluate the significance of the difference among various methods, and found that when using the same features, weighted M^3Ns significantly outperforms all the other models (p value < 0.001). There are no significant differences among CRFs, AP and PA. Using recovered n-gram features and in-between features significantly improves all sequence labeling models (p value < 0.001).

We also list the state-of-the-art systems evaluated on the same dataset, as shown in Table 6. We achieved the best F-score. The most competitive system is (Zwarts and Johnson, 2011), which uses extra resources to train language models.

System	F score
(Johnson and Charniak, 2004)	79.7
(Kahn et al., 2005)	78.2
(Zhang et al., 2006) [†]	81.2
(Georgila, 2009)*	80.1
(Zwarts and Johnson, 2011) ⁺	83.8
This paper	84.1

Table 6: Comparison with other systems. [†] they used the re-segmented Switchboard corpus, which is not exactly the same as ours. * they reported the F-score of BE tag (beginning of the edited sequences). ⁺ they used language model learned from 3 additional corpora.

5 Conclusion

In this paper, we proposed multi-step stacked learning to extract n-gram features step by step. The first level removes the filler words providing new ngrams for the second level to remove edited words. The

third level uses the n-grams from the original text and the cleaned text generated by the previous two steps for accurate edit detection. To minimize the F-loss approximately, we modified the hamming loss in M^3Ns . Experimental results show that our method is effective, and achieved the best reported performance on the Switchboard corpus without the use of any additional resources.

Using Semantic Unification to Generate Regular Expressions from Natural Language

Nate Kushman Regina Barzilay

`{nkushman, regina}@csail.mit.edu`

Abstract

We consider the problem of translating natural language text queries into regular expressions which represent their meaning. The mismatch in the level of abstraction between the natural language representation and the regular expression representation make this a novel and challenging problem. However, a given regular expression can be written in many semantically equivalent forms, and we exploit this flexibility to facilitate translation by finding a form which more directly corresponds to the natural language. We evaluate our technique on a set of natural language queries and their associated regular expressions which we gathered from Amazon Mechanical Turk. Our model substantially outperforms a state-of-the-art semantic parsing baseline, yielding a 29% absolute improvement in accuracy.¹

1 Introduction

Regular expressions (regexps) have proven themselves to be an extremely powerful and versatile formalism that has made its way into everything from spreadsheets to databases. However, despite their usefulness and wide availability, they are still considered a dark art that even many programmers do not fully understand (Friedl, 2006). Thus, the ability to automatically generate regular expressions from natural language would be useful in many contexts.

Our goal is to learn to generate regexps from natural language, using a training set of natural language and regular expression pairs such as the one in Figure 1. We do not assume that the data includes an alignment between fragments of the natural language and fragments of the regular expression. In

¹The dataset used in this work is available at <http://groups.csail.mit.edu/rbg/code/regexp/>

Text Description	Regular Expression
three letter word starting with 'X'	<code>\bX[A-Za-z]{2}\b</code>

Figure 1: An example text description and its associated regular expression.³

ducing such an alignment during learning is particularly challenging because oftentimes even humans are unable to perform a *fragment-by-fragment* alignment.

We can think of this task as an instance of grounded semantic parsing, similar to the work done in the domain of database queries (Kate and Mooney, 2006; Zettlemoyer and Collins, 2005; Kwiatkowski et al., 2010). However, the current success in semantic parsing relies on two important properties of the data. First, while the past work did not assume the alignment was given, they did assume that finding a fine grained fragment-by-fragment alignment was possible. Secondly, the semantic domains considered in the past were strongly typed. This typing provides constraints which significantly reduce the space of possible parses, thereby greatly reducing the ambiguity.

However, in many interesting domains these two properties may not hold. In our domain, the alignment between the natural language and the regular expressions often happens at the level of the whole phrase, making fragment-by-fragment alignment impossible. For example, in Figure 1 no fragment of the regexp maps clearly to the phrase “three letter”. Instead, the regexp explicitly represents the fact that there is only two characters after X, which is not stated explicitly by the text description and must be inferred. Furthermore, regular expressions have

³Our regular expression syntax supports Perl regular expression shorthand which utilizes `\b` to represent a break (i.e. a space or the start or end of the line). Our regular expression syntax also supports intersection (&) and complement (^).

$([A-Za-z]\{3\}) \& (\backslash b[A-Za-z]+\backslash b) \& (X.\star)$

three letter	$[A-Za-z]\{3\}$
word	$\backslash b[A-Za-z]+\backslash b$
starting with 'X'	$X.\star$
(b)	

Figure 2: (a) shows a regexp which is semantically equivalent to that in Figure 1, yet admits a fragment-by-fragment mapping to the natural language. (b) shows this mapping.

relatively few type constraints.

The key idea of our work is to utilize semantic unification in the logical domain to disambiguate the meaning of the natural language. Semantic unification utilizes an inference engine to determine the semantic equality of two syntactically divergent expressions. This is a departure from past work on semantic parsing which has largely focused on the *syntactic* interface between the natural language and the logical form, and on example-based semantic equality, neither of which utilize the inference power inherent in many symbolic domains.

To see how we can take advantage of semantic unification, consider the regular expression in Figure 2(a). This regular expression is semantically equivalent to the regular expression in Figure 1. Furthermore, it admits a fragment-by-fragment mapping as can be seen in Figure 2(b). In contrast, as we noted earlier, the regexp in Figure 1 does not admit such a mapping. In fact, learning can be quite difficult if our training data contains only the regexp in Figure 1. We can, nonetheless, use the regexp in Figure 2 as a stepping-stone for learning if we can use semantic inference to determine the equivalence between the two regular expressions. More generally, whenever the regexp in the training data does not factorize in a way that facilitates a direct mapping to the natural language description, we must find a regexp *which does factorize* and be able to compute its equivalence to the regexp we see in the training data. We compute this equivalence by converting each regexp to a minimal deterministic finite automaton (DFA) and leveraging the fact that minimal DFAs are guaranteed to be the same for semantically equivalent regexps (Hopcroft et al., 1979).

We handle the additional ambiguity stemming from the weak typing in our domain through the use of a more effective parsing algorithm. The state of the art semantic parsers (Kwiatkowski et al., 2011;

Liang et al., 2011) utilize a pruned chart parsing algorithm which fails to represent many of the top parses and is prohibitively slow in the face of weak typing. In contrast, we use an n-best parser which always represents the most likely parses, and can be made very efficient through the use of the parsing algorithm from Jimenez and Marzal (2000).

Our approach works by inducing a combinatory categorial grammar (CCG) (Steedman, 2001). This grammar consists of a lexicon which pairs words or phrases with regular expression functions. The learning process initializes the lexicon by pairing each sentence in the training data with the full regular expression associated with it. These lexical entries are iteratively refined by considering all possible ways to split the regular expression and all possible ways to split the phrase. At each iteration we find the n-best parses with the current lexicon, and find the subset of these parses which are correct using DFA equivalence. We update the weights of a log-linear model based on these parses and the calculated DFA equivalence.

We evaluate our technique using a dataset of sentence/regular expression pairs which we generated using Amazon Mechanical Turk (Turk, 2013). We find that our model generates the correct regexp for 66% of sentences, while the state-of-the-art semantic parsing technique from Kwiatkowski et al. (2010) generates correct regexps for only 37% of sentences. The results confirm our hypothesis that leveraging the inference capabilities of the semantic domain can help disambiguate natural language meaning.

2 Related Work

Generating Regular Expressions Past work has looked at generating regular expressions from natural language using rule based techniques (Ranta, 1998), and also at automatically generating regular expressions from examples (Angluin, 1987). To the best of our knowledge, however, our work is the first to use training data to learn to automatically generate regular expressions from natural language.

Language Grounding There is a large body of research mapping natural language to some form of meaning representation (Kate and Mooney, 2006; Kate et al., 2005; Raymond and Mooney, 2006; Thompson and Mooney, 2003; Wong and Mooney,

2006; Wong and Mooney, 2007; Zelle and Mooney, 1996; Branavan et al., 2009; Mihalcea et al., 2006; Poon and Domingos, 2009). In some of the considered domains the issue of semantic equivalence does not arise because of the way the data is generated. The most directly related work in these domains, is that by Kwiatkowski et al. (2010 and 2011) which is an extension of earlier work on CCG-based semantic parsing by Zettlemoyer and Collins (2005). Similar to our work, Kwiatkowski et al. utilize unification to find possible ways to decompose the logical form. However, they perform only *syntactic unification*. Syntactic unification determines equality using only variable substitutions and does not take advantage of the inference capabilities available in many semantic domains. Thus, syntactic unification is unable to determine the equivalence of two logical expressions which use different lexical items, such as “ $\cdot \ast$ ” and “ $\cdot \ast \cdot \ast$ ”. In contrast, our DFA based technique can determine the equivalence of such expressions. It does this by leveraging the equational inference capabilities of the regular expression domain, making it a form of *semantic unification*. Thus, the contribution of our work is to show that using semantic unification to find a deeper level of equivalence helps to disambiguate language meanings.

In many other domains of interest, determining semantic equivalence is important to the learning process. Previous work on such domains has focused on either heuristic or example-driven measures of semantic equivalence. For example, Artzi and Zettlemoyer (2011) estimate semantic equivalence using a heuristic loss function. Other past work has executed the logical form on an example world or in a situated context and then compared the outputs. This provides a very weak form of semantic equivalence valid only in that world/context (Clarke et al., 2010; Liang et al., 2009; Liang et al., 2011; Chen and Mooney, 2011; Artzi and Zettlemoyer, 2013). In contrast, our work uses an exact, theoretically sound measure of semantic equivalence that determines whether two logical representations are equivalent in *any* context, i.e. on any input string.

3 Background

3.1 Finding Regexp Equivalence Using DFAs

Regular expressions can be equivalently represented as minimal DFAs, which are guaranteed to be equal

function sig.	regexp		function signature	regexp
cons(R,R,...)	ab		rep*(R)	a^*
and(R,R,...)	[a-b] & [b-c]		repminmax(I,I,R)	$a\{3,5\}$
or(R,R,...)	a b		repmin(I,R)	$a\{3,\}$
not(R)	$\sim(a)$		repexact(I,R)	$a\{3\}$

Figure 3: This shows the signatures of all functions in our lambda calculus along with their regexp syntax.

for the same regular language (Hopcroft et al., 1979). The DFA representation of a regular expression may be exponentially larger than the original regular expression. However, past work has shown that most regular expressions do not exhibit this exponential behavior (Tabakov and Vardi, 2005; Moreira and Reis, 2012), and the conversion process is renowned for its good performance in practice (Moreira and Reis, 2012). Hence, we compare the equivalence of two regular expressions by converting them to minimal DFAs and comparing the DFAs. We do this using a modified version of Møller (2010).⁴

3.2 Lambda Calculus Representation

To take advantage of the inherent structure of regular expressions, we deterministically convert them from a flat string representation into simply typed lambda calculus expressions. The full set of functions available in our lambda calculus can be seen in Figure 3. As can be seen from the figures, our lambda calculus is very weakly typed. It has only two primitive types, integer (I) and regexp (R), with most arguments being of type R.

3.3 Parsing

Our parsing model is based on a Combinatory Categorical Grammar. In CCG parsing most of the grammar complexity is contained in the lexicon, Λ , while the parser itself contains only a few simple rewrite rules called combinators.

Lexicon The lexicon, Λ , consists of a set of lexical entries that couple natural language with a lambda calculus expression. Our lexical entries contain words or phrases, each of which is associated with a function from the lambda calculus we described in §3.2. For example:

⁴We set a timeout on this process to catch any cases where the resulting DFA might be prohibitively large. We use a one second timeout in our experiments, which results in timeouts on less than 0.25% of the regular expressions.

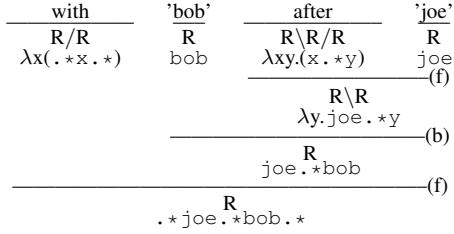

Figure 4: This shows an example parse.

$$\langle \text{after}, R\backslash R/R: \lambda xy.(x.*y) \rangle \\ \langle \text{at least}, R/I/R: \lambda xy.((x)\{y,\}) \rangle$$

Note that the lambda expressions contain type information indicating the number of arguments and the type of those arguments as described in §3.2. However, this information is augmented with a $(/)$ or a (\backslash) for each argument indicating whether that argument comes from the left or the right, in sentence order. Thus $R\backslash R/R$ can be read as a function which first takes an argument of type R on the right then takes another argument of type R on the left, and returns an expression of type R .

Combinators Parses are built by combining lexical entries through the use of a set of combinators. Our parser uses only the two most basic combinators, forward function application and backward function application.⁵ These combinators work as follows:

$$R/R:f \quad R:g \rightarrow R:f(g) \quad (\text{forward}) \\ R:f \quad R\backslash R:g \rightarrow R:g(f) \quad (\text{backward})$$

The forward combinator applies a function to an argument on its right when the type of the argument matches the type of the function's first argument. The backward combinator works analogously. Figure 4 shows an example parse.

4 Parsing Model

For a given lexicon, Λ , and sentence, \vec{w} , there will in general be many valid parse trees, $t \in T(\vec{w}; \Lambda)$. We assign probabilities to these parses using a standard log-linear parsing model with parameters θ :

$$p(t|\vec{w}; \theta, \Lambda) = \frac{e^{\theta \cdot \phi(t, \vec{w})}}{\sum_{t'} e^{\theta \cdot \phi(t', \vec{w})}}$$

Our training data, however, includes only the correct regular expression, r , and not the correct parse,

⁵Technically, this choice of combinators makes our model just a Categorial Grammar instead of a CCG.

t . The training objective used by the past work in such circumstances, is to maximize the probability of the correct regular expression by marginalizing over all parses which generate that exact regular expression. Such an objective is limited, however, because it does not allow parses that generate semantically correct regexps which are not syntactically equivalent to r , such as those in Figure 2. The main departure of our work is to use an objective which allows such parses through the use of the `DFA-EQUAL` procedure. `DFA-EQUAL` uses the process described in §3.1 to determine whether parse t evaluates to a regexp which is semantically equivalent to r , leading to the following objective:

$$O = \sum_i \log \sum_{t | \text{DFA-EQUAL}(t, r_i)} p(t|\vec{w}_i; \theta, \Lambda) \quad (1)$$

At testing time, for efficiency reasons, we calculate only the top parse. Specifically, if $r = \text{eval}(t)$ is the regexp which results from evaluating parse t , then we generate $t^* = \arg \max_{t \in T(\vec{w})} p(t|\vec{w}; \theta, \Lambda)$, and return $r^* = \text{eval}(t^*)$.

5 Learning

Our learning algorithm starts by generating a single lexical entry for each training sample which pairs the full sentence, \vec{w}_i , with the associated regular expression, r_i . Formally, we initialize the lexicon as $\Lambda = \{\langle \vec{w}_i, R : r_i \rangle | i = 1 \dots n\}$. We then run an iterative process where in each iteration we update both Λ and θ for each training sample. Our initial Λ will perfectly parse the training data. However it won't generalize at all to the test data since the lexical entries contain only full sentences. Hence, in each iteration we refine the lexicon by splitting existing lexical entries to generate more granular lexical entries which will generalize better. The candidates for splitting are all lexical entries used by parses which generate the correct regular expression, r_i , for the current training sample. We consider all possible ways to factorize each lexical entry, and we add to Λ a new lexical entry for each possible factorization, as discussed in §5.2. Finally, we update θ by performing a single stochastic gradient ascent update step for each training sample, as discussed in §5.1. See Algorithm 1 for details.

This learning approach follows the structure of the previous work on CCG based semantic parsers (Zettlemoyer and Collins, 2005;

Inputs: Training set of sentence regular expression pairs.
 $\{\langle \vec{w}_i, r_i \rangle | i = 1 \dots n\}$

Functions:

- $\text{N-BEST}(\vec{w}; \theta, \Lambda)$ n-best parse trees for \vec{w} using the algorithm from §5.1
- $\text{DFA-EQUAL}(t, r)$ calculates the equality of the regexp from parse t and regexp r using the algorithm from §3.1
- $\text{SPLIT-LEX}(T)$ splits all lexical entries used by any parse tree in set T , using the process described in §5.2

Initialization: $\Lambda = \{\langle \vec{w}_i, R : r_i \rangle | i = 1 \dots n\}$

For $k = 1 \dots K, i = 1 \dots n$

Update Lexicon: Λ

- $T = \text{N-BEST}(\vec{w}_i; \theta, \Lambda)$
- $C = \{t | t \in T \wedge \text{DFA-EQUAL}(t, r_i)\}$
- $\Lambda = \Lambda \cup \text{SPLIT-LEX}(C)$

Update Parameters: θ

- $T = \text{N-BEST}(\vec{w}_i; \theta, \Lambda)$
- $C = \{t | t \in T \wedge \text{DFA-EQUAL}(t, r_i)\}$
- $\Delta = E_{p(t|t \in C)}[\phi(t, \vec{w})] - E_{p(t|t \in T)}[\phi(t, \vec{w})]$
- $\theta = \theta + \alpha \Delta$

Output: The lexicon and the parameters, (Λ, θ)

Algorithm 1: The full learning algorithm.

Kwiatkowski et al., 2010). However, our domain has distinct properties that led to three important departures from this past work.

First, we use the DFA based semantic unification process described in §3.1 to determine the set of correct parses when performing parameter updates. This is in contrast to the *syntactic* unification technique, used by Kwiatkowski et al. (2010), and the example based unification used by other semantic parsers, e.g. Artzi and Zettlemoyer (2011). Using semantic unification allows us to handle training data which does not admit a fragment-by-fragment mapping between the natural language and the regular expression, such as the example in Figure 2.

Second, our parser is based on the efficient n-best parsing algorithm of Jimenez and Marzal (2000) instead of the pruned chart parsing algorithm used by the past work (Zettlemoyer and Collins, 2005; Kwiatkowski et al., 2010). As we show in §8.2, this results in a parser which more effectively represents the most likely parses. This allows our parser to better handle the large number of potential parses that exist in our domain due to the weak typing.

Third, we consider splitting lexical entries used in *any* correct parse, while the past work (Zettlemoyer and Collins, 2005; Kwiatkowski et al., 2010) considers splitting only those used in the *best* parse. We

must utilize a less constrictive splitting policy since our domain does not admit the feature weight initialization technique used in the domains of the past work. We discuss this in §5.2.1. In the remainder of this section we discuss the process for learning θ and for generating the lexicon, Λ .

5.1 Estimating Theta

To estimate θ we will use stochastic gradient ascent, updating the parameters based on one training example at a time. Hence, we can differentiate the objective from equation 1 to get the gradient of parameter θ_j for training example i , as follows:

$$\frac{\partial O_i}{\partial \theta_j} = E_{p(t|\text{DFA-EQUAL}(t, r_i), \cdot)} [\phi_j(t, \vec{w}_i)] - E_{p(t| \cdot)} [\phi_j(t, \vec{w}_i)] \quad (2)$$

This gives us the standard log-linear gradient, which requires calculating expected feature counts. We define the features in our model over individual parse productions, admitting the use of dynamic programming to efficiently calculate the unconditioned expected counts. However, when we condition on generating the correct regular expression, as in the first term in (2), the calculation no longer factorizes, rendering exact algorithms computationally infeasible.

To handle this, we use an approximate gradient calculation based on the n-best parses. Our n-best parser uses an efficient algorithm developed originally by (Jimenez and Marzal, 2000), and subsequently improved by (Huang and Chiang, 2005). This algorithm utilizes the fact that the first best parse, t_1 , makes the optimal choice at each decision point, and the 2nd best parse, t_2 must make the same optimal choice at every decision point, *except for one*. To execute on this intuition, the algorithm first calculates t_1 by generating an unpruned CKY-style parse forest which includes a priority queue of possible subparsing for each constituent. The set of possible 2nd best parses T are those that choose the 2nd best subparse for exactly one constituent of t_1 but are otherwise identical to t_1 . The algorithm chooses $t_2 = \arg \max_{t \in T} p(t)$. More generally, T is maintained as a priority queue of possible nth best parses. At each iteration, i , the algorithm sets $t_i = \arg \max_{t \in T} p(t)$ and augments T by all parses which both differ from t_i at exactly one constituent c_i and choose the next best possible subparse for c_i .

We use the n-best parses to calculate an approximate version of the gradient. Specifically, T_i is the

set of n-best parses for training sample i , and C_i includes all parses t in T_i such that $\text{DFA-EQUAL}(t, r_i)$. We calculate the approximate gradient as:

$$\Delta = E_{p(t|t \in C_i; \theta, \Lambda)}[\phi(t, \vec{w}_i)] - E_{p(t|t \in T_i; \theta, \Lambda)}[\phi(t, \vec{w}_i)] \quad (3)$$

In contrast to our n-best technique, the past work has calculated equation (2) using a beam search approximation of the full inside-outside algorithm (Zettlemoyer and Collins, 2005; Kwiatkowski et al., 2010; Liang et al., 2011). Specifically, since the conditional probability of t given r does not factorize, a standard chart parser would need to maintain the full logical form (i.e. regular expression) for each subparse, and there may be an exponential number of such subparsing at each chart cell. Thus, they approximate this full computation using beam search, maintaining only the m-best logical forms at each chart cell.

Qualitatively, our n-best approximation always represents the most likely parses in the approximation, but the number of represented parses scales only linearly with n . In contrast, the number of parses represented by the beam search algorithm of the past work can potentially scale exponentially with the beam size, m , due to its use of dynamic programming. However, since the beam search prunes myopically at each chart cell, it often prunes out the highest probability parses. In fact, we find that the single most likely parse is pruned out almost 20% of the time. Furthermore, our results in §8 show that the beam search’s inability to represent the likely parses significantly impacts the overall performance. It is also important to note that the runtime of the n-best algorithm scales much better. Specifically, as n increases, the n-best runtime increases as $O(n|\vec{w}| \log(|\vec{w}| |P| + n))$, where P is the set of possible parse productions. In contrast, as m is increased, the beam search runtime scales as $O(|\vec{w}|^5 m^2)$, where the $|\vec{w}|^5$ factor comes from our use of headwords, as discussed in §6. In practice, we find that even with n set to 10,000 and m set to 200, our algorithm still runs almost 20 times faster.

5.2 Lexical Entry Splitting

Each lexical entry consists of a sequence of n words aligned to a typed regular expression function, $\langle w_{0:l}, T : r \rangle$. Our splitting algorithm considers all possible ways to split a lexical entry into two new

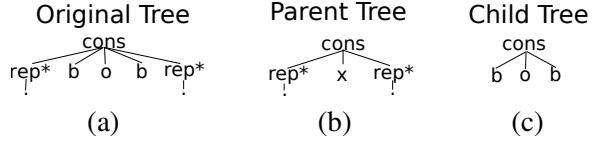

Figure 5: The tree in (a) represents the lambda expression from the lexical entry $\langle \text{with bob}, R: . * \text{bob} . * \rangle$. One possible split of this lexical entry generates the parent lexical entry $\langle \text{with}, R/R: \lambda x. (. * x . *) \rangle$ and the child lexical entry, $\langle \text{bob}, R: \text{bob} \rangle$, whose lambda expressions are represented by (b) and (c), respectively.

lexical entries such that they can be recombined via function application to obtain the original lexical entry. This process is analogous to the syntactic unification process done by Kwiatkowski et al. (2010).

We first consider all possible ways to split the lambda expression r . The splitting process is most easily explained using a tree representation for r , as shown in Figure 5(a). This tree format is simply a convenient visual representation of a lambda calculus function, with each node representing one of the function type constants from Figure 3. Each split, $s \in S(r)$, generates a child expression s_c and a parent expression s_p such that $r = s_p(s_c)$. For each node, n , in r besides the root node, we generate a split where s_c is the subtree rooted at node n . For such splits, s_p is the lambda expression r with the sub-expression s_c replaced with a bound variable, say x . In addition to these simple splits, we also consider a set of more complicated splits at each node whose associated function type constant can take any number of arguments, i.e. or, and, or cons. If $C(n)$ are the children of node n , then we generate a split for each possible subset, $\{V | V \subset C(n)\}$. Note that for cons nodes V must be contiguous. In §6 we discuss additional restrictions placed on the splitting process to avoid generating an exponential number of splits. For the split with subset V , the child tree, s_c , is a version of the tree rooted at node n pruned to contain only the children in V . Additionally, the parent tree, s_p , is generated from r by replacing all the children in V with a single bound variable, say x . Figure 5 shows an example of such a split. We only consider splits in which s_c does not have any bound variables, so its type, T_c , is always either R or I . The type of s_p is then type of the original expression, T augmented by an additional argument of the child type, i.e. either T/T_c or $T \setminus T_c$.

Each split s generates two pairs of lexical entries,

one for forward application, and one for backward application. The set of such pairs of pairs is:

$$\begin{aligned} & \{(\langle w_{0:j}, T/T_c : s_p \rangle, \langle w_{j:l}, T_c : s_c \rangle), \\ & (\langle w_{0:j}, T_c : s_c \rangle, \langle w_{j:l}, T \setminus T_c : s_p \rangle) | \\ & (0 \leq j \leq l) \wedge (s \in S(r))\} \end{aligned}$$

5.2.1 Adding New Lexical Entries

Our model splits all lexical entries used in parses which generate correct regular expressions, i.e. those in C_i , and adds *all* of the generated lexical entries to Λ . In contrast, the previous work (Zettlemoyer and Collins, 2005; Kwiatkowski et al., 2010) has a very conservative process for adding new lexical entries. This process relies on a good initialization of the feature weights associated with a new lexical entry. They perform this initialization using a Giza++ alignment of the words in the training sentences with the names of functions in the associated lambda calculus expression. Such an initialization is ineffective in our domain since it has very few primitive functions and most of the training examples use more than half of these functions. Instead, we add new lexical entries more aggressively, and rely on the n-best parser to effectively ignore any lexicon entries which do not generate high probability parses.

6 Applying the Model

Features To allow inclusion of head words in our features, our chart cells are indexed by start word, end word, and head word. Thus for each parse production we have a set of features that combine the head word and CCG type, of the two children and the newly generated parent. Additionally, for each lexical entry $\langle \vec{w}_i, R : r_i \rangle \in \Lambda$, we have four types of features: (1) a feature for $\langle \vec{w}_i, R : r_i \rangle$, (2) a feature for \vec{w}_i , (3) a feature for $R : r_i$, and (4) a set of features indicating whether \vec{w}_i contains a string literal and whether the leaves of r_i contain any exact character matches (rather than character range matches).

Initialization In addition to the sentence level initialization discussed in §5 we also initialize the lexicon, Λ , with two other sets of lexical entries. The first set is all of the quoted string literals in the natural language phrases from the training set. Thus for the phrase, ‘lines with ‘bob’ twice’ we would add the lexical entry $\langle \text{'bob'}, R:\text{bob} \rangle$. We also add lexical entries for both numeric and word representations of numbers, such as $\langle 1, R:1 \rangle$ and $\langle \text{one}, R:1 \rangle$.

We add these last two types of lexical entries because learning them from the data is almost impossible due to data sparsity. Lastly, for every individual word in our training set vocabulary, we add an identity lexical entry whose lambda expression is just a function which takes one argument and returns that argument. This allows our parser to learn to skip semantically unimportant words in the natural language description, and ensures that it generates at least one parse for every example in the dataset. At test time we also add both identity lexical entries for every word in the test set vocabulary as well as lexical entries for every quoted string literal seen in the test queries. Note that the addition of these lexical entries requires only access to the test queries and does not make use of the regular expressions (i.e. labels) in the test data in any way.

Parameters We initialize the weight of all lexical entry features except the identity features to a default value of 1 and initialize all other features to a default weight of 0. We regularize our log-linear model using the L^2 -norm and a λ value of 0.001. We use a learning rate of $\alpha = 1.0$, set $n = 10,000$ in our n-best parser, and run each experiment with 5 random restarts and $K = 50$ iterations. We report results using the pocket algorithm technique originated by Gallant (1990).

Constraints on Lexical Entry Splitting To prevent the generation of an exponential number of splits, we constrain the lexical entry splitting process as follows:

- We only consider splits at nodes which are at most a depth of 2 from the root of the original tree.
- We limit lambda expressions to 2 arguments.
- In unordered node splits (`and` and `or`) the resulting child can contain at most 4 of the arguments.

These restrictions ensure the number of splits is at most an M-degree polynomial of the regexp size. The unification process used by Kwiatkowski et al. (2010) bounded the number of splits similarly.

7 Experimental Setup

Dataset Our dataset consists of 824 natural language and regular expression pairs gathered using Amazon Mechanical Turk (Turk, 2013) and oDesk (oDesk, 2013).⁶ On Mechanical Turk we asked workers to

⁶This is similar to the size of the datasets used by past work.

generate their own original natural language queries to capture a subset of the lines in a file (similar to UNIX `grep`). In order to compare to example based techniques we also ask the Mechanical Turk workers to generate 5 positive and 5 negative examples for each query. On oDesk we hired a set of programmers to generate regular expressions for each of these natural language queries. We split our data into 3 sets of 275 queries each and tested using 3-fold cross validation. We tuned our parameters separately on each development set but ended up with the same values in each case.

Evaluation Metrics We evaluate by comparing the generated regular expression for each sentence with the correct regular expression using our DFA equivalence technique. As discussed in §3.1 this metric is exact, indicating whether the generated regular expression is semantically equivalent to the correct regular expression. Additionally, as discussed in §6, our identity lexical entries ensure we generate a valid parse for every sentence, so we report only accuracy instead of precision and recall.

Baselines We compared against six different baselines. The *UBL* baseline uses the published code from Kwiatkowski et al. (2010) after configuring it to handle the lambda calculus format of our regular expressions.⁷ The other baselines are ablated and/or modified versions of our model. The *BeamParse* baselines replace the *N-BEST* procedure from Algorithm 1 with the beam search algorithm used for parsing by past CCG parsers (Zettlemoyer and Collins, 2005; Kwiatkowski et al., 2010).⁸ The *StringUnify* baseline replaces the *DFA-EQUAL* procedure from Algorithm 1 with exact regular expression string equality. The *HeuristicUnify* baselines strengthen this by replacing *DFA-EQUAL* with a smart heuristic form of semantic unification. Our heuristic unification procedure first flattens the regexp trees by merging all children into the parent node if they are both of the same type and of type `or`, `and`, or `cons`. It then sorts all children of the `and` and `or` operators. Finally, it converts both regexps back to a flat string and compares these strings for equivalence. This process should more effective than any

⁷This was done in consultation with the original authors.

⁸we set the beam size to 200, which is equivalent to the past work. With this setting, the slow runtime of this algorithm allowed us to run only two random restarts.

Model	Percent Correct
UBL	36.5%
BeamParse-HeuristicUnify	9.4%
BeamParse-HeuristicUnify-TopParse	22.1%
NBestParse-StringUnify	31.1%
NBestParse-ExampleUnify	52.3%
NBestParse-HeuristicUnify	56.8%
Our Full Model	65.5%

Table 1: Accuracy of our model and the baselines.

form of syntactic unification and any simpler heuristics. The *ExampleUnify* baseline represents the performance of the example based semantic unification techniques. It replaces *DFA-EQUAL* with a procedure that evaluates the regexp on all the positive and negative examples associated with the given query and returns true if all 10 are correctly classified. Finally, *BeamParse-HeuristicUnify-TopParse* uses the same algorithm as that for *BeamParse-HeuristicUnify* except that it only generates lexical entries from the top parse instead of all parses. This more closely resembles the conservative lexical entry splitting algorithm used by Kwiatkowski et al.

8 Results

Our model outperforms all of the baselines, as shown in Table 1. The first three baselines – *UBL*, *BeamParse-HeuristicUnify*, and *BeamParse-HeuristicUnify-TopParse* – represent the algorithm used by Kwiatkowski et al. Our model outperforms the best of these by over 30% in absolute terms and 180% in relative terms.

The improvement in performance of our model over the *NBestParse-StringUnify*, *NBestParse-ExampleUnify* and *NBestParse-HeuristicUnify* baselines highlights the importance of our DFA based semantic unification technique. Specifically, our model outperforms exact string based unification by over 30%, example based semantic unification by over 13% and our smart heuristic unification procedure by 9%. These improvements confirm that leveraging exact semantic unification during the learning process helps to disambiguate language meanings.

8.1 Effect of Additional Training Data

Table 2 shows the change in performance as we increase the amount of training data. We see that our model provides particularly large gains when there

%age of Data	15%	30%	50%	75%
NBestParse-HeuristicUnify	12.4%	26.4%	39.0%	45.4%
Our Model	29.0%	50.3%	58.7%	65.2%
Relative Gain	2.34x	1.91x	1.51x	1.43x

Table 2: Results for varying amounts of training data.

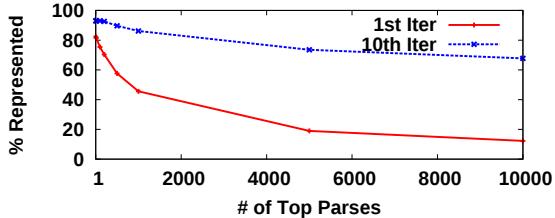

Figure 6: This graph compares the set of parses represented by the n-best algorithm used in our model to the set of parses represented by the beam search algorithm used by the past work. Note that our n-best algorithm represents 100% of the top 10000 parses.

is a small amount of training data. These gains decrease as the amount of training data increases because the additional data allows the baseline to learn new lexical entries for every special case. This reduces the need for the fine grained lexicon decomposition which is enabled by our DFA based unification. For example, our DFA based model will learn separate lexical entries for “line”, “word”, “starting with”, and “ending with”. The baseline instead will just learn separate lexical entries for every possible combination such as “line starting with”, “word ending with”, etc. Our model’s ability to decompose, however, allows it to provide equivalent accuracy to even the best baseline with less than half the amount of training data. Furthermore, we would expect this gain to be even larger for domains with more complex mappings and a larger number of different combinations.

8.2 Beam Search vs. N-Best

A critical step in the training process is calculating the expected feature counts over all parses that generate the correct regular expression. In §4 we discussed the trade-off between approximating this calculation using the n-best parses, as our model does, versus the beam search model used by the past work. The effect of this trade-off can be seen clearly in Figure 6. The n-best parser always represents the n-best

parses, which is set to 10,000 in our experiments. In contrast, on the first iteration, the beam search algorithm fails to represent the top parse almost 20% of the time and represents less than 15% of the 10,000 most likely parses. Even after 10 iterations it still only represents 70% of the top parses and fails to represent the top parse almost 10% of the time. This difference in representation ability is what provides the more than 30% difference in accuracy between the *BeamParse-HeuristicUnify* version of our model and the *NBestParse-HeuristicUnify* version of our model.

9 Conclusions and Future Work

In this paper, we present a technique for learning a probabilistic CCG which can parse a natural language text search into the regular expression that performs that search. The key idea behind our approach is to use a DFA based form of semantic unification to disambiguate the meaning of the natural language descriptions. Experiments on a dataset of natural language regular expression pairs show that our model significantly outperforms baselines based on a state-of-the-art model.

We performed our work on the domain of regular expressions, for which semantic unification is tractable. In more general domains, semantic unification is undecidable. Nevertheless, we believe our work motivates the use of semantic inference techniques for language grounding in more general domains, potentially through the use of some form of approximation or by restricting those domains in some way. For example, SAT and SMT solvers have seen significant success in performing semantic inference for program induction and hardware verification despite the computational intractability of these problems in the general case.

Abstract

In natural-language discourse, related events tend to appear near each other to describe a larger scenario. Such structures can be formalized by the notion of a *frame* (a.k.a. template), which comprises a set of related events and prototypical participants and event transitions. Identifying frames is a prerequisite for information extraction and natural language generation, and is usually done manually. Methods for inducing frames have been proposed recently, but they typically use ad hoc procedures and are difficult to diagnose or extend. In this paper, we propose the first probabilistic approach to frame induction, which incorporates frames, events, and participants as latent topics and learns those frame and event transitions that best explain the text. The number of frame components is inferred by a novel application of a split-merge method from syntactic parsing. In end-to-end evaluations from text to induced frames and extracted facts, our method produces state-of-the-art results while substantially reducing engineering effort.

1 Introduction

Events with causal or temporal relations tend to occur near each other in text. For example, a BOMBING scenario in an article on terrorism might begin with a DETONATION event, in which terrorists set off a bomb. Then, a DAMAGE event might ensue to describe the resulting destruction and any casualties, followed by an INVESTIGATION event

* This research was undertaken during the author's internship at Microsoft Research.

covering subsequent police investigations. Afterwards, the BOMBING scenario may transition into a CRIMINAL-PROCESSING scenario, which begins with police catching the terrorists, and proceeds to a trial, sentencing, etc. A common set of participants serves as the event arguments; e.g., the agent (or subject) of DETONATION is often the same as the theme (or object) of INVESTIGATION and corresponds to a PERPETRATOR.

Such structures can be formally captured by the notion of a *frame* (a.k.a. template, scenario), which consists of a set of *events* with prototypical transitions, as well as a set of *slots* representing the common participants. Identifying frames is an explicit or implicit prerequisite for many NLP tasks. Information extraction, for example, stipulates the types of events and slots that are extracted for a frame or template. Online applications such as dialogue systems and personal-assistant applications also model users' goals and subgoals using frame-like representations. In natural-language generation, frames are often used to represent contents to be expressed as well as to support surface realization.

Until recently, frames and related representations have been manually constructed, which has limited their applicability to a relatively small number of domains and a few slots within a domain. Furthermore, additional manual effort is needed after the frames are defined in order to extract frame components from text (e.g., in annotating examples and designing features to train a supervised learning model). This paradigm makes generalizing across tasks difficult, and might suffer from annotator bias.

Recently, there has been increasing interest in au-

tomatically inducing frames from text. A notable example is Chambers and Jurafsky (2011), which first clusters related verbs to form frames, and then clusters the verbs’ syntactic arguments to identify slots. While Chambers and Jurafsky (2011) represents a major step forward in frame induction, it is also limited in several aspects. The clustering used ad hoc steps and customized similarity metrics, as well as an additional retrieval step from a large external text corpus for slot generation. This makes it hard to replicate their approach or adapt it to new domains. Lacking a coherent model, it is also difficult to incorporate additional linguistic insights and prior knowledge.

In this paper, we present PROFINDER (PRObabilistic Frame INDucer), the first probabilistic approach to frame induction. PROFINDER defines a joint distribution over the words in a document and their frame assignments by modeling frame and event transitions, correlations among events and slots, and their surface realizations. Given a set of documents, PROFINDER outputs a set of induced frames with learned parameters, as well as the most probable frame assignments that can be used for event and entity extraction. The numbers of events and slots are dynamically determined by a novel application of the split-merge approach from syntactic parsing (Petrov et al., 2006). In end-to-end evaluations from text to entity extraction using standard MUC and TAC datasets, PROFINDER achieved state-of-the-art results while significantly reducing engineering effort and requiring no external data.

2 Related Work

In information extraction and other semantic processing tasks, the dominant paradigm requires two stages of manual effort. First, the target representation is defined manually by domain experts. Then, manual effort is required to construct an extractor or to annotate examples to train a machine-learning system. Recently, there has been a burgeoning body of work in reducing such manual effort. For example, a popular approach to reduce annotation effort is bootstrapping from seed examples (Patwardhan and Riloff, 2007; Huang and Riloff, 2012). However, this still requires prespecified frames or templates, and selecting seed words is often a challenging task

(Curran et al., 2007). Filatova et al. (2006) construct simple domain templates by mining verbs and the named entity type of verbal arguments that are topical, whereas Shinyama and Sekine (2006) identify query-focused slots by clustering common named entities and their syntactic contexts. Open IE (Banko and Etzioni, 2008) limits the manual effort to designing a few domain-independent relation patterns, which can then be applied to extract relational triples from text. While extremely scalable, this approach can only extract atomic factoids within a sentence, and the resulting triples are noisy, non-canonicalized text fragments.

More relevant to our approach is the recent work in unsupervised semantic induction, such as unsupervised semantic parsing (Poon and Domingos, 2009), unsupervised semantical role labeling (Swier and Stevenson, 2004) and induction (Lang and Lapata, 2011, e.g.), and slot induction from web search logs (Cheung and Li, 2012). As in PROFINDER, they model distributional contexts for slots and roles. However, these approaches focus on the semantics of independent sentences or queries, and do not capture discourse-level dependencies.

The modeling of frame and event transitions in PROFINDER is similar to a sequential topic model (Gruber et al., 2007), and is inspired by the successful applications of such topic models in summarization (Barzilay and Lee, 2004; Daumé III and Marcu, 2006; Haghghi and Vanderwende, 2009, inter alia). There are, however, two main differences. First, PROFINDER contains not a single sequential topic model, but two (for frames and events, respectively). In addition, it also models the interdependencies among events, slots, and surface text, which is analogous to the USP model (Poon and Domingos, 2009). PROFINDER can thus be viewed as a novel combination of state-of-the-art models in unsupervised semantics and discourse modeling.

In terms of aim and capability, PROFINDER is most similar to Chambers and Jurafsky (2011), which culminated from a series of work for identifying correlated events and arguments in narratives (Chambers and Jurafsky, 2008; Chambers and Jurafsky, 2009). By adopting a probabilistic approach, PROFINDER has a sound theoretical underpinning, and is easy to modify or extend. For example, in Section 3, we show how PROFINDER can easily be

augmented with additional linguistically-motivated features. Likewise, PROFINDER can easily be used as a semi-supervised system if some slot designations and labeled examples are available.

The idea of representing and capturing stereotypical knowledge has a long history in artificial intelligence and psychology, and has assumed various names such as *frames* (Minsky, 1974), *schemata* (Rumelhart, 1975), and *scripts* (Schank and Abelson, 1977). In the linguistics and computational linguistics communities, frame semantics (Fillmore, 1982) uses frames as the central representation of word meaning, culminating in the development of FrameNet (Baker et al., 1998), which contains over 1000 manually annotated frames. A similarly rich lexical resource is the MindNet project (Richardson et al., 1998). Our notion of frame is related to these representations, but there are also subtle differences. For example, Minsky’s frame emphasizes *inheritance*, which we do not model in this paper¹. As in semantic role labeling, FrameNet focuses on semantic roles and does not model event or frame transitions, so the scope of its frames is often no more than an event in our model. Perhaps the most similar to our frame is Roger Schank’s scripts, which capture prototypical events and participants in a scenario such as restaurant dining. In their approach, however, scripts are manually defined, making it hard to generalize. In this regard, our work may be viewed as an attempt to revive a long tradition in AI and linguistics, by leveraging the recent advances in computational power, NLP, and machine learning.

3 Probabilistic Frame Induction

In this section, we present PROFINDER, a probabilistic model for frame induction. Let \mathcal{F} be a set of frames, where each frame $F = (E_F, S_F)$ comprises a unique set of events E_F and slots S_F . Given a document D and a word w in D , $Z_w = (f, e)$ represents an assignment of w to frame $f \in \mathcal{F}$ and frame element $e \in E_f \cup S_f$. At the heart of PROFINDER is a generative model $P_\theta(D, Z)$ that defines a joint distribution over document D and the frame assignment to its words Z . Given a set of documents \mathcal{D} ,

¹This should be a straightforward extension — using the split-and-merge approach, PROFINDER already produces a hierarchy of events and slots in learning, although currently it makes no use of the intermediate levels.

frame induction in PROFINDER amounts to determining the number of events and slots in each frame, as well as learning the parameters θ by summing out the latent assignments Z to maximize the likelihood of the document set

$$\prod_{D \in \mathcal{D}} P_\theta(D).$$

The induced frames identify the key event structures in the document set. Additionally, PROFINDER can conduct event and entity extraction by computing the most probable frame assignment Z . In the remainder of the section, we first present the base model for PROFINDER. We then introduce several linguistically motivated refinements, as well as efficient algorithms for learning and inference in PROFINDER.

3.1 Base Model

The probabilistic formulation of PROFINDER makes it extremely flexible for incorporating linguistic intuition and prior knowledge. In this paper, we design our PROFINDER model to capture three types of dependencies.

Frame transitions between clauses A sentence contains one or more clauses, each of which is a minimal unit expressing a proposition. A clause is unlikely to straddle different frames, so we stipulate that the words in a clause be assigned to the same frame. On the other hand, frame transitions can happen between clauses, and we adopt the common Markov assumption that the frame of a clause only depends on the previous clause in the document. Clauses are automatically extracted from the dependency parse and further decomposed into an *event head* and its syntactic arguments.

Event transitions within a frame Events tend to transition into related events in the same frame, as determined by their causal or temporal relations. Each clause is assigned an event compatible with its frame assignment (i.e., the event is in the given frame). Like frame transitions, we assume that the event assignment of a clause depends only on the event of the previous clause.

Emission of event heads and slot words Similar to topics in topic models, each event determines

a multinomial from which the event head is generated; e.g., a DETONATION event might use verbs such as *detonate*, *set off* or nouns such as *detonation*, *bombing* as its event head. Additionally, as in USP (Poon and Domingos, 2009), an event also contains a multinomial of slots for each of its argument types²; e.g., the agent argument of a DETONATION event is generally the PERPETRATOR slot of the BOMBING frame. Finally, each slot has its own multinomials for generating the argument head and dependency label, regardless of the event.

Formally, let D be a document and C_1, \dots, C_l be its clauses, the PROFINDER model is defined by

$$\begin{aligned} P_\theta(D, Z) = & P_{\text{F-INIT}}(F_1) \times \prod_i P_{\text{F-TRAN}}(F_{i+1}|F_i) \\ & \times P_{\text{E-INIT}}(E_1|F_1) \\ & \times \prod_i P_{\text{E-TRAN}}(E_{i+1}|E_i, F_{i+1}, F_i) \\ & \times \prod_i P_{\text{E-HEAD}}(e_i|E_i) \\ & \times \prod_{i,j} P_{\text{SLOT}}(S_{i,j}|E_{i,j}, A_{i,j}) \\ & \times \prod_{i,j} P_{\text{A-HEAD}}(a_{i,j}|S_{i,j}) \\ & \times \prod_{i,j} P_{\text{A-DEP}}(\text{dep}_{i,j}|S_{i,j}) \end{aligned}$$

Here, F_i, E_i denote the frame and event assignment to clause C_i , respectively, and e_i denotes the event head. For the j -th argument of clause i , $S_{i,j}$ denotes the slot assignment, $A_{i,j}$ the argument type, $a_{i,j}$ the head word, and $\text{dep}_{i,j}$ the dependency from the event head. $P_{\text{E-TRAN}}(E_{i+1}|E_i, F_{i+1}, F_i) = P_{\text{E-INIT}}(E_{i+1}|F_{i+1})$ if $F_{i+1} \neq F_i$.

Essentially, PROFINDER combines a frame HMM with an event HMM, where the first models frame transition and emits events, and the second models event transition within a frame and emits argument slots.

3.2 Model refinements

The base model captures the main dependencies in event narrative, but it can be easily extended to lever-

²USP generates the argument types along with events from clustering. For simplicity, in PROFINDER we simply classify a syntactic argument into subject, object, and prepositional object, according to its Stanford dependency to the event head.

age additional linguistic intuition. PROFINDER incorporates three such refinements.

Background frame Event narratives often contain interjections of general content common to all frames. For example, in newswire articles, ATTRIBUTION is commonplace to describe who said or reported a particular quote or fact. To avoid contaminating frames with generic content, we introduce a background frame with its own events, slots, and emission distributions, and a binary switch variable $B_i \in \{BKG, CNT\}$ that determines whether clause i is generated from the actual content frame F_i (CNT) or background (BKG). We also stipulate that if BKG is chosen, the nominal frame stays the same as the previous clause.

Stickiness in frame and event transitions Prior work has demonstrated that promoting topic coherence in natural-language discourse helps discourse modeling (Barzilay and Lee, 2004). We extend PROFINDER to leverage this intuition by incorporating a “stickiness” prior (Haghghi and Vanderwende, 2009) to encourage neighboring clauses to stay in the same frame. Specifically, along with introducing the background frame, the frame transition component now becomes

$$P_{\text{F-TRAN}}(F_{i+1}|F_i, B_{i+1}) = \begin{cases} \mathbf{1}(F_{i+1} = F_i), & \text{if } B_{i+1} = BKG \\ \beta \mathbf{1}(F_{i+1} = F_i) + (1 - \beta) P_{\text{F-TRAN}}(F_{i+1}|F_i), & \text{if } B_{i+1} = CNT \end{cases} \quad (1)$$

where β is the stickiness parameter, and the event transition component correspondingly becomes

$$\begin{aligned} P_{\text{E-TRAN}}(E_{i+1}|E_i, F_{i+1}, F_i, B_{i+1}) = & \\ \begin{cases} \mathbf{1}(E_{i+1} = E_i), & \text{if } B_{i+1} = BKG \\ P_{\text{E-TRAN}}(E_{i+1}|E_i), & \text{if } B_{i+1} = CNT, F_i = F_{i+1} \\ P_{\text{E-INIT}}(E_{i+1}), & \text{if } B_{i+1} = CNT, F_i \neq F_{i+1} \end{cases} & \end{aligned} \quad (2)$$

Argument dependencies as caseframes As noticed in previous work such as Chambers and Jurafsky (2011), the combination of an event head and a dependency relation often gives a strong signal of the slot that is indicated. For example, *bomb* > *nsubj* (subject argument of *bomb*) often indicates a PERPETRATOR. Thus, rather than simply emitting

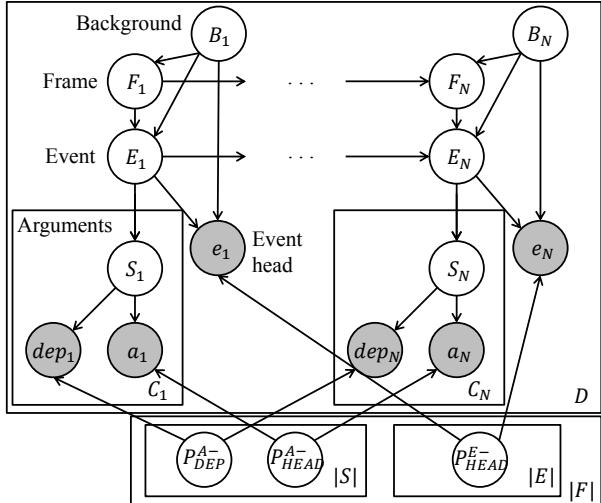

Figure 1: Graphical representation of our model. Hyperparameters, the stickiness factor, and the frame and event initial and transition distributions are not shown for clarity.

the dependency from the event head to an event argument $dep_{i,j}$, our model instead emits the pair of event head and dependency relation, which we call a *caseframe* following Bean and Riloff (2004).

3.3 Full generative story

To summarize, the distributions that are learned by our model are the default distributions $P_{\text{BKG}}(B)$, $P_{\text{F-INIT}}(F)$, $P_{\text{E-INIT}}(E)$; the transition distributions $P_{\text{F-TRAN}}(F_{i+1}|F_i)$, $P_{\text{E-TRAN}}(E_{i+1}|E_i)$; and the emission distributions $P_{\text{SLOT}}(S|E, A, B)$, $P_{\text{E-HEAD}}(e|E, B)$, $P_{\text{A-HEAD}}(a|S)$, $P_{\text{A-DEP}}(dep|S)$. We used additive smoothing with uniform Dirichlet priors for all the multinomials. The overall generative story of our model is as follows:

1. Draw a Bernoulli distribution for $P_{\text{BKG}}(B)$
2. Draw the frame, event, and slot distributions
3. Draw an event head emission distribution $P_{\text{E-HEAD}}(e|E, B)$ for each frame including the background frame
4. Draw event argument lemma and caseframe emission distributions for each slot in each frame including the background frame
5. For each clause in each document, generate the clause-internal structure.

The clause-internal structure at clause i is generated by the following steps:

1. Generate whether this clause is background ($B_i \in \{CNT, BKG\} \sim P_{\text{BKG}}(B)$)
2. Generate the frame F_i and event E_i from $P_{\text{F-INIT}}(F)$, $P_{\text{E-INIT}}(E)$, or according to equations 1 and 2
3. Generate the observed event head e_i from $P_{\text{E-HEAD}}(e_i|E_i)$.
4. For each event argument:
 - (a) Generate the slot $S_{i,j}$ from $P_{\text{SLOT}}(S|E, A, B)$.
 - (b) Generate the dependency/caseframe emission $dep_{i,j} \sim P_{\text{A-DEP}}(dep|S)$ and the lemma of the head word of the event argument $a_{i,j} \sim P_{\text{A-HEAD}}(a|S)$.

3.4 Learning and Inference

Our generative model admits efficient inference by dynamic programming. In particular, after collapsing the latent assignment of frame, event, and background into a single hidden variable for each clause, the expectation and most probable assignment can be computed using standard forward-backward and Viterbi algorithms on fixed tree structures.

Parameter learning can be done using EM by alternating the computation of expected counts and the maximization of multinomial parameters. In particular, PROFINDER uses incremental EM, which has been shown to have better and faster convergence properties than standard EM (Liang and Klein, 2009).

Determining the optimal number of events and slots is challenging. One solution is to adopt a non-parametric Bayesian method by incorporating a hierarchical prior over the parameters (e.g., a Dirichlet process). However, this approach can impose unrealistic restrictions on the model choice and result in intractability which requires sampling or approximate inference to overcome. Additionally, EM learning can suffer from local optima due to its non-convex learning objective, especially when dealing with a large number hidden states without a good initialization.

To address these issues, we adopt a novel application of the split-merge method previously used in syntactic parsing for inferring refined latent syntactic categories (Petrov et al., 2006). First, the model is initialized with a number of frames, which is a hyperparameter, and each frame is associated with

one event and two slots. Starting from this minimal structure, EM training begins. After a number of iterations, each event and slot state is “split” in two; that is, each original state now becomes two new states. Each of the new states is generated with half of the probability of the original, and contains a duplicate of the associated emission distributions. Some perturbation is then added to the probabilities to break symmetry. After splitting, we merge back a portion of the newly split events and slots that result in the least improvement in the likelihood of the training data. For more details on split-merge, see Petrov et al. (2006)

By adjusting the number of split-merge cycles and the merge parameters, our model learns the number of events and slots in a dynamical fashion that is tailored to the data. Moreover, our model starts with a small number of frame elements, which reduces the number of local optima and facilitates initial learning. After each split, the subsequent learning starts with (a perturbed version of) the previously learned parameters, which makes a good initialization that is crucial for EM. Finally, it is also compatible with the hierarchical nature of events and slots. For example, slots can first be coarsely split into persons versus locations, and later refined into subcategories such as perpetrators and victims.

4 MUC-4 Entity Extraction Experiments

We first evaluate our model on a standard entity extraction task, using the evaluation settings from Chambers and Jurafsky (2011) (henceforth, C&J) to enable a head-to-head comparison. Specifically, we use the MUC-4 data set (1992), which contains 1300 training and development documents on terrorism in South America, with 200 additional documents for testing. MUC-4 contains four templates: ATTACK, KIDNAPPING, BOMBING, and ARSON.³ All templates share the same set of predefined slots, with the evaluation focusing on the following four: PERPETRATOR, PHYSICAL TARGET, HUMAN TARGET, and INSTRUMENT.

For each slot in a MUC template, the system first identifies an induced slot that best maps to it by F_1 on the development set. As in C&J, tem-

³Two other templates have negligible counts and are ignored as in C&J.

plate is ignored in final evaluation, so all the clusters that belong to the same slot are then merged across the templates; e.g., the PERPETRATOR clusters for KIDNAPPING and BOMBING are merged. The final precision, recall, and F_1 are computed based on these merged clusters. Correctness is determined by matching head words, and slots marked as optional in MUC are ignored when computing recall. All hyperparameters are tuned on the development set (see Appendix A for their values).

Named entity type Named entity type is a useful feature to filter out entities for particular slots; e.g. a location cannot be an INSTRUMENT. We thus divide each induced cluster into four clusters by named entity type before performing the mapping, following C&J’s heuristic and using a named entity recognizer and word lists derived from WordNet: PERSON/ORGANIZATION, PHYSICAL OBJECT, LOCATION, and OTHER.

Document classification The MUC-4 dataset contains many documents that have words related to MUC slots (e.g., *plane* and *aviation*), but are not about terrorism. To reduce precision errors, C&J first filtered irrelevant documents based on the specificity of event heads to learned frames. To estimate the specificity, they used additional data retrieved from a large external corpus. In PROFINDER, however, specificity can be easily estimated using the probability distributions learned during training. In particular, we define the probability of an event head in a frame j as:

$$P_F(w) = \sum_{E \in F} P_{E-\text{HEAD}}(w|E)/|F|, \quad (3)$$

and the probability of a frame given an event head as:

$$P(F|w) = P_F(w) / \sum_{F' \in \mathcal{F}} P_{F'}(w). \quad (4)$$

We then follow the rest of C&J’s procedure to score each learned frame with each MUC document. Specifically, a document is mapped to a frame if the average $P_F(w)$ in the document is above a threshold and the document contains at least one *trigger word* w' with $P(F|w') > 0.2$. The threshold and the induced frame were determined on the development set, and were used to filter irrelevant documents in the test set.

Unsupervised methods	<i>P</i>	<i>R</i>	<i>F</i> ₁
PROFINDER (This work)	32	37	34
Chambers and Jurafsky (2011)	48	25	33
With additional information			
PROFINDER +doc. classification	41	44	43
C&J 2011 +granularity	44	36	40

Table 1: Results on MUC-4 entity extraction. C&J 2011 +granularity refers to their experiment in which they mapped one of their templates to five learned clusters rather than one.

Results Compared to C&J, PROFINDER is conceptually much simpler, using a single probabilistic model and standard learning and inference algorithms, and not requiring multiple processing steps or customized similarity metrics. It only used the data in MUC-4, whereas C&J required additional text to be retrieved from a large external corpus (Gigaword (Graff et al., 2005)) for each event cluster. It currently does not make use of coreference information, whereas C&J did. Remarkably, despite all these, PROFINDER was still able to outperform C&J on entity extraction, as shown in Table 1. We also evaluated PROFINDER’s performance assuming perfect document classification (+doc. classification). This led to a substantially higher precision, suggesting that further improvement is possible from better document classification.

Figure 2 shows part of a frame learned by PROFINDER, which includes some slots and events annotated in MUC. PROFINDER is also able to identify events and slots not annotated in MUC, a desirable characteristic of unsupervised methods. For example, it found a DISCUSSION event, an ARREST event (*call, arrest, express, meet, charge*), a PEACE AGREEMENT slot (*agreement, rights, law, proposal*), and an AUTHORITIES slot (*police, government, force, command*). The background frame was able to capture many verbs related to attribution, such as *say, continue, add, believe*, although it missed *report*.

5 Evaluating Frame Induction Using Guided Summarization Templates

The MUC-4 dataset was originally designed for information extraction and focuses on a limited number of template and slot types. To evaluate

Event: Attack <i>report, participate, kidnap, kill, release</i>	Event: Discussion <i>hold, meeting, talk, discuss, investigate</i>
Slot: Perpetrator PERSON/ORG	Slot: Victim PERSON/ORG
Words: <i>guerrilla, police, source, person, group</i>	Words: <i>people, priest, leader, member, judge</i>
Caseframes: <i>report>nsubj,</i> <i>kidnap>nsubj,</i> <i>kill>nsubj,</i> <i>participate>nsubj,</i> <i>release>nsubj</i>	Caseframes: <i>kill>dobj,</i> <i>murder>dobj,</i> <i>release>dobj,</i> <i>report>dobj,</i> <i>kidnap>dobj</i>

Figure 2: A partial frame learned by PROFINDER from the MUC-4 data set, with the most probable emissions for each event and slot. Labels are assigned by the authors for readability.

ate PROFINDER’s capabilities in generalizing to a greater variety of text, we designed and conducted a novel evaluation based on the TAC guided-summarization dataset. This evaluation was inspired by the connection between summarization and information extraction (White et al., 2001), and reflects a conceptualization of summarization as inducing and extracting structured information from source text. Essentially, we adapted the TAC summarization annotation to create gold-standard slots, and used them to evaluate entity extraction as in MUC-4.

Dataset We used the TAC 2010 guided-summarization dataset in our experiments (Owczarzak and Dang, 2010). This data set consists of text from five domains (termed *categories* in TAC), each with a template defined by TAC organizers. In total, there are 46 document clusters (termed *topics* in TAC), each of which contains 20 documents and has eight human-written summaries. Each summary was manually segmented using the Pyramid method (Nenkova and Passonneau, 2004) and each segment was annotated with a slot (termed *aspect* in TAC) from the corresponding template. Figure 3 shows an example and the full set of templates is available at <http://www.nist.gov/tac/2010/Summarization/Guided-Summ.2010.guidelines.html>. In

- (a) **Accidents and Natural Disasters:**
- WHAT: what happened
 - WHEN: date, time, other temporal markers
 - WHERE: physical location
 - WHY: reasons for accident/disaster
 - WHO_AFFECTED: casualties...
 - DAMAGES: ... caused by the disaster
 - COUNTERMEASURES: rescue efforts...
- (b) (WHEN *During the night of July 17,* (WHAT *a 23-foot <WHAT tsunami>*) hit the north coast of Papua New Guinea (PNG), (WHY triggered by a 7.0 undersea earthquake in the area).
- (c) WHEN: *night* WHAT: *tsunami, coast*
WHY: *earthquake*

Figure 3: (a) A frame from the TAC Guided Summarization task with abbreviated slot descriptions. (b) A TAC text span, segmented into several contributors with slot labels. Note that the two WHAT contributors overlap, and are demarcated by different bracket types. (c) The entities that are extracted for evaluation.

TAC, each annotated segment (Figure 3b) is called a *contributor*.

Evaluation Method We converted the contributors into a form that is more similar to the previous MUC evaluation, so that we can fairly compare against previous work such as C&J that were designed to extract information into that form. Specifically, we extracted the head lemma from all the maximal noun phrases found in the contributor (Figure 3c) and treated them as gold-standard entity slots to extract. While this conversion may not be ideal in some cases, it simplifies the TAC slots and enables automatic evaluation. We leave the refinement of this conversion to future work, and believe it could be done by crowdsourcing.

For each TAC slot in a TAC category, we extract entities from the summaries that belong to the given TAC category. A system-induced entity is considered a match to a TAC-derived entity from the same document if the head lemma in the former matches one in the latter. Based on this matching criterion, the system-induced slots are mapped to the TAC slots in a way that achieves the best F_1 for each TAC slot. We allow a system slot to map to multiple TAC slots, due to potential overlaps in entities

Systems	1-best			5-best		
	P	R	F_1	P	R	F_1
PROFINDER	24	25	24	21	38	27
C&J	58	6.1	11	50	12	20

Table 2: Results on TAC 2010 entity extraction with N -best mapping for $N = 1$ and $N = 5$. Intermediate values of N produce intermediate results, and are not shown for brevity.

among TAC slots. For example, in a document about a tsunami, *earthquake* may appear both in the WHAT slot as a disaster itself, and in the CAUSE slot as a cause for the tsunami.

One salient difference between TAC and MUC slots is that TAC slots are often more general than MUC slots. For example, TAC slots such as WHY and COUNTERMEASURES likely correspond to multiple slots at the granularity of MUC. As a result, we also consider mapping the N -best system-induced slots to each TAC slot, for N up to 5.

Experiments We trained PROFINDER and a reimplementation of C&J on the 920 full source texts of TAC 2010, and tested them on the 368 model summaries. We did not provide C&J’s model with access to external data, in order to enable fair comparison with our model. Since all of the summary sentences are expected to be relevant, we did not conduct document or sentence relevance classification in C&J or PROFINDER. We tuned all parameters by two-fold cross validation on the summaries. We computed the overall precision, recall, and F_1 by taking a micro-average over the results for each TAC slot.

Results The results are shown in Table 2. PROFINDER substantially outperformed C&J in F_1 , in both 1-best and N -best cases. As in MUC-4, the precision of C&J is higher, partly because C&J often did not do much in clustering and produced many small clusters. For example, in the 1-best setting, the average number of entities mapped to each TAC slot by C&J is 21, whereas it is 208 for PROFINDER. For both systems, the results are generally lower compared to that in MUC-4, which is expected since this task is harder given the greater diversity in frames and slots to be induced.

6 Conclusion

We have presented PROFINDER, the first probabilistic approach to frame induction and shown that it achieves state-of-the-art results on end-to-end entity extraction in standard MUC and TAC data sets. Our model is inspired by recent advances in unsupervised semantic induction and content modeling in summarization. Our probabilistic approach makes it easy to extend the model with additional linguistic insights and prior knowledge. While we have made a case for unsupervised methods and the importance of robustness across domains, our method is also amenable to semi-supervised or supervised learning if annotated data is available. In future work, we would like to further investigate frame induction evaluation, particularly in evaluating event clustering.

Acknowledgments

We would like to thank Nate Chambers for answering questions about his system. We would also like to thank Chris Quirk for help with preprocessing the MUC corpus, and the members of the NLP group at Microsoft Research for useful discussions.

Appendix A. Hyperparameter Settings

We document below the hyperparameter settings for PROFINDER that were used to generate the results in the paper.

Hyperparameter	MUC	TAC
Number of frames, $ \mathcal{F} $	9	8
Frame stickiness, β	0.125	0.5
Smoothing (frames, events, slots)	0.5	2
Smoothing (emissions)	0.05	0.2
Number of split-merge cycles	4	2
Iterations per cycle	10	10

Abstract

In this paper we explore the potential of quantum theory as a formal framework for capturing lexical meaning. We present a novel semantic space model that is syntactically aware, takes word order into account, and features key quantum aspects such as superposition and entanglement. We define a dependency-based Hilbert space and show how to represent the meaning of words by density matrices that encode dependency neighborhoods. Experiments on word similarity and association reveal that our model achieves results competitive with a variety of classical models.

1 Introduction

The fields of cognitive science and natural language processing have recently produced an ensemble of semantic models which have an impressive track record of replicating human behavior and enabling real-world applications. Examples include simulations of word association (Denhière and Lemaire, 2004; Griffiths et al., 2007), semantic priming (Lund and Burgess, 1996; Landauer and Dumais, 1997; Griffiths et al., 2007), categorization (Laham, 2000), numerous studies of lexicon acquisition (Grefenstette, 1994; Lin, 1998), word sense discrimination (Schütze, 1998), and paraphrase recognition (Socher et al., 2011). The term “semantic” derives from the intuition that words seen in the context of a given word contribute to its meaning (Firth, 1957). Although the specific details of the individual models differ, they all process a corpus of text as input and represent words (or concepts) in a (reduced) high-dimensional space.

In this paper, we explore the potential of quantum theory as a formal framework for capturing lexical meaning and modeling semantic processes such

as word similarity and association (see Section 6 for an overview of related research in this area). We use the term *quantum theory* to refer to the abstract mathematical foundation of quantum mechanics which is not specifically tied to physics (Hughes, 1989; Isham, 1989). Quantum theory is in principle applicable in any discipline where there is a need to formalize uncertainty. Indeed, researchers have been pursuing applications in areas as diverse as economics (Baaquie, 2004), information theory (Nielsen and Chuang, 2010), psychology (Khrennikov, 2010; Pothos and Busemeyer, 2012), and cognitive science (Busemeyer and Bruza, 2012; Aerts, 2009; Bruza et al., 2008). But what are the features of quantum theory which make it a promising framework for modeling meaning?

Superposition, entanglement, incompatibility, and interference are all related aspects of quantum theory, which endow it with a unique character.¹ *Superposition* is a way of modeling uncertainty, more so than in classical probability theory. It contains information about the potentialities of a system’s state. An electron whose location in an atom is uncertain can be modeled as being in a superposition of locations. Analogously, words in natural language can have multiple meanings. In isolation, the word *pen* may refer to a writing implement, an enclosure for confining livestock, a playpen, a penitentiary or a female swan. However, when observed in the context of the word *ink* the ambiguity resolves into the sense of the word dealing with writing. The meanings of words in a semantic space are superposed in a way which is intuitively similar to the atom’s electron.

Entanglement concerns the relationship between

¹It is outside the scope of the current paper to give a detailed introduction on the history of quantum mechanics. We refer the interested reader to Vedral (2006) and Kleppner and Jackiw (2000) for comprehensive overviews.

systems for which it is impossible to specify a joint probability distribution from the probability distributions of their constituent parts. With regard to word meanings, entanglement encodes (hidden) relationships between concepts. The different senses of a word “exist in parallel” until it is observed in some context. This reduction of ambiguity has effects on other concepts connected via entanglement. The notion of *incompatibility* is fundamental to quantum systems. In classical systems, it is assumed by default that measurements are compatible, that is, independent, and as a result the order in which these take place does not matter. By contrast in quantum theory, measurements may share (hidden) order-sensitive inter-dependencies and the outcome of the first measurement can change the outcome of the second measurement.

Interference is a feature of quantum probability that can cause classical assumptions such as the law of total probability to be violated. When concepts interact their joint representation can exhibit non-classical behavior, e.g., with regard to conjunction and disjunction (Aerts, 2009). An often cited example is the “guppy effect”. Although *guppy* is an example of a *pet-fish* it is neither a very typical *pet* nor *fish* (Osherson and Smith, 1981).

In the following we use the rich mathematical framework of quantum theory to model semantic information. Specifically, we show how word meanings can be expressed as quantum states. A word brings with it its own subspace which is spanned by vectors representing its potential usages. We present a specific implementation of a semantic space that is syntactically aware, takes word order into account, and features key aspects of quantum theory. We empirically evaluate our model on word similarity and association and show that it achieves results competitive with a variety of classical models. We begin by introducing some of the mathematical background needed for describing our approach (Section 2). Next, we present our semantic space model (Section 3) and our evaluation experiments (Sections 4 and 5). We conclude by discussing related work (Section 6).

2 Preliminaries

Let $c = re^{i\theta}$ be a complex number, expressed in polar form, with absolute value $r = |c|$ and phase θ . Its complex conjugate $c^* = re^{-i\theta}$ has the inverse phase. Thus, their product $cc^* = (re^{i\theta})(re^{-i\theta}) = r^2$ is real.

2.1 Vectors

We are interested in finite-dimensional, complex-valued vector spaces \mathbb{C}^n with an inner product, otherwise known as Hilbert space. A column vector $\vec{\psi} \in \mathbb{C}^n$ can be written as an ordered vertical array of its n complex-valued components, or alternatively as a weighted sum of base vectors:

$$\vec{\psi} = \begin{pmatrix} \psi_1 \\ \psi_2 \\ \vdots \\ \psi_n \end{pmatrix} = \psi_1 \begin{pmatrix} 1 \\ 0 \\ \vdots \\ 0 \end{pmatrix} + \dots + \psi_n \begin{pmatrix} 0 \\ \vdots \\ 0 \\ 1 \end{pmatrix} \quad (1)$$

Whereas Equation (1) uses base vectors from the standard base $\mathcal{B}_{std} = \{\vec{b}_1, \dots, \vec{b}_n\}$, any other set of n orthonormal vectors serves just as well as a base for the same space. Dirac (1939) introduced the so-called bra-ket notation which is equally expressive but notationally more convenient. A column vector becomes a ket:

$$\vec{\psi} \equiv |\psi\rangle = \psi_1|b_1\rangle + \psi_2|b_2\rangle + \dots + \psi_n|b_n\rangle \quad (2)$$

and a row vector becomes a bra $\langle\psi|$. Transposing a complex-valued vector or matrix (via the superscript “ \dagger ”) involves complex-conjugating all components:

$$|\psi\rangle^\dagger = \langle\psi| = \psi_1^*\langle b_1| + \psi_2^*\langle b_2| + \dots + \psi_n^*\langle b_n| \quad (3)$$

The Dirac notation for the inner product $\langle\cdot|\cdot\rangle$ illustrates the origin of the terminology “bra-ket”. Since \mathcal{B}_{std} ’s elements are normalised and pairwise orthogonal their inner product is:

$$\langle b_i | b_j \rangle = \begin{cases} 1, & \text{if } i = j \\ 0, & \text{otherwise} \end{cases} \quad (4)$$

The inner product is also applicable to pairs of non-base kets:

$$\begin{aligned} (\psi_1^* \psi_2^* \dots \psi_n^*) \begin{pmatrix} \phi_1 \\ \phi_2 \\ \vdots \\ \phi_n \end{pmatrix} &\equiv \langle\psi|\phi\rangle \\ &= (\sum_i \psi_i^* \langle b_i|) (\sum_j \phi_j |b_j\rangle) \\ &= \sum_{i,j} \psi_i^* \phi_j \langle b_i | b_j \rangle = \sum_i \psi_i^* \phi_i \langle b_i | b_i \rangle \\ &= \sum_i \psi_i^* \phi_i \end{aligned} \quad (5)$$

Reversing the order of an inner product complex-conjugates it:

$$(\langle \psi | \phi \rangle)^* = \langle \phi | \psi \rangle \quad (6)$$

2.2 Matrices

Matrices are sums of outer products $|\cdot\rangle\langle\cdot|$. For example, the matrix $(M_{i,j})_{i,j}$ can be thought of as the weighted sum of “base-matrices” $B_{i,j} \equiv |b_i\rangle\langle b_j|$, whose components are all 0 except for a 1 in the i -th row and j -th column. The outer product extends linearly to non-base kets in the following manor:

$$\begin{aligned} |\psi\rangle\langle\phi| &= (\sum_i \psi_i |b_i\rangle) \left(\sum_j \phi_j^* \langle b_j| \right) \\ &= \sum_{i,j} \psi_i \phi_j^* |b_i\rangle\langle b_j| \end{aligned} \quad (7)$$

This is analogous to the conventional multiplication:

$$\begin{pmatrix} \psi_1 \\ \vdots \\ \psi_n \end{pmatrix} (\phi_1^* \cdots \phi_n^*) = \begin{pmatrix} \psi_1 \phi_1^* & \cdots & \psi_1 \phi_n^* \\ \vdots & \ddots & \vdots \\ \psi_n \phi_1^* & \cdots & \psi_n \phi_n^* \end{pmatrix} \quad (8)$$

We will also make use of the tensor product. Its application to kets, bras and outer products is linear:

$$\begin{aligned} (|a\rangle + |b\rangle) \otimes |c\rangle &= |a\rangle \otimes |c\rangle + |b\rangle \otimes |c\rangle \\ (\langle a| + \langle b|) \otimes \langle c| &= \langle a| \otimes \langle c| + \langle b| \otimes \langle c| \\ (|a\rangle\langle b| + |c\rangle\langle d|) \otimes |e\rangle\langle f| &= \\ (|a\rangle\otimes|e\rangle)(\langle b|\otimes\langle f|) + (|c\rangle\otimes|e\rangle)(\langle d|\otimes\langle f|) \end{aligned} \quad (9)$$

For convenience we omit “ \otimes ” where no confusion arises, e.g., $|a\rangle \otimes |b\rangle = |a\rangle|b\rangle$. When applied to Hilbert spaces, the tensor product creates the composed Hilbert space $\mathcal{H} = \mathcal{H}_1 \otimes \dots \otimes \mathcal{H}_n$ whose base kets are simply induced by the tensor product of its subspaces’ base kets:

$$\begin{aligned} \text{base}(\mathcal{H}_1 \otimes \dots \otimes \mathcal{H}_n) &= \\ \left\{ \bigotimes_{i=1}^n |b\rangle_i : |b\rangle_i \in \text{base}(\mathcal{H}_i), 1 \leq i \leq n \right\} \end{aligned} \quad (10)$$

Whereas the order of composed kets $|a\rangle|b\rangle|c\rangle$ usually suffices to identify which subket lives in which subspace, we make this explicit by giving subkets

the same subscript as the corresponding subspace. Thus, the order no longer matters, as in the following inner product of composed kets:

$$(\langle a|_1 \langle b|_2 \langle c|_3) (\langle e|_3 \langle d|_1 \langle f|_2) = \langle a|d\rangle \langle b|f\rangle \langle c|e\rangle \quad (11)$$

Definition 1. Self-adjoint Matrix

A matrix M is self-adjoint iff $M_{i,j} = M_{j,i}^*$ for all i, j . Consequently, all diagonal elements are real-valued, and $M = M^\dagger$ is its own transpose conjugate.

Definition 2. Density Matrix

A self-adjoint matrix M is a density matrix iff it is positive semi-definite, i.e., $\langle \phi | M | \phi \rangle \geq 0$ for all $|\phi\rangle \in \mathbb{C}^n$, and it has unit trace, i.e., $\text{Tr}(M) = \sum_{|b\rangle \in \mathcal{B}} \langle b | M | b \rangle = 1$.

The term “density matrix” is synonymous with “density operator”. Any density matrix ρ can be decomposed arbitrarily as $\rho = \sum_i p_i |s_i\rangle\langle s_i|$, the weighted sum of sub-matrices $|s_i\rangle\langle s_i|$ with $p_i \in \mathbb{R}_{>0}$ and $\langle s_i | s_i \rangle = 1$. The p_i need not sum to 1. In fact the decomposition where the p_i sum to 1 and the $|s_i\rangle$ are mutually orthogonal is unique and is called the eigen decomposition. Consequently $\mathcal{B}_{\text{eig}} = \{|s_i\rangle\}_i$ constitutes an orthonormal base, ρ ’s so-called eigen base. Density operators are used in quantum theory to describe the state of some system. If the system’s state ρ is certain we call it a pure state and write $\rho = |s\rangle\langle s|$ for some unit ket $|s\rangle$. Systems whose state is uncertain are described by a mixed state $\rho = \sum_i p_i |s_i\rangle\langle s_i|$ which represents an ensemble of substates or pure states $\{(p_i, s_i)\}_i$ where the system is in substate s_i with probability p_i . Hence, the term “density” as in probability density.

It is possible to normalize a density matrix without committing to any particular decomposition. Only the trace function is required, because $\text{norm}(\rho) = \rho / \text{Tr}(\rho)$. Definition 2 mentions what the trace function does. However, notice that the same result is produced for any orthonormal base \mathcal{B} , including ρ ’s eigen base $\mathcal{B}_{\text{eig}} = \{|e_i\rangle\}_i$. Even though we do not know the content of \mathcal{B}_{eig} , we know that it

exists. So we use it to show that dividing ρ by:

$$\begin{aligned}
Tr(\rho) &= Tr(\sum_i p_i |e_i\rangle \langle e_i|) \\
&= \sum_j \langle e_j | (\sum_i p_i |e_i\rangle \langle e_i|) |e_j\rangle \\
&= \sum_{i,j} p_i \langle e_j | e_i \rangle \langle e_i | e_j \rangle \\
&= \sum_i p_i \langle e_i | e_i \rangle \langle e_i | e_i \rangle = \sum_i p_i
\end{aligned} \tag{12}$$

normalizes its probability distribution over eigenkets:

$$\frac{\rho}{Tr(\rho)} = \frac{\sum_i p_i |e_i\rangle \langle e_i|}{\sum_j p_j} = \sum_i \frac{p_i}{\sum_j p_j} |e_i\rangle \langle e_i| \tag{13}$$

3 Semantic Space Model

We represent the meaning of words by density matrices. Specifically, a lexical item w is modeled as an ensemble $U_w = \{(p_i, u_i)\}_i$ of usages u_i and the corresponding probabilities p_i that w gets used “in the i -th manor”. A word’s usage is comprised of distributional information about its syntactic and semantic preferences, in the form of a ket $|u_i\rangle$. The density matrix $\rho_w = \sum_i p_i |u_i\rangle \langle u_i|$ represents the ensemble U_w . This section explains our method of extracting lexical density matrices from a dependency-parsed corpus. Once density matrices have been learned, we can predict the expected usage similarity of two words as a simple function of their density matrices. Our explication will be formally precise, but at the same time illustrate each principle through a toy example.

3.1 Dependency Hilbert Space

Our model learns the meaning of words from a dependency-parsed corpus. Our experiments have used the Stanford parser (de Marneffe and Manning, 2008), however any other dependency parser with broadly similar output could be used instead. A word’s usage is learned from the type of dependency relations it has with its immediate neighbors in dependency graphs. Its semantic content is thus approximated by its “neighborhood”, i.e., its co-occurrence frequency with neighboring words.

Neighborhoods are defined by a vocabulary $V = \{w_1, \dots, w_{n_V}\}$ of the n_V most frequent (non-stop) words in the corpus. Let $Rel = \{\text{sub}^{-1}, \text{dobj}^{-1}, \text{amod}, \text{num}, \text{poss}, \dots\}$ denote

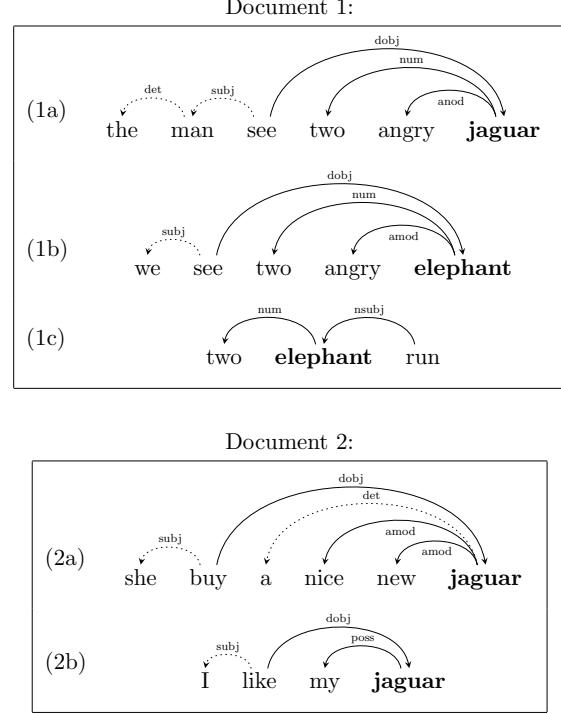

Figure 1: Example dependency trees in a toy corpus. Dotted arcs are ignored because they are either not connected to the target words *jaguar* and *elephant* or because their relation is not taken into account in constructing the semantic space. Words are shown as lemmas.

a subset of all dependency relations provided by the parser and their inverses. The choice of Rel is a model parameter. We considered only the most frequently occurring relations above a certain threshold, which turned out to be about half of the full inventory. Relation symbols with the superscript “ -1 ” indicate the inversion of the dependency direction (dependent to head). All other relation symbols have the conventional direction (head to dependent).

Hence, $w \xrightarrow{xyz} v$ is equivalent to $v \xrightarrow{xyz^{-1}} w$. We then partition Rel into disjoint clusters of syntactically similar relations $Part = \{RC_1, \dots, RC_{n_{Part}}\}$. For example, we consider syntactically similar relations which connect target words with neighbors with the same part of speech. Each relation cluster RC_k is assigned a Hilbert space \mathcal{H}_k whose base kets $\{|w_j^{(k)}\rangle\}_j$ correspond to the words in $V = \{w_j\}_j$.

Figure 1 shows the dependency parses for a toy corpus consisting of two documents and five sentences. To create a density matrix for the target words *jaguar* and *elephant*, let us assume that we

will consider the following relation clusters:
 $RC_1 = \{\text{dobj}^{-1}, \text{iobj}^{-1}, \text{agent}^{-1}, \text{nsubj}^{-1}, \dots\}$,
 $RC_2 = \{\text{advmod}, \text{amod}, \text{tmod}, \dots\}$ and $RC_3 = \{\text{nn}, \text{appos}, \text{num}, \text{poss}, \dots\}$.

3.2 Mapping from Dependency Graphs to Kets

Next, we create kets which encode syntactic and semantic relations as follows. For each occurrence of the target word w in a dependency graph, we only consider the subtree made up of w and the immediate neighbors connected to it via a relation in Rel . In Figure 1, arcs from the dependency parse that we ignore are shown as dotted. Let the subtree of interest be $st = \{(RC_1, v_1), \dots, (RC_{n_{Part}}, v_{n_{Part}})\}$, that is, w is connected to v_k via some relation in RC_k , for $k \in \{1, \dots, n_{Part}\}$. For any relation cluster RC_k that does not feature in the subtree, let RC_k be paired with the abstract symbol w_\emptyset in st . This symbol represents uncertainty about a potential RC_k -neighbor.

We convert all subtrees st in the corpus for the target word w into kets $|\Psi_{st}\rangle \in \mathcal{H}_1 \otimes \dots \otimes \mathcal{H}_{n_{Part}}$. These in turn make up the word’s density matrix ρ_w . Before we do so, we assign each relation cluster RC_k a complex value $\alpha_k = e^{i\theta_k}$. The idea behind these values is to control for how much each subtree contributes to the overall density matrix. This becomes more apparent after we formulate our method of inducing usage kets and density matrices.

$$|\Psi_{st}\rangle = \alpha_{st} \bigotimes_{(RC_k, v) \in st} |v\rangle_k, \quad (14)$$

where $\alpha_{st} = \sum_{(RC_k, v) \in st, v \neq w_\emptyset} \alpha_k$. Every RC_k paired with some neighbor $v \in V$ induces a basic subket $|v\rangle_k \in \text{base}(\mathcal{H}_k)$, i.e., a base ket of the k -th subspace or subsystem. All other subkets $|w_\emptyset\rangle_k = \sum_{v \in V} |V|^{-\frac{1}{2}} |v\rangle_k$ are in a uniformly weighted superposition of all base kets. The factor $|V|^{-\frac{1}{2}}$ ensures that $\langle w_\emptyset | w_\emptyset \rangle = 1$. The composed ket for the subtree st is again weighted by the complex-valued α_{st} .

α_{st} is the sum of complex values $\alpha_k = e^{i\theta_k}$, each with absolute value 1. Therefore, its own absolute value depends highly on the relative orientation θ_k among its summands: equal phases reinforce absolute value, but the more phases are opposed (i.e., their difference approaches π), the more they cancel out the sum’s absolute value. Only those α_k contribute to this sum whose relation cluster is not paired with w_\emptyset . The choice of the parameters θ_k allows us to put more weight on some combinations

	$\langle \Psi_{st_1} $	$\langle \Psi_{st_2} $	$\langle \Psi_{st_3} $
(a)	$ \Psi_{st_1}\rangle$	$\neq 0$	$\neq 0$
	$ \Psi_{st_2}\rangle$	$\neq 0$	$\neq 0$
	$ \Psi_{st_3}\rangle$	$\neq 0$	$\neq 0$

	$\langle \Psi_{st_1} $	$\langle \Psi_{st_2} $	$\langle \Psi_{st_3} $
(b)	$ \Psi_{st_1}\rangle$	$\neq 0$	0
	$ \Psi_{st_2}\rangle$	0	$\neq 0$
	$ \Psi_{st_3}\rangle$	0	$\neq 0$

Figure 2: Excerpts of density matrices that result from the dependency subtrees st_1, st_2, st_3 . Element $m_{i,j}$ in row i and column j is $m_{i,j} |\Psi_{st_i}\rangle \langle \Psi_{st_j}|$ in Dirac notation. (a) All three subtrees are in the same document. Thus their kets contribute to diagonal and off-diagonal matrix elements. (b) Each subtree is in a separate document. Therefore their kets do not group, affecting only diagonal matrix elements.

of dependency relations than others.

Arbitrarily choosing $\theta_1 = \frac{\pi}{4}$, $\theta_2 = \frac{7\pi}{4}$, and $\theta_3 = \frac{3\pi}{4}$ renders the subtrees in Figure 1 as $|\Psi_{st_{1a}}\rangle = e^{i\pi/4} |see\rangle_1 |angry\rangle_2 |two\rangle_3$, $|\Psi_{st_{2a}}\rangle = \sqrt{2} |buy\rangle_1 (|nice\rangle_2 + |new\rangle_2) |w_\emptyset\rangle_3$, $|\Psi_{st_{2b}}\rangle = \sqrt{2} e^{i\pi/2} |like\rangle_1 |w_\emptyset\rangle_2 |my\rangle_3$, which are relevant for *jaguar*, and $|\Psi_{st_{1b}}\rangle = e^{i\pi/4} |see\rangle_1 |angry\rangle_2 |two\rangle_3$, $|\Psi_{st_{1c}}\rangle = \sqrt{2} e^{i\pi/2} |run\rangle_1 |w_\emptyset\rangle_2 |two\rangle_3$, which are relevant for *elephant*. The subscripts outside of the subkets correspond to those of the relation clusters RC_1, RC_2, RC_3 chosen in Section 3.1.

In sentence 2a, *jaguar* has two neighbors under RC_2 . Therefore the subket from \mathcal{H}_2 is a superposition of the base kets $|nice\rangle_2$ and $|new\rangle_2$. This is a more intuitive formulation of the equivalent approach which first splits the subtree for *buy nice new jaguar* into two similar subtrees for *buy nice jaguar* and for *buy new jaguar*, and then processes them as separate subtrees within the same document.

3.3 Creating Lexical Density Matrices

We assume that a word’s usage is uniform throughout the same document. In our toy corpus in Figure 1, *jaguar* is always the direct object of the main verb. However, in Document 1 it is used in the animal sense, whereas in Document 2 it is used in the car sense. Even though the usage of *jaguar* in sentence (2b) is ambiguous, we group it with that of sentence (2a).

These considerations can all be comfortably en-

$\rho_{jaguar} = (\Psi_{st_{1a}}\rangle\langle\Psi_{st_{1a}} + (\Psi_{st_{2a}}\rangle\langle\Psi_{st_{2a}} + \Psi_{st_{2b}}\rangle\langle\Psi_{st_{2b}}))(\langle\Psi_{st_{2a}} + \langle\Psi_{st_{2b}}))/7 =$ $0.14 see\rangle_1 angry\rangle_2 two\rangle_3\langle see _1\langle angry _2\langle two _3 + 0.29 buy\rangle_1 nice\rangle_2 w_0\rangle_3\langle buy _1\langle nice _2\langle w_0 _3 +$ $0.29 buy\rangle_1 nice\rangle_2 w_0\rangle_3\langle buy _1\langle new _2\langle w_0 _3 + 0.29 buy\rangle_1 new\rangle_2 w_0\rangle_3\langle buy _1\langle nice _2\langle w_0 _3 +$ $0.29 buy\rangle_1 new\rangle_2 w_0\rangle_3\langle buy _1\langle new _2\langle w_0 _3 + 0.29e^{\pi/2} like\rangle_1 w_0\rangle_2 my\rangle_3\langle buy _1\langle nice _2\langle w_0 _3 +$ $0.29e^{\pi/2} like\rangle_1 w_0\rangle_2 my\rangle_3\langle buy _1\langle new _2\langle w_0 _3 + 0.29e^{-\pi/2} buy\rangle_1 nice\rangle_2 w_0\rangle_3\langle like _1\langle w_0 _2\langle my _3 +$ $0.29e^{-\pi/2} buy\rangle_1 new\rangle_2 w_0\rangle_3\langle like _1\langle w_0 _2\langle my _3 + 0.29 like\rangle_1 w_0\rangle_2 my\rangle_3\langle like _1\langle w_0 _2\langle my _3$
$\rho_{elephant} = ((\Psi_{st_{1b}}\rangle + \Psi_{st_{1c}}\rangle)(\langle\Psi_{st_{1b}} + \langle\Psi_{st_{1c}}))/3 =$ $0.33 see\rangle_1 angry\rangle_2 two\rangle_3\langle see _1\langle angry _2\langle two _3 + 0.47e^{\pi/4} run\rangle_1 w_0\rangle_2 two\rangle_3\langle see _1\langle angry _2\langle two _3 +$ $0.47e^{-\pi/4} see\rangle_1 angry\rangle_2 two\rangle_3\langle run _1\langle w_0 _2\langle two _3 + 0.67 run\rangle_1 w_0\rangle_2 two\rangle_3\langle run _1\langle w_0 _2\langle two _3$
$Tr(\rho_{jaguar}\rho_{elephant}) = Tr(0.05 \Psi_{st_{1a}}\rangle\langle\Psi_{st_{1a}} + 0.05e^{i\pi/4} \Psi_{st_{1b}}\rangle\langle\Psi_{st_{1b}}) = Tr(0.05 see\rangle_1 angry\rangle_2 two\rangle_3\langle see _1\langle angry _2\langle two _3 +$ $0.07e^{-\pi/4} see\rangle_1 angry\rangle_2 two\rangle_3\langle run _1\langle w_0 _2\langle two _3) = \sum_{ b\rangle \in base(\mathcal{H}_1 \otimes \mathcal{H}_2 \otimes \mathcal{H}_3)} \langle b (0.05 see\rangle_1 angry\rangle_2 two\rangle_3\langle see _1\langle angry _2\langle two _3 +$ $0.07e^{-\pi/4} see\rangle_1 angry\rangle_2 two\rangle_3\langle run _1\langle w_0 _2\langle two _3) b\rangle = 0.05$

Figure 3: Lexical density matrices for the words *jaguar* and *elephant* and their similarity.

coded in a density matrix. This is simply generated via the outer product of our subtree kets $|\Psi_{st}\rangle$. For example, $\rho_{D_1,jaguar} = |\Psi_{st_{1a}}\rangle\langle\Psi_{st_{1a}}|$ represents the contribution that document D_1 makes to ρ_{jaguar} . Document D_2 , however, has more than one ket relevant to ρ_{jaguar} . Due to our assumption of document-internal uniformity of word usage, we group D_2 's subtree-kets additively: $\rho_{D_2,jaguar} = (|\Psi_{st_{2a}}\rangle + |\Psi_{st_{2b}}\rangle)(\langle\Psi_{st_{2a}}| + \langle\Psi_{st_{2b}}|)$. The target word's density matrix ρ_w is the normalized sum of all density matrices $\rho_{D,w}$ obtained from each D :

$$\rho_{D,w} = \left(\sum_{st \in ST_{D,w}} |\Psi_{st}\rangle \right) \left(\sum_{st \in ST_{D,w}} \langle\Psi_{st}| \right) \quad (15)$$

where $ST_{D,w}$ is the set of all subtrees for target word w in document D . To illustrate the difference that this grouping makes, consider the density matrices in Figure 2. Whereas in (a) the subtrees st_1, st_2, st_3 share a document, in (b) they are from distinct documents. This grouping causes them to not only contribute to diagonal matrix elements, e.g., $|\Psi_{st_2}\rangle\langle\Psi_{st_2}|$, as in (b), but also to off diagonal ones, e.g., $|\Psi_{st_2}\rangle\langle\Psi_{st_1}|$, as in (a).

Over the course of many documents the summation of all contributions, no matter how small or large the groups are, causes “clusters of weight” to form, which hopefully coincide with word usages. As mentioned in Section 3.2, adding complex-valued matrix elements increases or decreases the sum's absolute value depending on relative phase orientation. This makes it possible for interference

to occur. Since the same word appears in varying contexts, the corresponding complex-valued outer products interact upon summation. Finally, the density matrix gets normalized, i.e., divided by its trace. This leaves the distributional information intact and merely normalizes the probabilities. Figure 3 illustrates the estimation of the density matrices for the words *jaguar* and *elephant* from the toy corpus in Figure 1.

3.4 Usage Similarity

Decomposing the density matrix of the target word w , $\rho_w = \sum_i p_i |u_i\rangle\langle u_i|$ recovers the usage ensemble $U_w = \{(p_i, u_i)\}_i$. However, in general there are infinitely many possible ensembles which ρ_w might represent. This subsection explains our metric for estimating the usage similarity of two words. The math involved shows that we can avoid the question of how to best decompose ρ_w .

We compute the usage similarity of two words w and v by comparing each usage of w with each usage of v and weighting these similarity values with the corresponding usage probabilities. Let $\rho_w = \sum_i p_i^{(w)} |u_i^{(w)}\rangle\langle u_i^{(w)}|$ and $\rho_v = \sum_i p_i^{(v)} |u_i^{(v)}\rangle\langle u_i^{(v)}|$. The similarity of some usage kets $|u_i^{(w)}\rangle$ and $|u_j^{(v)}\rangle$ is obtained, as is common in the literature, by their inner product $\langle u_i^{(w)}|u_j^{(v)}\rangle$. However, as this is a complex value, we multiply it with its complex conjugate, rendering the real value $\langle u_j^{(v)}|u_i^{(w)}\rangle\langle u_i^{(w)}|u_j^{(v)}\rangle = |\langle u_i^{(w)}|u_j^{(v)}\rangle|^2$. Therefore, in total the expected similarity of w and v is:

$$\begin{aligned}
sim(w, v) &= \sum_{i,j} p_i^{(w)} p_j^{(v)} \langle u_j^{(v)} | u_i^{(w)} \rangle \langle u_i^{(w)} | u_j^{(v)} \rangle \quad (16) \\
&= Tr \left(\sum_{i,j} p_i^{(w)} p_j^{(v)} |u_i^{(w)}\rangle \langle u_i^{(w)}| |u_j^{(v)}\rangle \langle u_j^{(v)}| \right) = \\
&Tr \left((\sum_i p_i^{(w)} |u_i^{(w)}\rangle \langle u_i^{(w)}|) (\sum_j p_j^{(v)} |u_j^{(v)}\rangle \langle u_j^{(v)}|) \right) \\
&= Tr(\rho_w \rho_v)
\end{aligned}$$

We see that the similarity function simply reduces to multiplying ρ_w with ρ_v and applying the trace function. The so-called cyclic property of the trace function (i.e., $Tr(M_1 M_2) = Tr(M_2 M_1)$ for any two matrices M_1, M_2) gives us the corollary that this particular similarity function is symmetric.

Figure 3 (bottom) shows how to calculate the similarity of *jaguar* and *elephant*. Only the coefficient of the first outer product survives the tracing process because its ket and bra are equal modulo transpose conjugate. As for the second outer product, $0.05e^{\pi/4}\langle b|\Psi_{st_{1a}}\rangle\langle\Psi_{st_{1c}}|b\rangle$ is 0 for all base kets $|b\rangle$.

3.5 What Does This Achieve?

We represent word meanings as described above for several reasons. The density matrix decomposes into usages each of which are a superposition of combinations of dependents. Internally, these usages are established automatically by way of “clustering”.

Our model is parameterized with regard to the phases of sub-systems (i.e., clusters of syntactic relations) which allows us to make optimal use of interference, as this plays a large role in the overall quality of representation. It is possible for a combination of (groups of) dependents to get entangled if they repeatedly appear together under the same word, and only in that combination. If the co-occurrence of (groups of) dependents is uncorrelated, though, they remain unentangled. Quantum entanglement gives our semantic structures the potential for long-distance effects, once quantum measurement becomes involved. This is in analogy to the nonlocal correlation between properties of subatomic particles, such as the magnetic spin of electrons or the polarization of photons. Such an extension to our implementation will also uncover which sets of measurements are order-sensitive, i.e., incompatible.

Our similarity metric allows two words to “select” each other’s usages via their pairwise inner prod-

ucts. Usage pairs with a high distributional similarity roughly “align” and then get weighted by the probabilities of those usages. Two words are similar if they are substitutable, that is, if they can be used in the same syntactic environment and have the same meaning. Hopefully, this leads to more accurate estimation of distributional similarity and can be used to compute word meaning in context.

4 Experimental Setup

Data All our experiments used a dependency parsed and lemmatized version of the British National Corpus (BNC). As mentioned in Section 3, we obtained dependencies from the output of the Stanford parser (de Marneffe and Manning, 2008). The BNC comprises 4,049 texts totalling approximately 100 million words.

Evaluation Tasks We evaluated our model on word similarity and association. Both tasks are employed routinely to assess how well semantic models predict human judgments of word relatedness. We used the WordSim353 test collection (Finkelstein et al., 2002) which consists of similarity judgments for word pairs. Participants gave each pair a similarity rating using a 0 to 10 scale (e.g., *tiger–cat* are very similar, whereas *delay–racism* are not). The average rating for each pair represents an estimate of the perceived similarity of the two words. The collection contains ratings for 437 unique words (353 pairs) all of which appeared in our corpus. Word association is a slightly different task: Participants are given a cue word (e.g., *rice*) and asked to name an associate in response (e.g., *Chinese*, *wedding*, *food*, *white*). We used the norms collected by Nelson et al. (1998). We estimated the strength of association between a cue and its associate, as the relative frequency with which it was named. The norms contain 9,968 unique words (70,739 pairs) out of which 9,862 were found in our corpus, excluding multi-word expressions.

For both tasks, we used correlation analysis to examine the degree of linear relationship between human ratings and model similarity values. We report correlation coefficients using Spearman’s rank correlation coefficient.

Quantum Model Parameters The quantum framework presented in Section 3 is quite flexible. Depending on the choice of dependency relations Rel , dependency clusters RC_j , and complex

values $\alpha_j = e^{i\theta_j}$, different classes of models can be derived. To explore these parameters, we partitioned the WordSim353 dataset and Nelson et al.’s (1998) norms into a development and test set following a 70–30 split. We tested 9 different intuitively chosen relation partitions $\{RC_1, \dots, RC_{n_{Part}}\}$, creating models that considered only neighboring heads, models that considered only neighboring dependents, and models that considered both. For the latter two we experimented with partitions of one, two or three clusters. In addition to these more coarse grained clusters, for models that included both heads and dependents we explored a partition with twelve clusters broadly corresponding to objects, subjects, modifiers, auxiliaries, determiners and so on. In all cases stopwords were not taken into account in the construction of the semantic space.

For each model variant we performed a grid search over the possible phases $\theta_j = k\pi$ with range $k = \frac{0}{4}, \frac{1}{4}, \dots, \frac{7}{4}$ for the complex-valued α_j assigned to the respective relation cluster RC_j (see Section 3.2 for details). In general, we observed that the choice of dependency relations and their clustering as well as the phases assigned to each cluster greatly influenced the semantic space. On both tasks, the best performing model had the relation partition described in Section 3.1. Section 5 reports our results on the test set using this model.

Comparison Models We compared our quantum space against three classical distributional models. These include a simple semantic space, where a word’s meaning is a vector of co-occurrences with neighboring words (Mitchell and Lapata, 2010), a syntax-aware space based on weighted distributional triples that encode typed co-occurrence relations among words (Baroni and Lenci, 2010) and word embeddings computed with a neural language model (Bengio, 2001; Collobert and Weston, 2008) For all three models we used parameters that have been reported in the literature as optimal.

Specifically, for the simple co-occurrence-based space we follow the settings of Mitchell and Lapata (2010): a context window of five words on either side of the target word and 2,000 vector dimensions (i.e., the 2000 most common context words in the BNC). Vector components were set to the ratio of the probability of the context word given the target word to the probability of the context word overall. For the neural language model, we adopted the best

Models	WordSim353	Nelson Norms
SDS	0.433	0.151
DM	0.318	0.123
NLM	0.196	0.091
QM	0.535	0.185

Table 1: Performance of distributional models on WordSim353 dataset and Nelson et al.’s (1998) norms (test set). Correlation coefficients are all statistically significant ($p < 0.01$).

performing parameters from our earlier comparison of different vector sources for distributional semantics (Blacoe and Lapata, 2012) where we also used the BNC for training. There we obtained best results with 50 dimensions, a context window of size 4, and an embedding learning rate of 10^{-9} . Our third comparison model uses Baroni and Lenci’s (2010) third-order tensor² which they obtained from a very large dependency-parsed corpus containing approximately 2.3 billion words. Their tensor assigns a mutual information score to instances of word pairs w, v and a linking word l . We obtained vectors \vec{w} from the tensor following the methodology proposed in Blacoe and Lapata (2012) using 100 (l, v) contexts as dimensions.

5 Results

Our results are summarized in Table 1. As can be seen, the quantum model (QM) obtains performance superior to other better-known models such as Mitchell and Lapata’s (2010) simple semantic space (SDS), Baroni and Lenci’s (2010) distributional memory tensor (DM), and Collobert and Weston’s (2008) neural language model (NLM). Our results on the association norms are comparable to the state of the art (Silberer and Lapata, 2012; Griffiths et al., 2007). With regard to WordSim353, Huang et al. (2012) report correlations in the range of 0.713–0.769, however they use Wikipedia as a training corpus and a more sophisticated version of the NLM presented here, that takes into account global context and performs word sense discrimination. In the future, we also plan to evaluate our model on larger Wikipedia-scale corpora. We would also like to model semantic composition as our approach can do this easily by taking advantage of the notion of quantum measurement. Specifically, we

Models	bar	order
SDS	pub, snack, restaurant, <u>grill</u> , cocktail	form, direct, procedure, plan, request
DM	counter, rack, strip, pipe, code	court, demand, <u>form</u> , law, list
NLM	room, pole, <u>drink</u> , rail, coctail	direct, command, plan, court, demand
QM	prison, liquor, <u>beer</u> , club, graph	organization, <u>food</u> , law, structure, regulation
HS	drink, beer, stool, alcohol, grill	food, form, law, heat, court

Table 2: Associates for *bar* and *order* ranked according to similarity. Underlined associates overlap with the human responses (HS).

can work out the meaning of a dependency tree by measuring the meaning of its heads in the context of their dependents.

Table 2 shows the five most similar associates (ordered from high to low) for the cues *bar* and *order* for the quantum model and the comparison models. We also show the human responses (HS) according to Nelson et al.’s (1998) norms. The associates generated by the quantum model correspond to several different meanings correlated with the target. For example, *prison* refers to the “behind bars” sense of *bar*, *liquor* and *beer* refer to what is consumed or served in bars, *club* refers to the entertainment function of bars, whereas *graph* refers to how data is displayed in a chart.

6 Related Work

Within cognitive science the formal apparatus of quantum theory has been used to formulate models of cognition that are superior to those based on traditional probability theory. For example, conjunction fallacies³ (Tversky and Kahneman, 1983) have been explained by making reference to quantum theory’s context dependence of the probability assessment. Violations of the sure-thing principle⁴ (Tversky and Shafir, 1992) have been modeled in terms of a quantum interference effect. And the asymmetry of similarity relations has been explained by postulating that different concepts correspond to subspaces of different dimensionality (Pothos and Busemeyer, 2012). Several approaches have drawn on

³A conjunction fallacy occurs when it is assumed that specific conditions are more probable than a single general one.

⁴The principle is the expectation that human behavior ought to conform to the law of total probability

quantum theory in order to model semantic phenomena such as concept combination (Bruza and Cole, 2005), the emergence of new concepts (Aerts and Gabora, 2005), and the human mental lexicon (Bruza et al., 2009). Chen (2002) captures syllogisms in a quantum theoretic framework; the model takes statements like *All whales are mammals and all mammals are animals* as input and outputs conclusions like *All whales are animals*.

The first attempts to connect the mathematical basis of semantic space models with quantum theory are due to Aerts and Czachor (2004) and Bruza and Cole (2005). They respectively demonstrate that Latent Semantic Analysis (Landauer and Dumais, 1997) and the Hyperspace Analog to Language model (Lund and Burgess, 1996) are essentially Hilbert space formalisms, without, however, providing concrete ways of building these models beyond a few hand-picked examples. Interestingly, Bruza and Cole (2005) show how lexical operators may be contrived from corpus co-occurrence counts, albeit admitting to the fact that their operators do not provide sensical eigenkets, most likely because of the simplified method of populating the matrix from corpus statistics. Grefenstette et al. (2011) present a model for capturing semantic composition in a quantum theoretical context, although it appears to be reducible to the classical probabilistic paradigm. It does not make use of the unique aspects of quantum theory (e.g., entanglement, interference, or quantum collapse).

Our own work follows Aerts and Czachor (2004) and Bruza and Cole (2005) in formulating a model that exhibits important aspects of quantum theory. Contrary to them, we present a fully-fledged semantic space rather than a proof-of-concept. We obtain quantum states (i.e., lexical representations) for each word by taking its *syntactic* context into account. Quantum states are expressed as density operators rather than kets. While a ket can only capture one pure state of a system, a density operator contains an ensemble of pure states which we argue is advantageous from a modeling perspective. Within this framework, not only can we compute the meaning of individual words but also phrases or sentences, without postulating any additional operations. Compositional meaning reduces to quantum measurement at each inner node of the (dependency) parse of the structure in question.

Answer Extraction as Sequence Tagging with Tree Edit Distance

Abstract

Our goal is to extract answers from pre-retrieved sentences for Question Answering (QA). We construct a linear-chain Conditional Random Field based on pairs of questions and their possible answer sentences, learning the association between questions and answer types. This casts answer extraction as an answer sequence tagging problem for the first time, where knowledge of shared structure between question and source sentence is incorporated through features based on Tree Edit Distance (TED). Our model is free of manually created question and answer templates, fast to run (processing 200 QA pairs per second excluding parsing time), and yields an F1 of 63.3% on a new public dataset based on prior TREC QA evaluations. The developed system is open-source, and includes an implementation of the TED model that is state of the art in the task of ranking QA pairs.

1 Introduction

The success of IBM’s Watson system for Question Answering (QA) (Ferrucci et al., 2010) has illustrated a continued public interest in this topic. Watson is a sophisticated piece of software engineering consisting of many components tied together in a large parallel architecture. It took many researchers working full time for years to construct. Such resources are not available to individual academic researchers. If they are interested in evaluating new ideas on some aspect of QA, they must either construct a full system, or create a focused subtask

*Performed while faculty at Johns Hopkins University.

paired with a representative dataset. We follow the latter approach and focus on the task of answer extraction, i.e., producing the exact answer strings for a question.

We propose the use of a linear-chain Conditional Random Field (CRF) (Lafferty et al., 2001) in order to cast the problem as one of *sequence tagging* by labeling each token in a candidate sentence as either Beginning, Inside or Outside (BIO) of an answer. This is to our knowledge the first time a CRF has been used to extract answers.¹ We utilize not only traditional contextual features based on POS tagging, dependency parsing and Named Entity Recognition (NER), but most importantly, features extracted from a Tree Edit Distance (TED) model for aligning an answer sentence tree with the question tree. The linear-chain CRF, when trained to learn the associations between question and answer types, is a robust approach against error propagation introduced in the NLP pipeline. For instance, given an NER tool that always (i.e., in both training and test data) recognizes the pesticide DDT as an ORG, our model realizes, when a question is asked about the type of chemicals, the correct answer might be *incorrectly but consistently* recognized as ORG by NER. This helps reduce errors introduced by wrong answer types, which were estimated as the most significant contributor (36.4%) of errors in the then state-of-the-art QA system of Moldovan et al. (2003).

The features based on TED allow us to draw the

¹CRFs have been used in judging answer-bearing sentences (Shima et al., 2008; Ding et al., 2008; Wang and Manning, 2010), but not extracting exact answers from these sentences.

connection between the question and answer sentences *before* answer extraction, whereas traditionally the exercise of *answer validation* (Magnini et al., 2002; Penas et al., 2008; Rodrigo et al., 2009) has been performed *after* as a remedy to ensure the answer is really “about” the question.

Motivated by a desire for a fast runtime,² we base our TED implementation on the dynamic-programming approach of Zhang and Shasha (1989), which helps our final system process 200 QA pairs per second on standard desktop hardware, when input is syntactically pre-parsed.

In the following we first provide background on the TED model, going on to evaluate our implementation against prior work in the context of question answer sentence ranking (QASR), achieving state of the art in that task. We then describe how we couple TED features to a linear-chain CRF for answer extraction, providing the set of features used, and finally experimental results on an extraction dataset we make public (together with the software) to the community.³ Related prior work is interspersed throughout the paper.

2 Tree Edit Distance Model

Tree Edit Distance (§2.1) models have been shown effective in a variety of applications, including textual entailment, paraphrase identification, answer ranking and information retrieval (Reis et al., 2004; Kouylekov and Magnini, 2005; Heilman and Smith, 2010; Augsten et al., 2010). We chose the variant proposed by Heilman and Smith (2010), inspired by its simplicity, generality, and effectiveness. Our approach differs from those authors in their reliance on a greedy search routine to make use of a complex tree kernel. With speed a consideration, we opted for the dynamic-programming solution of Zhang and Shasha (1989) (§2.1). We added new lexical-semantic features §(2.2) to the model and then evaluated our implementation on the QASR task, showing strong results §(2.3).

Feature	Description
distance	tree edit distance from answer sentence to question
renNoun	# edits changing POS from or to noun, verb, or other types
renVerb	
renOther	
insN, insV, insPunc, insDet, insOtherPos	# edits inserting a noun, verb, punctuation mark, determiner or other POS types
delN, delV, ...	deletion mirror of above
ins{N,V,P}Mod insSub, insObj insOtherRel	# edits inserting a modifier for {noun, verb, preposition}, subject, object or other relations
delNMod, ...	deletion mirror of above
renNMod, ...	rename mirror of above
XEdits	# basic edits plus sum of ins/del/ren edits
alignNodes, alignNum, alignN, alignV, alignProper	# aligned nodes, and those that are numbers, nouns, verbs, or proper nouns

Table 1: Features for ranking QA pairs.

2.1 Cost Design and Edit Search

Following Bille (2005), we define an *edit script* between trees T_1, T_2 as the edit sequence transforming T_1 to T_2 according to a *cost function*, with the total summed cost known as the *tree edit distance*. *Basic edit* operations include: *insert*, *delete* and *rename*.

With T a dependency tree, we represent each node by three fields: lemma, POS and the type of dependency relation to the node’s parent (DEP). For instance, Mary/nnp/sub is the proper noun *Mary* in subject position.

Basic edits are refined into 9 types, where the first six (INS.LEAF, INS.SUBTREE, INS, DEL.LEAF, DEL.SUBTREE, DEL) insert or delete a leaf node, a whole subtree, or a node that is neither a leaf nor part of a whole inserted subtree. The last three (REN.POS, REN.DEP, REN.POS.DEP) serve to rename a POS tag, dependency relation, or both.

²For instance, Watson was designed under the constraint of a 3 second response time, arising from its intended live use in the television game show, Jeopardy!.

³<http://code.google.com/p/jacana/>

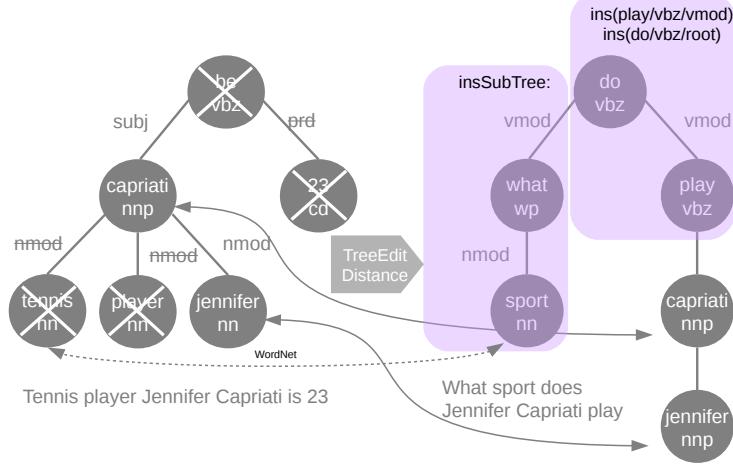

Figure 1: Edits transforming a source sentence (left) to a question (right). Each node consists of: lemma, POS tag and dependency relation, with root nodes and punctuation not shown. Shown includes deletion (\times and strikethrough) and insertion (shaded area). Order of operations is not displayed. The standard TED model does not capture the alignment between *tennis* and *sport* (see Section 2.2).

We begin by uniformly assigning basic edits a cost of 1.0,⁴ which brings the cost of a full node insertion or deletion to 3 (all the three fields inserted or deleted). We allow renaming of POS and/or relation type iff the lemmas of source and target nodes are identical.⁵ When two nodes are identical and thus do not appear in the edit script, or when two nodes are renamed due to the same lemma, we say they are *aligned* by the tree edit model (see Figure 1).

We used Zhang and Shasha (1989)'s dynamic programming algorithm to produce an optimal edit script with the lowest tree edit distance. The approach explores both trees in a bottom-up, post-order manner, running in time:

$$O(|T_1| |T_2| \min(D_1, L_1) \min(D_2, L_2))$$

where $|T_i|$ is the number of nodes, D_i is the depth, and L_i is the number of leaves, with respect to tree T_i .

Additionally, we fix the cost of stopword renaming to 2.5, even in the case of identity, regardless of whether two stopwords have the same POS tags or relations. Stopwords tend to have fixed POS tags and dependency relations, which often leads to less expensive alignments as compared to renaming con-

tent terms. In practice this gave stopwords “too much say” in guiding the overall edit sequence.

The resultant system is fast in practice, processing 10,000 pre-parsed tree pairs per second on a contemporary machine.⁶

2.2 TED for Sentence Ranking

The task of Question Answer Sentence Ranking (QASR) takes a question and a set of source sentences, returning a list sorted by the probability likelihood that each sentence contains an appropriate answer. Prior work in this includes that of: Punyakanok et al. (2004), based on mapping syntactic dependency trees; Wang et al. (2007) utilizing Quasi-Synchronous Grammar (Smith and Eisner, 2006); Heilman and Smith (2010) using TED; and Shima et al. (2008), Ding et al. (2008) and Wang and Manning (2010), who each employed a CRF in various ways. Wang et al. (2007) made their dataset public, which we use here for system validation. To date, models based on TED have shown the best performance for this task.

Our implementation follows Heilman and Smith (2010), with the addition of 15 new features beyond their original 33 (see Table 1). Based on results

⁴This applies separately to each element of the tripartite structure; e.g., deleting a POS entry, inserting a lemma, etc.

⁵This is aimed at minimizing node variations introduced by morphology differences, tagging or parsing errors.

⁶In later tasks, feature extraction and decoding will slow down the system, but the final system was still able to process 200 pairs per second.

set	source	#ques.	#pairs	%pos.	len.
TRAIN-ALL	TREC8-12	1229	53417	12.0	any
TRAIN	TREC8-12	94	4718	7.4	≤ 40
DEV	TREC13	82	1148	19.3	≤ 40
TEST	TREC13	89	1517	18.7	≤ 40

Table 2: Distribution of data, with imbalance towards negative examples (sentences without an answer).

in DEV, we extract edits in the direction from the source sentence to the question.

In addition to syntactic features, we incorporated the following lexical-semantic relations from WordNet: *hypernym* and *synonym* (nouns and verbs); *entailment* and *causing* (verbs); and *membersOf*, *substancesOf*, *partsOf*, *haveMember*, *haveSubstance*, *havePart* (nouns). Such relations have been used in prior approaches to this task (Wang et al., 2007; Wang and Manning, 2010), but not in conjunction with the model of Heilman and Smith (2010).

These were made into features in two ways: **WNsearch** loosens renaming and alignment within the TED model from requiring strict lemma equality to allowing lemmas that shared any of the above relations, leading to renaming operations such as REN_{...}(country, china) and REN_{...}(sport, tennis); **WNfeature** counts how many words between the sentence and answer sentence have each of the above relations, separately as 10 independent features, plus an aggregate count for a total of 11 new features beyond the earlier 48.

These features were then used to train a logistic regression model using Weka (Hall et al., 2009).

2.3 QA Sentence Ranking Experiment

We trained and tested on the dataset from Wang et al. (2007), which spans QA pairs from TREC QA 8-13 (see Table 2). Per question, sentences with non-stopword overlap were first retrieved from the task collection, which were then compared against the TREC answer pattern (in the form of Perl regular expressions). If a sentence matched, then it was deemed a (noisy) positive example. Finally, TRAIN, DEV and TEST were manually corrected for errors. Those authors decided to limit candidate source sen-

System	MAP	MRR

Table 3: Results on the QA Sentence Ranking task.

tences to be no longer than 40 words.⁷ Keeping with prior work, those questions with only positive or negative examples were removed, leaving 94 of the original 100 questions for evaluation.

The data was processed by Wang et al. (2007) with the following tool chain: POS tags via MXPOST (Ratnaparkhi, 1996); parse trees via MST-Parser (McDonald et al., 2005) with 12 coarse-grained dependency relation labels; and named entities via Identifinder (Bikel et al., 1999). Mean Average Precision (MAP) and Mean Reciprocal Rank (MRR) are reported in Table 3. Our implementation gives state of the art performance, and is furthered improved by our inclusion of semantic features drawn from WordNet.⁸

3 CRF with TED for Answer Extraction

In this section we move from *ranking* source sentences, to the next QA stage: *answer extraction*. Given our competitive TED-based alignment model, the most obvious solution to extraction would be to report those spans aligned from a source sentence to a question’s *wh*- terms. However, we show that this approach is better formulated as a (strongly indicative) feature of a larger set of answer extraction signals.

3.1 Sequence Model

Figure 2 illustrates the task of tagging each token in a candidate sentence with one of the following la-

⁷TRAIN-ALL is not used in QASR, but later for answer extraction; TRAIN comes from the first 100 questions of TRAIN-ALL.

⁸As the test set is of limited size (94 questions), then while our MAP/MRR scores are 2.8% ~ 5.6% higher than prior work, this is not statistically significant according to the Paired Randomization Test (Smucker et al., 2007), and thus should be considered *on par* with the current state of the art.

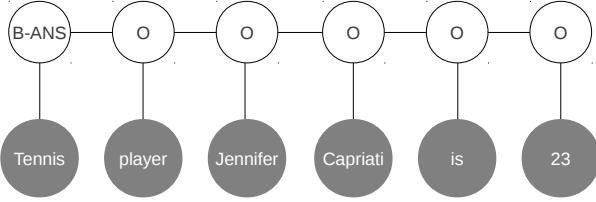

Figure 2: An example of linear-chain CRF for answer sequence tagging.

labels: B-ANSWER (beginning of answer), I-ANSWER (inside of answer), O (outside of answer).

Besides local POS/NER/DEP features, at each token we need to inspect the entire input to connect the answer sentence with the question sentence through tree edits, drawing features from the question and the edit script, motivating the use of a linear-chain CRF model (Lafferty et al., 2001) over HMMs. To the best of our knowledge this is the first time a CRF has been used to label answer fragments, despite success in other sequence tagging tasks.

3.2 Feature Design

In this subsection we describe the local and global features used by the CRF.

Chunking We use the POS/NER/DEP tags directly just as one would in a chunking task. Specifically, suppose t represents the current token position and $pos[t]$ its POS tag, we extract unigram, bigram and trigram features over the local context, e.g., $pos[t - 2], pos[t - 2] : pos[t - 1]$, and $pos[t - 2] : pos[t - 1] : pos[t]$. Similar features are extracted for named entity types ($ner[t]$), and dependency relation labels ($dep[t]$).

Our intuition is these chunking features should allow for learning which types of words tend to be answers. For instance, we expect adverbs to be assigned lower feature weights as they are rarely a part of answer, while prepositions may have different feature weights depending on their context. For instance, *of* in *kind of silly* has an adjective on the right, and is unlikely to be the Beginning of an answer to a TREC-style question, as compared to *in* when paired with a question on time, such as seen in an answer *in 90 days*, where the preposition is followed by a number then a noun.

Feature	Description
edit=X	type of edit feature. X: DEL, DEL_SUBTREE, DEL_LEAF, REN_POS, REN_DEP, REN_POS_DEP or ALIGN.
X_pos=? X_ner=? X_dep=?	Delete features. X is either DEL, DEL_SUBTREE or DEL_LEAF. ? represents the corresponding POS/NER/DEP of the current token.
Xpos_from=?_f Xpos_to=?_t Xpos_f_t=?_f ?_t Xner_from=?_f Xner_to=?_t Xner_f_t=?_f ?_t Xdep_from=?_f Xdep_to=?_t Xdep_f_t=?_f ?_t	Rename features. X is either REN_POS, REN_DEP or REN_POS_DEP. Suppose word f in answer is renamed to word t in question, then $?_f$ and $?_t$ represent corresponding POS/NER/DEP of f and t .
align_pos=? align_ner=? align_dep=?	Align features. ? represents the corresponding POS/NER/DEP of the current token.

Table 4: Features based on edit script for answer sequence tagging.

Question-type Chunking features do not capture the connection between question word and answer types. Thus they have to be combined with question types. For instance, how many questions are usually associated with numeric answer types. We encode each major question-type: who, whom, when, where, how many, how much, how long, and then for each token, we combine the question term with its chunking features described in (most tokens have different features because they have different POS/NER/DEP types). One feature example of the QA pair *how.much/100.dollars* for the word *100* would be: *qword=how.much|pos[t]=CD|pos[t+1]=NNS*. We expect high weight for this feature since it is a good pattern for matching question type and answer type. Similar features also apply to what, which, why and how questions, even though they do not indicate an answer type as clearly as how much does.

Some extra features are designed for what/which questions per required answer types. The question

dependency tree is analyzed and the Lexical Answer Type (LAT) is extracted. The following are some examples of LAT for what questions:

- color: what is Crips' gang color?
- animal: what kind of animal is an agouti?

The extra LAT=? feature is also used with chunking features for what/which questions.

There is significant prior work in building specialized templates or classifiers for labeling question types (Hermjakob, 2001; Li and Roth, 2002; Zhang and Lee, 2003; Hacioglu and Ward, 2003; Metzler and Croft, 2005; Blunsom et al., 2006; Moschitti et al., 2007). We designed our shallow question type features based on the intuitions of these prior work, with the goal of having a relatively compact approach that still extracts useful predictive signal. One possible drawback, however, is that if an LAT is not observed during training but shows up in testing, the sequence tagger would not know which answer type to associate with the question. In this case it falls back to the more general qword=? feature and will most likely pick the type of answers that are mostly associated with what questions in training.

Edit script Our TED module produces an edit trace for each word in a candidate sentence: the word is either deleted, renamed (if there is a word of the same lemma in the question tree) or strictly aligned (if there is an identical node in the question tree). A word in the deleted edit sequence is a cue that it could be the answer. A word being aligned suggests it is less likely to be an answer. Thus for each word we extract features based on its edit type, shown in Table 4.

These features are also appended with the token's POS/NER/DEP information. For instance, a deleted noun usually carries higher edit feature weights than an aligned adjective.

Alignment distance We observed that a candidate answer often appears close to an aligned word (i.e., answer tokens tend to be located "nearby" portions of text that align across the pair), especially in compound noun constructions, restrictive clauses, preposition phrases, etc. For instance, in the following pair, the answer Limp Bizkit comes from the leading compound noun:

- What is the name of Durst 's group?
- Limp Bizkit lead singer Fred Durst did a lot ...

Past work has designed large numbers of specific templates aimed at these constructions (Soubbotin, 2001; Ravichandran et al., 2003; Clark et al., 2003; Sneiders, 2002). Here we use a single general feature that we expect to pick up much of this signal, without the significant feature engineering.

Thus we incorporated a simple feature to *roughly* model this phenomenon. It is defined as the distance to the nearest aligned nonstop word in the original word order. In the above example, the only aligned nonstop word is Durst. Then this nearest alignment distance feature for the word Limp is:

`nearest_dist_to_align(Limp):5`

This is the only integer-valued feature. All other features are binary-valued. Note this feature does not specify answer types: an adverb close to an aligned word can also be wrongly taken as a strong candidate. Thus we also include a version of the POS/NER/DEP based feature for each token:

- `nearest_dist_pos(Limp)=NNP`
- `nearest_dist_dep(Limp)=NMOD`
- `nearest_dist_ner(Limp)=B-PERSON`

3.3 Overproduce-and-vote

We make an assumption that each sentence produces a candidate answer and then vote among all answer candidates to select the most-voted as the answer to the original question. Specifically, this overproduce-and-vote strategy applies voting in two places:

1. If there are overlaps between two answer candidates, a partial vote is performed. For instance, for a when question, if one answer candidate is April , 1994 and the other is 1994, then besides the base vote of 1, both candidates have an extra partial vote of $\#overlap/\#total\ words = 1/4$. We call this *adjusted vote*.
2. If the CRF fails to find an answer, we still try to "force" an answer out of the tagged sequence, O's). thus *forced vote*. Due to its lower credibility (the sequence tagger does not think it is an answer), we manually downweight the prediction score by a factor of 0.1 (divide by 10).

		During what war did Nimitz serve ?
O	O:0.921060	Conant
O	O:0.991168	had
O	O:0.997307	been
O	O:0.998570	a
O	O:0.998608	photographer
O	O:0.999005	for
O	O:0.877619	Adm
O	O:0.988293	.
O	O:0.874101	Chester
O	O:0.924568	Nimitz
O	O:0.970045	during
B-ANS	O:0.464799	World
I-ANS	O:0.493715	War
I-ANS	O:0.449017	II
O	O:0.915448	.

Figure 3: A sample sequence tagging output that fails to predict an answer. From line 2 on, the first column is the reference output and the second column is the model output with the marginal probability for predicated labels. Note that World War II has much lower probabilities as an “O” than others.

The modified score for an answer candidate is thus: total vote = adjusted vote + $0.1 \times$ forced vote. To compute forced vote, we make the following observation. Sometimes the sequence tagger does not tag an answer in a candidate sentence at all, if there is not enough probability mass accumulated for B-ANS. However, a possible answer can still be caught if it has an “outlier” marginal probability. Figure 3 shows an example. The answer candidate World War II has a much lower marginal probability as an “O” but still not low enough to be part of B-ANS/I-ANS.

To catch such an outlier, we use Median Absolute Deviation (MAD), which is the median of the absolute deviation from the median of a data sequence. Given a data sequence \mathbf{x} , MAD is defined as:

$$\text{MAD}(\mathbf{x}) = \text{median}(|\mathbf{x} - \text{median}(\mathbf{x})|)$$

Compared to mean value and standard deviation, MAD is more robust against the influence of outliers since it does not directly depend on them. We select those words whose marginal probability is 50 times of MAD away from the median of the whole sequence as answer candidates. They contribute to the forced vote. Downweight ratio (0.1) and MAD

System	Train	Prec.%	Rec.%	F1%
CRF	TRAIN	55.7	43.8	49.1
	TRAIN-ALL	67.2	50.6	57.7
CRF	TRAIN	58.6	46.1	51.6
+WNsearch	TRAIN-ALL	66.7	49.4	56.8
CRF forced	TRAIN	54.5	53.9	54.2
	TRAIN-ALL	60.9	59.6	60.2
CRF forced	TRAIN	55.2	53.9	54.5
+WNsearch	TRAIN-ALL	63.6	62.9	63.3

Table 5: Performance on TEST. “CRF” only takes votes from candidates tagged by the sequence tagger. “CRF forced” (described in §3.3) further collects answer candidates from sentences that CRF does not tag an answer by detecting outliers.

ratio (50) were hand-tuned on DEV.⁹

4 Experiments

4.1 QA Results

The dataset listed in Table 2 was not designed to include an answer for each positive answer sentence, but only a binary indicator on whether a sentence contains an answer. We used the answer pattern files (in Perl regular expressions) released along with TREC8-13 to pinpoint the exact answer fragments. Then we manually checked TRAIN, DEV, and TEST for errors. TRAIN-ALL already came as a noisy dataset so we did not manually clean it, also due to its large size.

We trained on only the positive examples of TRAIN and TRAIN-ALL separately with CRFsuite (Okazaki, 2007). The reason for training solely with positive examples is that they only constitute 10% of all training data and if trained on all, the CRF tagger was very biased on negative examples and reluctant to give an answer for most of the questions. The CRF tagger attempted an answer for about 2/3 of all questions when training on just positive examples.

DEV was used to help design features. A practical benefit of our compact approach is that an entire round of feature extraction, training on TRAIN and testing on DEV took less than one minute. Table 5

⁹One might further improve this by leveraging the probability of a sentence containing an answer from the QA pair ranker described in Section 2 or via the conditional probability of the sequence labels, $p(y | x)$, under the CRF.

reports F1 scores on both the positive and negative examples of TEST.

Our baseline model, which aligns the question word with some content word in the answer sentence,¹⁰ achieves 31.4% in F1. This model does not require any training. “CRF” only takes votes from those sentences with an identified answer. It has the best precision among all models. “CRF forced” also detects outliers from sentences not tagged with an answer. Large amount of training data, even noisy, is helpful. In general TRAIN-ALL is able to boost the F1 value by 7 ~ 8%. Also, the overgenerate-and-vote strategy, used by the “forced” approach, greatly increased recall and achieved the best F1 value.

We also experimented with the two methods utilizing WordNet in Section 2.2 , i.e., WNsearch and WNfeature. In general, WNsearch helps F1 and yields the best score (63.3%) for this task. For WNfeature¹¹ we observed that the CRF model converged to a larger objective likelihood with these features. However, it did not make a difference in F1 after overgenerate-and-vote.

Finally, we found it difficult to do a head-to-head comparison with other QA systems on this task.¹² Thus we contribute this dataset to the community, hoping to solicit direct comparisons in the future. Also, we believe our chunking and question-type features capture many intuitions most current QA systems rely on, while our novel features are based on TED. We further conduct an ablation test to compare traditional and new QA features.

4.2 Ablation Test

We did an ablation test for each of the four types of features. Note that the question type features are used in combination with chunking features (e.g., `qword=how_much|pos[t]=CD|pos[t+1]=NN`), while the chunking feature is defined over POS/NER/DEP

¹⁰This only requires minimal modification to the original TED algorithm: the question word is aligned with a certain word in the answer tree instead of being inserted. Then the whole subtree headed by the aligned word counts as the answer.

¹¹These are binary features indicating whether an answer candidate has a WordNet relation (c.f. §2.2) with the LAT. For instance, `tennis` is a hyponym of the LAT word `sport` in the what sport question in Figure 1.

¹²Reasons include: most available QA systems either retrieve sentences from the web, have different preprocessing steps, or even include templates learned from our test set.

	CRF	Forced		CRF	Forced
All	49.1	54.2	-above 3	19.4	25.3
-POS	44.7	48.9	-EDIT	44.3	47.5
-NER	44.0	50.8	-ALIGN	47.4	51.1
-DEP	49.4	54.5	-above 2	40.5	42.0

Table 6: F1 based on feature ablation tests.

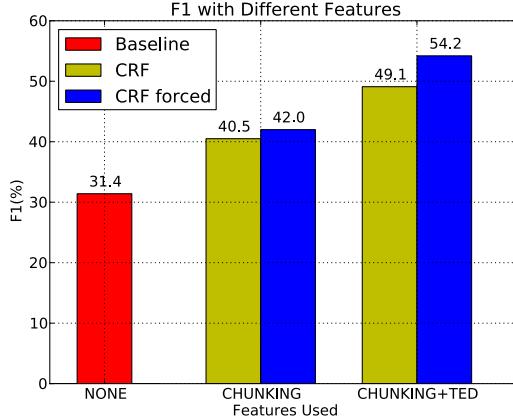

Figure 4: Impact of adding features based on chunking and question-type (CHUNKING) and tree edits (TED), e.g., EDIT and ALIGN.

separately. We tested the CRF model with deletion of one of the following features each time:

- POS, NER or DEP. These features are all combined with question types.
- The three of the above. Deletion of these features also deletes question type feature implicitly.
- EDIT. Features extracted from edit script.
- ALIGN. Alignment distance features.
- The two of the above, based on the TED model.

Table 6 shows the F1 scores of ablation test when trained on TRAIN. NER and EDIT are the two single most significant features. NER is important because it closely relates question types with answer entity types (e.g., `qword=who|ner[t]=PERSON`). EDIT is also important because it captures the syntactic association between question tree and answer tree. Taking out all three POS/NER/DEP features means the chunking and question type features do not fire anymore. This has the biggest impact on F1. Note the feature redundancy here: the question type features are combined with all three POS/NER/DEP features

thus taking out a single one does not decrease performance much. However, since TED related features do not combine question type features, taking out all three POS/NER/DEP features decreases F1 by 30%. Without TED related features (both EDIT and ALIGN) F1 also drops more than 10%.

Figure 4 is a bar chart showing how much improvement each feature brings. While having a baseline model with 31.4% in F1, traditional features based on POS/DEP/NER and question types brings a 10% increase with a simple sequence tagging model (second bar labeled “CHUNKING” in the figure). Furthermore, adding TED based features to the model boosted F1 by another 10%.

5 Conclusion

Answer extraction is an essential task for any text-based question-answering system to perform. In this paper, we have cast answer extraction as a sequence tagging problem by deploying a fast and compact CRF model with simple features that capture many of the intuitions in prior “deep pipeline” approaches. We introduced novel features based on TED that boosted F1 score by 10% compared with the use of more standard features. Besides answer extraction, our modified design of the TED model is the state of the art in the task of ranking QA pairs. Finally, to improve the community’s ability to evaluate QA components without requiring increasingly impractical end-to-end implementations, we have proposed answer extraction as a subtask worth evaluating in its own right, and contributed a dataset that could become a potential standard for this purpose. We believe all these developments will contribute to the continuing improvement of QA systems in the future.

Abstract

Traditional relation extraction seeks to identify pre-specified semantic relations within natural language text, while open Information Extraction (Open IE) takes a more general approach, and looks for a variety of relations without restriction to a fixed relation set. With this generalization comes the question, what is a relation? For example, should the more general task be restricted to relations mediated by verbs, nouns, or both? To help answer this question, we propose two levels of sub-tasks for Open IE. One task is to determine if a sentence potentially contains a relation between two entities? The other task looks to confirm explicit relation words for two entities. We propose multiple SVM models with dependency tree kernels for both tasks. For explicit relation extraction, our system can extract both noun and verb relations. Our results on three datasets show that our system is superior when compared to state-of-the-art systems like REVERB and OLLIE for both tasks. For example, in some experiments our system achieves 33% improvement on nominal relation extraction over OLLIE. In addition we propose an unsupervised rule-based approach which can serve as a strong baseline for Open IE systems.

1 Introduction

Relation Extraction (RE) systems are designed to discover various semantic relations (e.g. <Obama, president, the United States>) from natural language text. Traditional RE systems extract specific relations for prespecified name-entity types (Bunescu and Mooney, 2005; Chan and Dan, 2011;

Zhou and Zhu, 2011). To train such systems, every relation needs manually annotated training examples, which supports limited scope and is difficult to extend. For this reason, Banko et al. (2007) proposed Open Information Extraction (Open IE), whose goal is to extract general relations for two entities. The idea is to avoid the need for specific training examples, and to extract a diverse range of relations. This generalized form has received significant attention, e.g., (Banko et al., 2007; Akbik, 2009; Wu and Weld, 2010; Fader et al., 2011; Mausam et al., 2012).

Because Open IE is not guided by or not restricted to a prespecified list of relations, the immediate challenge is determining about what counts as a relation? Most recent Open IE systems have targeted verbal relations (Banko et al., 2007; Mausam et al., 2012), claiming that these are the majority. However, Chan and Dan (2011) show that only 20% of relations in the ACE programs Relation Detection and Characterization (RDC) are verbal. Our manually extracted relation triple set from the Penn Treebank shows that there are more nominal relations than verbal ones, 3 to 2. This difference arises because of the ambiguity of what constitutes a relation in Open IE. It is often difficult even for humans to agree on what constitutes a relation, and which words in the sentence establish a relation between a pair of entities. For example, in the sentence “Olivetti broke Cocom rules” is there a relation between *Olivetti* and *Cocom*? This ambiguity in the problem definition leads to significant challenges and confusion when evaluating and comparing the performance of different methods and systems. An example are the results in Fader et al. (2011) and Mausam et al. (2012). In Fader et al. (2011), REVERB ”is reported” as su-

perior to WOE^{parse}, a system proposed in Wu and Weld (2010); while in Mausam et al. (2012), it is reported the opposite.

To better answer the question, what counts as a relation? we propose two tasks for Open IE. The first task seeks to determine whether there is a relation between two entities (called “Binary task”). The other is to confirm whether the relation words extracted for the two entities are appropriate (the “Triple task”). The Binary task does not restrict relation word forms, whether they are mediated by nouns, verbs, prepositions, or even implicit relations. The Triple task requires an abstract representation of relation word forms, which we develop here. We assume that relation words are nouns or verbs; in our data, these two types comprise 71% of explicit relations.

We adapt an SVM dependency tree kernel model (Moschitti, 2006) for both tasks. The input to our tasks is a dependency parse, created by Stanford Parser. Selecting relevant features from a parse tree for semantic tasks is difficult. SVM tree kernels avoid extracting explicit features from parse trees by calculating the inner product of the two trees. For the Binary task, our dependency path is the path between two entities. For the Triple task, the path is among entities and relation words (i.e. relation triples). Tree kernels have been used in traditional RE and have helped achieve state of the art performance (Culotta and Sorensen, 2004; Bunescu and Mooney, 2005; Wang, 2008; Nguyen et al., 2009; Zhou and Zhu, 2011). But one challenge of using tree kernels on Open IE is that the lexicon of relations is much larger than those of traditional RE, making it difficult to include the lexical information as features. Here we proposed an unlexicalized tree structure for Open IE. As far as we know, this is the first time an SVM tree kernel has been applied in Open IE. Experimental results on multiple datasets show our system outperforms state-of-the-art systems REVERB and OLLIE. Typically an Open IE system is tested on one dataset. However, because the definition of relation is ambiguous, we believe that is necessary to test with multiple datasets.

In addition to the supervised model, we also propose an unsupervised model which relies on several heuristic rules. Results with this approach show that this simple unsupervised model provides a robust

strong baseline for other approaches.

In summary, our main contributions are:

- Use SVM tree kernels for Open IE. Our system is robust comparing with other Open IE systems, achieving superior scores in two test sets and comparative scores in another set.
- Extend beyond verbal relations, which are prevalent in current systems. Analyze implicit relation problem in Open IE, which is ignored by other work.
- Propose an unsupervised model for Open IE, which can be a strong baseline for other approaches.

The rest of this paper is organized as follows. Section 2 provides the problem description and system structure, before summarizing previous work in Section 3. Section 4 defines our representation of relation word patterns crucial to our task two, and Section 5 describes tree kernels for SVM. Section 6 describes the unsupervised model, and Section 7 explains our experiment design and results. Section 8 concludes with a summary, and anticipation of future work.

2 Problem Definition and System Structure

The common definition of the Open IE task is a function from a sentence, s , to a set of triples, $\{< E1, R, E2 >\}$, where $E1$ and $E2$ are entities (noun phrases) and R is a textual fragment indicating a semantic relation between the two entities. Our “Triple task” is within this definition. However it is often difficult to determine which textual fragments to extract. In addition, semantic relations can be implicit, e.g., consider the *located in* relation in the sentence fragment “Washington, US.” To illustrate how much information is lost when restricting the relation forms, we add another task (the “Binary task”), determining if there is a relation between the two entities. It is a function from s , to a set of binary relations over entities, $\{< E1, E2 >\}$. This binary task is designed to overcome the disadvantage of current Open IE systems, which suffer because of restricting the relation form, e.g., to only verbs, or only nouns. The two tasks are independent to each other.

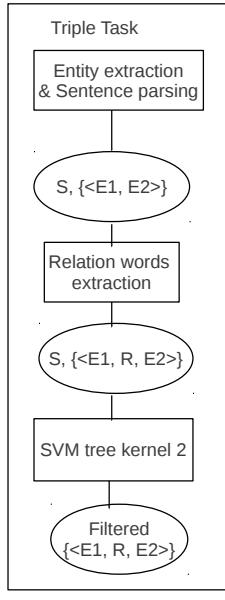

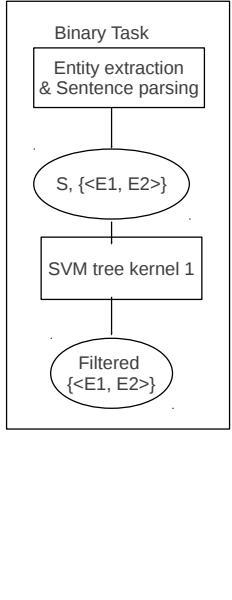

Figure 1: Our Open IE system structure.

Figure 1 presents our Open IE system structure. Both tasks need pre-processing with the Stanford NLP tools¹. Entities and pairs within a certain distance are extracted², and sentences are parsed. We employ the typed collapsed dependency parse (De Marneffe et al., 2006), which is computed from the constituent parsing and has proved to be useful for semantic tasks (MacCartney et al., 2006). For the Binary task, an SVM model is employed to filter out the extracted entity pair candidates, and output pairs which have certain relations. For the Triple task, we identify relation word candidates of the pairs, based on regular expression patterns. Then another SVM model is employed to decide if the relation triples are correct or not.

3 Related Work

In traditional relation extraction, SVM tree kernel models are the basis for the current state of the art (Culotta and Sorensen, 2004; Bunescu and Mooney, 2005; Wang, 2008; Nguyen et al., 2009; Zhou and Zhu, 2011). But there is more recent work on Open IE (Banko et al., 2007; Akbik, 2009; Wu and Weld, 2010; Christensen et al., 2011; Fader et al., 2011; Mausam et al., 2012).

¹Other equivalent tools such as Open NLP could be used.

²Here distance means number of tokens in between

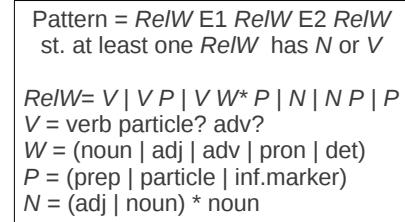

Figure 2: Relation Pattern Form (*RelW* represents *relation words*, *E1* and *E2* are two entities.)

Fader et al. (2011) have developed REVERB, which solves the problem of incoherent extractions and uninformative extractions of two previous systems. Instead of extracting entities first, they extract verbal relation sequences based on a set of POS patterns. Then entities are identified around the relation sequence, so their system only extracts relation tokens between two entities tokens, e.g. relations such as *<he, live in, city>* in “Living in this city, he loves the city.” are ignored. Finally, relation triple candidate noise is filtered by a supervised model which is based on lexical and POS features.

Mausam et al. (2012) present an improved system called OLLIE, which relaxes the previous systems’ constraints that relation words are mediated by verbs, or relation words that appear between two entities. OLLIE creates a training set which includes millions of relations extracted by REVERB with high confidence. Then OLLIE learns relation patterns composed of dependency path and lexicon information. Relations matching the patterns can then be extracted.

Both REVERB and OLLIE output a confidence value for every relation triples, instead of classifying them as true or false.

4 Relation Candidate Extraction

For the Triple task, we extract textual fragments which matches certain POS patterns in an entity pair’s context as relation candidates for that pair. In our experiments, the fragments are n-grams with $n < 5$ and between the pairs or in a window size of 10 before the first entity or after the second entity, which is experimentally a good choice to minimize noise while attaining maximum number of relations.

Our representation of POS regular expression pat-

tern sets expands that of Fader et al. (2011). The patterns are composed of verb and noun phrases (see Figure 2). A relation candidate can consist of words before, between, or after the pair, or the combination of two consecutive positions. Instead of extracting only verbal relations (e.g. *give birth to*), our patterns also extract relations specified through noun phrases. In the sentence “Obama, the president of the United States, made a speech” the relation “president” matches the relational form “RelW=N, N=noun”. Our method can also extract relation words interspersed between the two entities: e.g., ORG has NUM employees, which matches the pattern “E1 RelW E2 RelW”; the first RelW matches V, with V=verb, and the second RelW matches N, with N=noun. We choose not to use the dependency path for relation word extraction because of the reason mentioned in (Fader et al., 2011). The dependency method will create incoherent relations. For example, in the sentence “They recalled that Nungesser began his career as a precinct leader.” *recall began* will be extracted as a relation because the two words are linked. Although this pattern based method has limitations, finding further improvements remains future work.

5 Tree Kernels

Many methods recognize the value of leveraging parsing information in support of semantic tasks. But selecting relevant features from a parse tree is a difficult task. With kernel-based SVMs, both learning and classification relies on the inner-product between instances. SVM tree kernels avoid extracting explicit features from parse trees by calculating the inner product of the two trees, so the tree kernel value depends on the common substructure of two trees. A tree kernel function over Tree T_1 and T_2 is

$$K(T_1, T_2) = \sum_{n_1 \in N_{T_1}} \sum_{n_2 \in N_{T_2}} \Delta(n_1, n_2),$$

N_{T_1} and N_{T_2} are the set of trees’ nodes (Collins and Duffy, 2001). The Δ function provides the basis for identifying subtrees of nodes, which is the essential distinction between different tree kernel functions. Here we adapt the partial tree kernel (PTK) proposed by Moschitti (2006)³, which can be used with both constituent and dependency parse trees. The com-

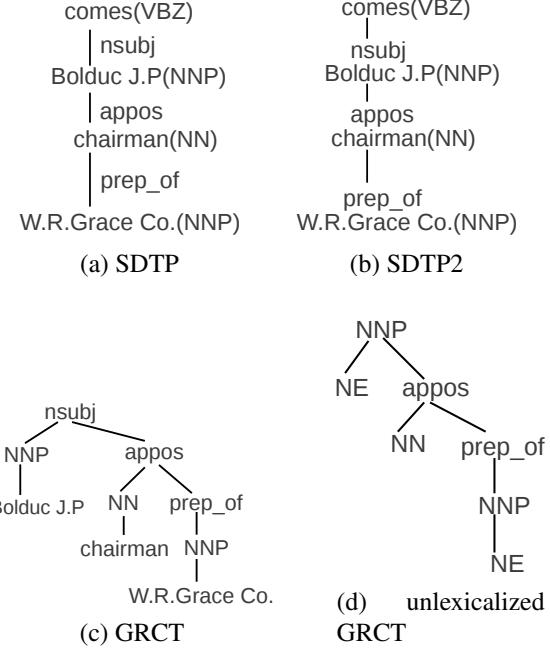

Figure 3: Example trees for shortest dependency path between *J.P. Bolduc* and *W.R. Grace Co.* in sentence “*J.P. Bolduc, vice chairman of W.R. Grace Co., comes here.*” Figure (a) is the shortest dependency tree path (SDTP), (b) is the collapsed form, (c) is the GRCT, (d) is an unlexicalized GRCT with “NE”.

putation of Δ function of PTK is

$$(\sum_{J_1, J_2, l(J_1)=l(J_2)} \lambda^{d(J_1)+d(J_2)} \prod_{i=1}^{l(J_1)} \Delta(c_{n_1}(J_{1i}), c_{n_2}(J_{2i})) + \lambda^2) \mu \quad (1)$$

when the node labels of n_1 and n_2 are the same, $\Delta = 0$ when they are different. c_{n_1} and c_{n_2} are child sequences of nodes n_1 and n_2 respectively, $J_1 = < J_{11}, J_{12}, J_{13} \dots >$ and $J_2 = < J_{21}, J_{22}, J_{23} \dots >$ are index sequences of the two child sequences, J_{1i} and J_{2i} are the i -th children of the two sequences. $l()$ means the sequence length, $d(J_1) = J_{1l(J_1)} - J_{11}$ and $d(J_2) = J_{2l(J_2)} - J_{21}$. μ and λ are two decay factors for the height of the tree and the length of the child sequences respectively, which we choose the default setting in the experiments. For a more detailed description of PTK, please refer to (Moschitti, 2006).

Now we present our unlexicalized dependency

³Thanks to Prof. Moschitti for his PTK package.

tree structures for the tree kernel. One question arising in the conversion dependency structures (e.g., Figure 3a) for the tree kernel is how should we add POS tags and dependency link labels? The kernel cannot process labels on the arcs; they must be associated with tree nodes. Our conversion is similar to the idea of a Grammatical Relation Centered Tree (GRCT) of Croce et al. (2011). First we order the nodes of dependency trees so that the *dominant*, i.e. the parent of the dependency link is on the top, the *dependent*, i.e. the child at the bottom. At this stage, the link label is with the corresponding *dependent* POS-tag and the word (Figure 3b). If a dominant has more than one child, the children will be ordered according to their position in the sentence, from left to right. Next, every node is expanded such that the *dependent* POS-tags are the children of the link labels and parent of their words. For example, in Figure 3c, *NN* is the child of *appos*, parent of *chairman*. It is on the left of *prep_of* because *chairman* is on the left of *W.R.Grace Co.* in the sentence. As customary in Open IE, we do not add content words, while function words are optional. The unlexicalized GRCT is shown in Figure 3d. Note that for the root node, the link label is replaced by the POS-tag of the first node in the path.

Recall that we have two tasks: detecting whether there is a relation between two entities (the Binary task), and whether the relation triple $\langle E1, \text{relation}, E2 \rangle$ is correct (the Triplet task). We define two expanded versions of unlexicalized GRCT for the two tasks. The two versions contain different fragments of a dependency tree of a sentence.

For the Binary task, the shortest path between two entities' heads⁴ is extracted and represented as a GRCT. The root node is the POS-tag of the first node in the path. “NE” is used to represent the position of two entities while relation words are not specified. Figure 3d shows the example final outcome of our tree structure. It is used to decide if there is a relation between the entities *Bolduc J.P.* and *W.R.Grace Co.*

For the Triple task, we first extract relation words based on regular expression patterns as indicated in Section 4. If any relation word is between the short-

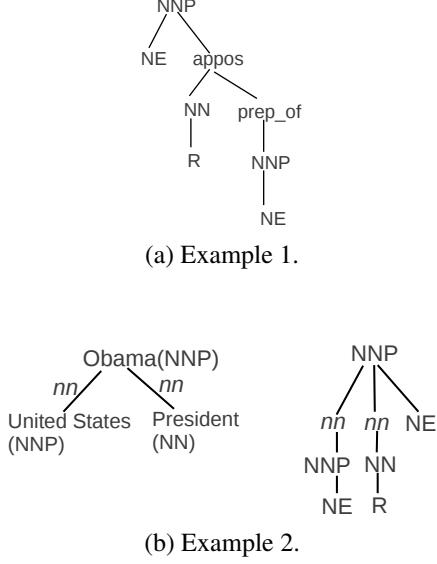

Figure 4: Tree structure with “R” added. Figure (a) is the example 1, which has R in the SDTP of the entity pair. Figure (b) is the example 2, with R not in the SDTP of the entity pair.

est path of the two entities, the path is chosen as the input for SVM. Otherwise, two shortest paths between two entities and relation words will be extracted separately. The shortest one will be attached to the path between two entities. In our representation, relation words are tagged by having “R” as the child. Figure 4a shows the path form of the previous example. Figure 4b shows another example where “R” is not in the shortest path of the pair. The triple is $\langle \text{United States, president, Obama} \rangle$ for the sentence “United States President Barack Obama says so.” The figure on the left is the dependency path. The figure on the right is the final tree for the triple task. The root is the POS-tag for *Obama*.

For the Triple task we combine the tree kernel with a polynomial kernel (Moschitti, 2005) applied to a feature vector. The feature set is in Table 1. F3 tries to preserve the semantic link between two discontinuous relation word segments. F6 constrains relation words to include only necessary prepositions. For verbal relations, if there is a preposition at the end of the relation word sequence, then there must be a preposition link between the relation and any of the two entities, and vice versa. For instance, in the sentence “Bob teaches at the Univer-

⁴The head words of phrases are words which do not depend on any words in the phrases.

sity” $\langle \text{Bob}, \text{teach at}, \text{University} \rangle$ is correct while $\langle \text{Bob}, \text{teach}, \text{University} \rangle$ is wrong. For nominal relations, inclusion of the head word is necessary. Prepositions can be ignored, but if they exist, they must match with the dependency link. We concentrate on verb prepositions because prepositions are more attached to noun phrases than verb phrases. Verb relations have more preposition choices, and different choices have different semantic impact, for example, the subject or object. But noun relations’ preposition are more fixed, such as “president of”. The last two features F7 and F8 are added according to the observation of experiment results in a development set: we note that one problem is the apposition or conjunction structure between entities⁵.

6 Unsupervised Method

We also propose the use of an unsupervised method based on heuristic rules to produce a relation word noise filter, as an alternative to using SVM in the Triple task. The heuristic rules are also based on the Stanford collapsed dependency parsing. There are two parts in the noise filter: one is that the relation words should have necessary links with two entities and the other is that relation words should be consistent.

We first mention the heuristic rules for necessary dependency links. The intuition is from Chan and Dan (2011), they classified relations into 5 different syntactic structures; premodifier, possessive, preposition, formulaic, and verbal. They proposed heuristic POS patterns covering the first four patterns with the exception of the verbal structure.

We present heuristic rules based on dependency paths instead of POS for the structures, except the category formulaic, which are implicit relations. In a premodifier structure one entity and the relation are modifiers of the other entity, (e.g., US. *President Obama*). In a possessive structure one entity is in a possessive case (e.g., Microsoft’s *CEO* Steve Ballmer). In a preposition structure, relation words are related with one entity by a preposition (e.g., Steve Ballmer, *CEO* of Microsoft). In a verbal structure relations are verb phrases.

The heuristic rules are presented in Figure 5. The

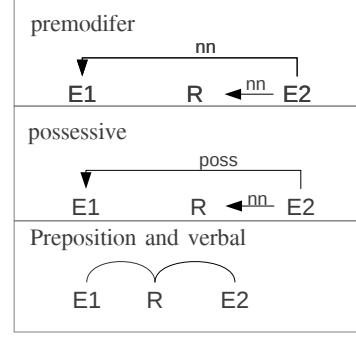

Figure 5: Dependent link heuristics for relation detection.

premodifier and possessive relation words are not in the Stanford collapsed form of the dependency path between two entities. When there is a direct dependency link between two entities that is labelled *nn* or *poss*, there should be an *nn* link between the second entity and the relation candidate (in Figure 5’s top two rows). Otherwise, there should be links between the two entities and the relation, respectively (in Figure 5’s last row). In this case, link types and directions are not constrained. For example, both $E1 \leftarrow(\text{nssubj}) R \rightarrow(\text{dobj}) E2$ for the triple $\langle \text{Obama}, \text{visit}, \text{Canada} \rangle$ in “*Obama visited Canada.*” and $E1 \rightarrow(\text{appos}) R \rightarrow(\text{prep_of}) E2$ for the triple $\langle \text{Obama}, \text{president}, \text{United States} \rangle$ in “*Obama, the president of the United States, visited Canada.*” belong to that structure. To refine the verbal pattern, the link between the relation words and entities cannot be a conjunction.

Next, we need to check the consistency of relation words. Two separated sequences of relation words should have a dependency link between each other to confirm that they are semantically related. Relation sequences should include only necessary prepositions.

7 Experiments

We compared the unsupervised heuristic rule method and the supervised SVM method discussed above against REVERB (Fader et al., 2011) and OL-LIE (Mausam et al., 2012), using three datasets. One dataset consists of sentences from the Penn Treebank, and the other two are the experiment datasets of each of the two systems being compared.

⁵But adding the two features seems does not solve the problem.

E feature	F1	the dependency link label between two entities, <i>null</i> if none.
R features	F2	whether relation is a noun phrase or a verb phrase
	F3	whether there is a link between the two segments (if there are two discontinuous segments)
between E and R	F4	whether there is a link between entities and the relation
	F5	the shortest dependency path distance between entities and the relation (1,2,3,4, or >4)
	F6	the preposition link and the last preposition word of relation (if there is such a link or word)
	F7	whether there is a conjunction link in the shortest path between entities and the relation
	F8	whether there is a apposition link in the shortest path between entities and the relation

Table 1: Noise filter feature vector.

7.1 Treebank Set

7.1.1 Preparing Data

Within the research community, it is difficult to find Open IE test data which includes all kinds of relations. So we have created our own data from the Penn Treebank for evaluation⁶. We assess the drop in performance introduced by using a tool to parse sentences compared to using "ideal" parse trees provided in the Penn Treebank. Named entities are tagged for every sentence using the Stanford NLP tool. Candidate NE pairs are extracted within a certain distance⁷. We randomly selected 756 sentences from WSJ Sections 2-21 as our training set, 100 each from Section 22 and Section 23-24 as the development and the test set, respectively. This is also the setting for most parsers.

We manually annotated whether there is a relation between two entities in a sentence (for evaluation of the Binary task). If there is a relation between two entities, the annotator needs to indicate which words are relation words (for evaluation of the Triple task). There is no restriction of relation forms for the annotator in this task.

We manually analyzed 417 relation instances from our training set. 28% are implicit relations, i.e., relations without words or with prepositions. Less than 1% are with adjectives, while 71% are noun or verb phrases. In the 71%, 60% are noun relations and 40% are verbal. The relation pattern in Section 4 can extract 80% of them. Our data contains more verbal relations than the ACE's RDC, less than corpora in other Open IE papers.

We compare every system by recall, precision, and F-score. The evaluation of the Binary task is

⁶The data can be downloaded from <http://cs.ualberta.ca/~yx2/>

⁷Here we set the distance as 20, determined by empirical evidence, a majority of the relations are within this distance.

based on entity pairs and is straightforward. The evaluation of the Triple task is based on relation triples. We need to manually compare the triples extracted by each system and the gold standard to avoid double-counting. For instance, if both *vice president* and *president* are extracted, it is counted as one⁸. Several entity pairs have multiple relations, such as "A is CEO and founder of B." Any relation which can not be represented by a verb or noun is counted as one miss in the Triple task.

To compare with the REVERB system, NE pairs are labelled as two noun phrase chunks for the system input. It is difficult to compare with OLLIE, as the system is a black box with integrated entity extraction and parsing. We compared manually the pairs extracted by OLLIE and the tagged data. Only results of intersection entity pairs are considered. The threshold of OLLIE and REVERB confidence is set to achieve the best F-score in the development set.

7.1.2 Results

The Binary task results on the test set are shown in Table 2. Each system decides whether there is a relation between two entities. The heuristic rule (DP rules) method, REVERB, and OLLIE each tag pairs containing a relation if any relation candidates are identified. As indicated, the SVM method performs the best with DP rules ranking second. Note that OLLIE uses MaltParser, so it's better to compare with the coupling of SVM with Stanford Parser, but that comparison doesn't change the result.

The Triple task results are shown in Table 3. Each system extracts relation triples from sentences. The SVM features include both tree (Figure 4) and vector features (Table 1). All *relations* in the table include nominal, verbal, and implicit relations. To scrutinize

⁸It is difficult to decide if *president* in this case is wrong. This is related to multi-word expression and will be future work.

OLLIE (MaltParser)	0.429	0.714	0.536

Table 3: Relation extraction results on Treebank set (Triple)

the result, we also show the results on noun and verb relations separately. The SVM model achieves best performance, 33% improvement on nominal relation extractions over OLLIE.

The loss of recall for systems (except SVM) in the Binary task can be explained by the fact that nearly 20% of relations are implicit.

In both the Binary and Triple tasks, one source of failure arose from conjunction and apposition structures. For example, in the sentence "...industry executives analyzed the appointment of the new chief executive, Robert Louis-Dreyfus, who joins Saatchi ..." the method can detect the relation *<chief executive, joins, Saatchi>*, but not *<Robert Louis-Dreyfus, joins, Saatchi>*. We attempted to address this problem by adding features into SVM linear kernel (Table 1), but this has not worked in our tests.

One cause of recall loss in the Triple task for REVERB and our two approaches is that verbal relation words can be non-consecutive. For instance, the preposition might be far away from the related verb in one sentence, in which case both our methods and REVERB can not confirm that extraction. OLLIE

	P	R	F-score
Stanford parsing + DP rules	0.711	0.811	0.756
Stanford parsing + SVM	0.718	0.859	0.781
REVERB	0.577	0.95	0.716

Table 4: Relation extraction results on REVERB set (Triple).

has better results on verb relations mainly because they use dependency link patterns to extract relation words, which alleviate the problem. On the other side, one drawback of OLLIE is that it failed to extract a few premodifier structure relations, e.g. "U.S. President Obama." That may happen because they do not have an independent step for named entity extraction, which is crucial for that type of relations.

7.2 REVERB Set

The authors of the REVERB method provide 1000 tagged training sentences and 500 test sentences. They also provide REVERB's extracted relations and instances' confidence for the 500 test sentences. The 500 test sentences are segmented into 5 folds for a significance t-test. At each iteration, the remaining 400 sentences are used as a development set to set the threshold of REVERB confidence.

To compare with REVERB, we use as input the sentences parsed by the Stanford parser and relation triples extracted by REVERB for both training and testing. The output of our system is true or false for every triple by using the tree kernel⁹. The SVM system is trained on the 1000 training sentences. The results are shown in Table 4. Only SVM is statistically significant better than REVERB (with $\alpha = 0.05$)¹⁰.

7.3 OLLIE set

The authors of the OLLIE system provide a test set which has 300 sentences and OLLIE extracted 900 triples. Experiment setting is similar to that of REVERB set. The SVM tree kernel model is trained on OLLIE's leave one out dataset. The results in Table

⁹The polynomial kernel is not used for REVERB and OLLIE data as the their relation word form is simpler than ours.

¹⁰Note that the results here seem better than the results shown on (Fader et al., 2011). It is because our evaluation is based on the set REVERB extracted, as we only want to compare noise filters not with entity extraction, while the results in (Fader et al., 2011) is based on the union relation set of several systems.

	P	R	F-score
Stanford parsing + SVM	0.685	0.941	0.793
OLLIE	0.667	0.961	0.787

Table 5: Relation extraction results on OLLIE set (Triple).

5 show our method achieves slightly better performance, although not statistically significant.

Besides errors caused by parsing, one main cause of loss of precision is that our system is unable to detect entities that are wrong as we only concern the head of the entity. For instance, “Bogan’s Birmingham Busters , before moving to Los Angeles , California” is one entity in one OLLIE relation, where only “Bogan’s Birmingham Busters” is the correct entity.

8 Conclusion

We have described some of the limits of current Open IE systems, which concentrate on identifying explicit relations, i.e., relations which are mediated by open class words. This strategy ignores what we describe as implicit relations, e.g., *locate* relations in “Washington, U.S.” We propose two subtasks for Open IE: first confirming whether there is a relation between two entities, and then whether a relation thus extracted is correct. The first task include both implicit and explicit relations; the second task is common in the previous Open IE which deals with explicit relations. In our case we have developed an Open IE system which uses SVM tree kernels applied to dependency parses for both tasks. Our system achieves superior results on several datasets. We also propose an unsupervised method which is based on heuristic rules from dependency parse links, and compared that with our SVM tree kernel methods. Our experiments show it is a strong baseline for Open IE.

For further work, we intend to improve Open IE by tackling the conjunction and apposition structure problem. Another direction will be to extract relation words for implicit relations. Relation words such as *locate* for “Washington, U.S.” will be considered.

Acknowledgments

We would like to acknowledge Prof. Grzegorz Kondrak’s valuable advice. We also want to thank the anonymous reviewers for their helpful suggestions. This work was funded in part by the NSERC Business Intelligence Network, Alberta Innovates Center for Machine Learning (AICML) and Alberta Innovates Technology Futures (AITF).

Abstract

In natural language question answering (QA) systems, questions often contain terms and phrases that are critically important for retrieving or finding answers from documents. We present a learnable system that can extract and rank these terms and phrases (dubbed *mandatory matching phrases* or MMPs), and demonstrate their utility in a QA system on Internet discussion forum data sets. The system relies on deep syntactic and semantic analysis of questions only and is independent of relevant documents. Our proposed model can predict MMPs with high accuracy. When used in a QA system features derived from the MMP model improve performance significantly over a state-of-the-art baseline. The final QA system was the best performing system in the DARPA BOLT-IR evaluation.

1 Introduction

In most question answering (QA) systems and search engines term-weights are assigned in a context independent fashion using simple TF-IDF like models (Robertson and Walker, 1994; Ponte and Croft, 1998). Even the more recent advances in information retrieval techniques for query term weighting (Bendersky et al., 2010; Bendersky, 2011) typically rely on bag-of-words models and corpus statistics, such as inverse-document-frequency (IDF), to assign weights to terms in questions. While such solutions may work for keyword queries of the type common on search engines such as Google, they do not exploit syntactic and semantic information when it comes to well formed natural language

questions. In this paper we propose a new model that identifies important terms and phrases in a natural language question, providing better query analysis that ultimately leads to significant improvements in a QA system.

To motivate the work presented here, consider the query “How does one apply for a New York day care license?”. A bag-of-words model would likely assign a high score to “**New licenses for day care** centers in **York** county, PA” because of high word overlap, but it does not answer the question, and also the state is wrong. A matching component that uses the phrases “New York,” “day care,” and “license” is likely to do better. However, a better matching component will understand that *in the context of this query* all three phrases “New York,” “day care” and “license” are important, and that “New York” needs to modify “day care.” A snippet that does not *contain*¹ these important phrases, is unlikely an answer. We call these important phrases *mandatory matching phrases* (MMPs).

In this paper, we explore deep syntactic and semantic analyses of questions to determine and rank MMPs. Unlike existing work (Zhao and Callan, 2010; Bendersky et al., 2010; Bendersky, 2011), where term/concept weights are learned from a set of questions and judged documents based on *corpus-based statistics*, we annotate *questions* and build a trainable system to select and score MMPs. This model relies heavily on existing syntactic parsers and semantic-oriented named-entity recognizers, but does not need question answer pairs. This is espe-

¹“contain” here means semantic equivalence or entailment, not necessarily the exact words or phrases.

cially attractive at the initial system-building stage when no or little answer data is available.

The main contributions of this paper are: firstly, we propose a framework to select and rank important question phrases (MMPs) for question answering in Section 3. This framework seamlessly incorporates lexical, syntactic and semantic information, resulting in an MMP prediction F-measure as high as 88.6%. Secondly, we show that features derived from identified MMPs improve significantly a relevance classification model, in Section 4.2. Thirdly, we show that using the improved relevance model into our QA system results in a statistically significant 5 point improvement in F-measure, in Section 5. This finding is further corroborated by the results on the official 2012 BOLT IR (IR, 2012) task where the combined system yielded the best performance in the evaluation.

2 Related Work

Popular information retrieval systems like BM25 (Robertson and Walker, 1994) and language models (Ponte and Croft, 1998) use unsupervised techniques based on corpus statistics for term weighting. Many of these techniques are variants of the one proposed by (Luhn, 1958). Recently, several researchers have studied approaches for term weighting using supervised learning techniques. However, much of this research has focused on information retrieval task rather than on question answering problems of the nature addressed in this paper. (Bendersky and Croft, 2008) restricted themselves to predicting key noun phrases, which is perhaps sufficient for a retrieval task. However, for questions like “Find comments about how American hedge funds legally avoid taxes,” the verb “avoid” is perhaps as important as the noun phrase “American hedge funds” and “taxes”. Works like that of (Lease et al., 2009) and (Zhao and Callan, 2010) predict importance at the word level. While word level importance is perhaps sufficient for an IR task, predicting the importance of phrases, especially those derived from a parse tree, gives a much richer representation that might also be useful for better question understanding and thus generate more relevant answers. Both (Lease et al., 2009; Zhao and Callan, 2010) propose supervised

methods that learn from a large set of queries and relevance judgments on their answers. While this is possible in a TREC Ad-hoc-retrieval-like task, such a large training corpus of question-answer pairs is unavailable for most scenarios. (Monz, 2007) learns term weights for the IR component of a question answering task. His work unlike ours does not aim to find the answers to the questions.

Most QA systems in the literature have dealt with answering factoid questions, where the answer is a noun phrase in response to questions of the form “Who,” “Where,” “When.” Most systems have a question analysis component that represents the question as syntactic relations in a parse or as deep semantic relations in a handcrafted ontology (Hermjakob et al., 2000; Chu-carroll et al., 2003; Moldovan et al., 2003). In addition certain systems (Bunescu and Huang, 2010) aim to find the “focus” of the question, that is, the noun-phrases in the question that would co-refer with answers. Additionally, much past work has focused on finding the lexical answer type (Pinchak, 2006; Li and Roth, 2002). Since these papers considered a small number of answer types, rules over the detected relations and answer types could be applied to find the relevant answer. However, since our system answers non-factoid questions that can have answer of arbitrary types, we want to use as few rules as possible. The MMPs therefore become a critical component of our system, both for question analysis and for relevance detection.

3 Question Data and MMP Model

To train the MMP model, we first create a set of questions and label their MMPs. The labeled data is then used to train a statistical model to predict MMPs for new questions as discussed next.

3.1 Question Corpus

We use a subset of the DARPA BOLT corpus (see Section 5.1) containing forum postings in English. Four annotators use a search tool to explore this document collection. They can perform keyword searches and retrieve forum threads from which they generate questions. The program participants decided a basic set of question types that are out-of-scope of the current research agenda. Accordingly,

annotators cannot generate questions (1) that require reasoning or calculation over the data to compute the answers; (2) that are vague or ambiguous; (3) that can be broken into multiple disjoint questions; (4) that are multiple choice questions; (5) that are factoid questions—the kinds that have already been well studied in TREC (Voorhees, 2004). Any other kind of question is allowed. Two other annotators, who have neither browsed the corpus nor generated the questions, mark selected spans of the questions into one of two categories—*MMP-Must* and *MMP-maybe*. The annotation tool allows arbitrary spans to be highlighted and the annotators are instructed to select spans corresponding to the smallest semantic units. The phrases that are very likely to appear contiguously in a relevant answer are marked as *MMP-Must*. Annotators can mark multiple spans per question, but not overlapping spans. We generated 201 annotated questions using this process.

Figure 1 contains an example, where “American,” “hedge fund,” and “legally avoid taxes” are required elements to find answers and are thus marked as *MMP-Musts* (signified by enclosing rectangles). We purposely annotate MMPs at the word level and not in the parse tree, because this requires minimal linguistic knowledge. We do, however, employ an automatic procedure to attach MMPs to parse tree nodes when generating MMP training instances.

3.2 MMP Training

Questions annotated in Section 3.1 are first processed by an information extraction (IE) pipeline consisting of syntactic parsing, mention detection and coreference resolution (Florian et al., 2004; Luo et al., 2004; Luo and Zitouni, 2005). After IE, we have access to the syntactic structure represented by a parse tree and semantic information represented by coreferenced mentions (including those of named entities).

To take advantage of the availability of the syntactic and semantic information, we first attach the MMP annotations to parse tree nodes of a question, and, if necessary, we augment the parse tree.

There are several reasons why we want to embed the MMPs into a parse tree. First, many constituents in parse trees correspond to important phrases we want to capture, especially proper names. Second, after an MMP is attached to a tree node, the problem

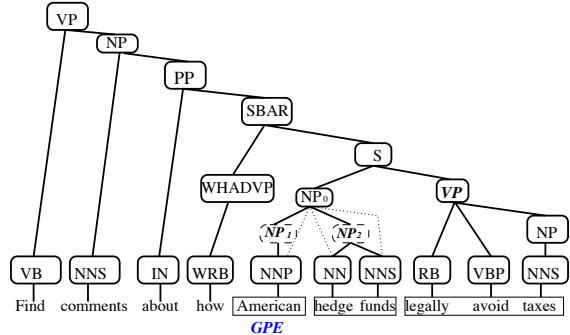

Figure 1: MMPs are aligned with tree nodes: MMPs are shown in rectangular boxes along with their aligned nodes (with slanted labels); augmented parse tree nodes (i.e., NP1, NP2) in dashed nodes. Dotted edges under NP0 are the structure before the tree is augmented.

of predicting MMPs reduces to classifying parse tree nodes, and syntactic information can be naturally built into the MMP classifier. Lastly, and more importantly, associating MMPs with tree nodes opens the door to explore features derived from the syntactic parse tree. For instance, it is easy to read bilexical dependencies from a parse tree (provided that head information is propagated); with MMPs aligned with the parse tree, bilexical dependencies can be ranked by examining whether or not an MMP phrase is a head or a dependent. This way, not only are the dependencies in a question captured, but MMP scores or ranks can be propagated to dependencies as well. We will discuss more how MMP features are computed in Section 4.2.2.

Annotators can mark MMPs that are not perfectly aligned with a tree node. Hence, care has to be taken when generating MMP training instances. As an example, In Figure 1, “American” and “hedge funds” are marked as two separate MMPs, but the Penn-Tree-style parse tree has a flat “NP0” constituent spanning directly on “American hedge fund,” illustrated in Figure 1 as dotted edges.

To anchor MMPs in the parse tree, we *augment* it by combining the IE output and the MMP annotation. In the aforementioned example, “American” is a named mention with the entity type GPE (geo-political entity) and there is no non-terminal node spanning it: so, a new node “NP1” is created; “hedge funds” is marked as an MMP: so, a second node (“NP2”) is created to anchor it.

A training instance for building the MMP model is defined as a span along with an MMP label. For instance, “hedge funds” in Figure 1 will generate a positive training instance as $\langle (5, 6), +1 \rangle$, where $(5, 6)$ is the span of “hedge funds” in the question sentence, and $+1$ signifies that it is a positive training instance. For the purpose of this paper we use only binary labels, mapping all MMP-Must to $+1$ and MMP-Skip and MMP-Maybe to -1 .

Formally, we use the following procedure to generate training instances:

Algorithm 1 Pseudo code to generate MMP training instances.

Input: An input question tree with detected mentions and marked MMPs

Output: A list of MMP training instances

- 1: Foreach mention m in the question
 - 2: if no node spans m , and m does not cross bracket
 - 3: Find lowest node N dominating m
 - 4: Insert a child node of N that spans exactly m
 - 5: Foreach mention p in marked MMPs
 - 6: Find lowest non-terminal N_p dominating p
 - 7: Generate a positive training example for N_p
 - 8: Mark N_p as visited
 - 9: Recursively generate instances for N_p ’s children
 - 10: Generate a negative training instance for all unvisited nodes in Step 5-9
-

Steps 1 to 4 augment the question tree by creating a node for each named mention, provided that no existing node spans exactly the mention and the mention does not cross-bracket tree constituents. Steps 5 to 8 generate positive training instances for marked MMPs; step 9 recursively generates positive training instances² for tree nodes dominated by N_p , where N_p is the lowest non-terminal node dominating the marked MMP p .

After MMP training instances are generated we design and compute features for each instance, and use them to train a classifier.

3.3 MMP Features and Classifier

We compute four types of features that will be used in a statistical classifier. These features are designed to characterize a phrase from the lexical, syntactic,

²One exception to this step is that if a node spans a single stop word, then a negative training instance is generated.

semantic and corpus-level aspect. The weights associated with these features are automatically learned from training data.

We will use “(NP1 American)” in Figure 1 as the running example below.

Lexical Features: Lexical features are motivated by the observation that spellings in English sometimes offer important cues about word significance. For example, an all-capitalized word often signifies an acronym; an all-digit word in a question is likely a year, etc. We compute the following lexical features for a candidate MMP:

CaseFeatures: is the first word of an MMP upper-case? Is it all capital letters? Does it contain numeric letters? For “(NP American)” in Figure 1, the upper-case feature fires.

CommonQWord: Does the MMP contain question words, including “What,” “When,” “Who,” etc.

Syntactic Features: The second group of features are computed from syntactic parse trees after annotated MMPs are aligned with question parse-trees as described previously.

PhraseLabel: this feature returns the phrasal label of the MMP. For “(NP American)” in Figure 1, the feature value is “NP.” This captures that an NP is more likely an MMP than, say, an ADVP.

NPUnique: this Boolean feature fires if a phrase is the only NP in a question, indicating that this constituent probably should be matched. For “(NP American),” the feature value would be false.

PosOfPTN: these features characterize the position of the parse tree node to which an MMP is anchored. They compute: (1) the position of the left-most word of the node; (2) whether the left-most word is the beginning of the question; (3) the depth of the anchoring node, defined as the length of the path to the root node. For “(NP American)” in Figure 1, the features state that it is the 5th word in the sentence; it is not the first word of the sentence; and the depth of the node is 6 (where root has depth 0).

PhrLenToQLenRatio: This feature computes the number of words in an MMP, and its relative ratio to the sentence length. This feature controls the length of MMPs at decoding time, since most of MMPs are short.

Semantic Features (NETypes): The third group of features are computed from named entities and aim to capture semantic information. The feature tests if

a phrase is or contains a named entity, and, if this is the case, the value is the entity type. For “(NP American)” in Figure 1, the feature value would be “GPE.”

Corpus-based Features (AvgCorpusIDF): This group of features computes the average of the IDFs of the words in this phrase. From the corpus IDF, we also compute the ratio between the number of stop words and the total number of words in the MMP, and use it as another feature.

3.4 MMP Classification Results

We now show that we can reliably predict MMPs of questions. We split our set of 201 annotated questions into a training set consisting of 174 questions and a test set with the remaining 27 questions. We use the procedure and features described in Section 3 to train a logistic regression binary classifier using WEKA. Then, the trained MMP classifier is applied to the test set question trees. Since the class bias is quite skewed (only 16% of the phrases are marked as MMP-Must) we also use re-sampling at training time to balance the prior probability of the two classes. At testing time, a parser and a mention detection algorithm (Florian et al., 2004; Luo et al., 2004; Luo and Zitouni, 2005) are run on each question. The detected mentions are then used to augment the question parse trees. The MMP classifier achieves an 88.6% F-measure (cf. Table 1, with 91.6% precision). This is a respectable number, considering the limited amount of training data. We experimented with decision trees and bagging as well but found logistic regression to work the best.

Feature	P	R	F1
AvgCorpusIDF	0.849	0.634	0.725
+NPUnique	0.868	0.634	0.732
+NETypes	0.867	0.662	0.750
+PhraseLabel	0.890	0.705	0.783
+CaseFeatures	0.829	0.820	0.824
+PosOfPTN	0.911	0.852	0.880
+PhrLenToQLenRatio	0.915	0.855	0.883
+commonQWord	0.916	0.858	0.886

Table 1: The performances of the MMP classifier while incrementally adding features.

The examples in Table 2 illustrate the top three MMPs produced by the model on two questions.

These results are encouraging: in the first example the word AIDS is clearly the most “important” word, but IDF alone is not adequate to place it in the top since AIDS is also a common verb (words are lower-cased before IDF look-up). Similarly, in the third example, the phrase “the causes” has a much higher MMP score than the phrase “the concerns” (MMP score of 0.109), even though the words “concerns” has a slightly higher IDF, 2.80, than the word “causes”(2.68). However, in this question, understanding that the word “causes” is critical to the meaning of the question is critical and is captured by the MMP model.

We analyzed feature importance for MMP classification by incrementally adding each feature group to the model. The result is tabulated in Table 1. Not surprisingly, syntactical (i.e., “NPUnique,” “PhraseLabel” and “PosOfPTN”) and semantic features (i.e., “NETypes”) are complementary to the corpus-based statistics features (i.e., average IDF). Lexical features also improve recall: the addition of “Case-Features” boosts the F-measure by 4 points. At first sight, it is surprising that the feature group “PosOfPTN,” which characterize the position of a candidate MMP relative to the sentence and relative to the parse tree, has such a large impact—it improves the F-measure by 5.6 points. However, a cursory browsing of the training questions reveals that most MMPs are short and concentrate towards the end of the sentence. So this feature group helps by directing the model to predict MMPs at the end of the sentence and to prefer short phrases versus long ones.

4 Relevance Model with MMPs

We now validate our second hypothesis that MMPs are effective for open domain question answering. We demonstrate this through the improvement in performance on relevance prediction. More specifically, given a natural language question, the task is one of finding relevant sentences in posts on online forums. The relevance prediction component is critical for question answering as has been seen in TREC(Itycheriah and Roukos, 2001) and more recently in the Jeopardy challenge(Gondek et al., 2012). The improved relevance model further improves our question answering system as seen in Section 5.

Question	Top 3 MMPs	MMP-score	Top words by IDF
List statistics about changes in the demographics of AIDS.	1: AIDS 2: changes 3: the demographics	0.955 0.525 0.349	demographics AIDS statistics
What are the concerns about the causes of autism?	1: autism 2: the causes 3: the causes of autism	0.989 0.422 0.362	autism concerns causes

Table 2: Example questions and the top-3 phrases ranked by the MMP model.

4.1 Data for Relevance Model

The data to train and test the relevance model is obtained as follows. First, a rudimentary version (i.e., key word search) of a QA system using Lucene is built. The Lucene index comprised of a large number of threads in online forums released to the participants of the BOLT-IR task(IR, 2012) for development of our systems. The corpus is described in more detail in Sec. 5. Top snippets returned by the search engine are judged for relevancy by our annotators. The initial (small) batch of data is used to train a relevance model which is deployed in the system. The new model is in turn used to create more answers for new questions. When more data is collected, the relevance model is retrained and redeployed to collect more data. The process is iterated for several months, and at the end of this process, a total of 390 training questions are created and about 28,915 snippets are judged by human annotators, out of which about 6,528 are relevant answers. These question-answers pairs are used to train the final relevance model used in our question-answering system. A separate held-out test set of 59 questions is created and its system output is also judged by humans. This data set is our test set.

4.2 Relevance Prediction

A key component in our question-answering system is the snippet relevance model, which is used to compute the probability that a snippet is relevant to a question. The relevance model is a conditional distribution $P(r|q, s; D)$, where r is a binary random variable indicating if the candidate snippet s is relevant to the question q . D is the document where the snippet s is found.

In our question answering system, MMPs ex-

tracted from questions are used to compute the features for the relevance model. To test their effectiveness, we conduct a controlled experiment by comparing the system with MMP features with 2 baselines: (1) a system without MMP features; (2) a baseline with each word as an MMP and the word’s IDF as the MMP score.

4.2.1 Baseline Features

We list the features used in our baseline system, where no MMP feature is used. The features can be categorized into the following types. **(1) Text Match Features:** One set of features are the cosine scores between different representations of the query and the snippet. In one version the query and snippet words are used as is; in another version the query and snippet are stemmed using porter stemmer; in yet another the words are morphed to their roots by a table extracted from WordNet. We also compute the inclusion scores (the proportion of query words found in the snippet) and other word overlap features. **(2) Answer Type Features:** The top 3 predictions of a statistical classifier trained to predict answer categories were used as features. **(3) Mention Match Features** compute whether a named entity in the query occurs in the snippet. The matching takes into consideration the results from within and cross document coreference resolution components for nominal and pronominal mentions. **(4) Event match features** use several hand-crafted dictionaries containing terms exclusive to various types of events like "violence", "legal", "election". Accordingly a set of features that take a value of "1" if both the query and snippet contain the same event type were designed. **(5) Snippet Statistics:** Several features based on snippet length, the position of the snippet in the post etc were created.

4.2.2 Features Derived from MMP

The MMPs extracted from questions are used to compute features in the following ways.

As MMPs are aligned with a question’s syntactic tree, they can be used to find answers by matching a question constituent with that of a candidate snippet. The MMP model also returns a score for each phrase, which can be used to compute the degree to which a question matches a candidate snippet.

In this section, we use $s = w_1^n$ to denote a snippet with words w_1, w_2, \dots, w_n , and m to denote a phrase from the MMP model along with a score $M(m)$. The features are listed below:

HardMatch: Let $I(m \in s)$ be a 1 or 0 function indicating if a snippet contains the MMP m , then the hard match score is computed as:

$$HM(q, s) = \frac{\sum_{m \in q} M(m) I(m \in s)}{\sum_{m \in q} M(m)}.$$

SoftLMMatch: The SoftLMMatch score is a language-model (LM) based score, similar to that used in (Bendersky and Croft, 2008), except that MMPs play the role of concepts. The snippet-side language model score $LM(v|s)$ is computed as:

$$LM(v|s) = \frac{\sum_{i=1}^n I(w_i = v) + 0.05}{n + 0.05|V|},$$

where w_i is the i^{th} word in snippet s ; $I(w_i = v)$ is an indicator function, taking value 1 if w_i is v and 0 otherwise; $|V|$ is the vocabulary size.

The soft match score between a question q and a snippet s is then:

$$SM(q, s) = \frac{\sum_{m \in q} (M(m) \prod_{w \in m} LM(w|s))}{\sum_{m \in q} M(m)},$$

where $m \in q$ denotes all MMPs in question q , and similarly, $w \in m$ signifying words in m .

MMPInclScore: An MMP m ’s inclusion score is:

$$IS(m, s) = \frac{\sum_{w \in m} I(l(w, s) > \delta) IDF(w)}{\sum_{w \in m} IDF(w)},$$

where $w \in m$ are the words in m ; $I(\cdot)$ is the indicator function taking value 1 when the argument is true and 0 otherwise; δ is a constant threshold; $IDF(w)$ is the IDF of word w . $l(w, s)$ is the similarity of word w to the snippet s as: $l(w, s) =$

$\max_{v \in s} JW(w, v)$, where $JW(w, v)$ is the Jaro Winkler similarity score between words w and v .

The MMP weighted inclusion score between the question q and snippet s is computed as:

$$IS(q, s) = \frac{\sum_{m \in q} M(m) IS(m, s)}{\sum_{m \in q} M(m)}$$

MMPRankDep: This feature, $RD(q, s)$ first tests if there exists a matched bireciprocal dependency between q and s ; if yes, it further tests if the head or dependent in the matched dependency is the head of any MMP.

Let $m_{(i)}$ be the i^{th} ranked MMP; let $\langle w_h, w_d | q \rangle$ and $\langle u_h, u_d | s \rangle$ be bireciprocal dependencies from q and s , respectively, where w_h and u_h are the heads and w_d and u_d are the dependents; let $EQ(w, u)$ be a function testing if the question word w and snippet word u are a match. In our implementation, $EQ(w, u)$ is true if either w and u are exactly the same, or their morphs are the same, or they head the same entity, or their synset in WordNet overlap. With these notations, $RD(q, s)$ is true if and only if

$$EQ(w_h, u_h) \wedge EQ(w_d, u_d) \wedge w_h \in m_{(i)} \wedge w_d \in m_{(j)}$$

is true for some $\langle w_h, w_d | q \rangle$, for some $\langle u_h, u_d | s \rangle$ and for some i and j .

$EQ(w_h, u_h) \wedge EQ(w_d, u_d)$ requires that the question dependency $\langle w_h, w_d | q \rangle$ and the snippet dependency $\langle u_h, u_d | s \rangle$ match; $w_h \in m_{(i)} \wedge w_d \in m_{(j)}$ requires that the head word and dependent word are in the i^{th} -rank and j^{th} rank MMP, respectively. Therefore, $RD(q, s)$ is a dependency feature enhanced with MMPs.

To test the effectiveness of the MMP features, we trained 3 snippet classifiers on the data described in Section 4.1: one baseline system without MMP features (henceforth “no-MMP”); a second baseline with words as MMPs and their IDFs as the scores in the MMP model (henceforth “IDF-as-MMP”); the third system uses the MMPs generated by the model from Section 3 and all MMP features described in this section. We used two types of classifiers: decision tree (DTree) and logistic regression (Logit).

The classification results on a set of 59 questions disjoint from the training set are shown in Table 3. The numbers in the table are F-measure on answer snippets (or positive snippets). Within a machine

Model	Learner	
	DTree	Logit
noMMP	0.426	0.458
IDF-as-MMP	0.413	0.455
MMP	0.451	0.470

Table 3: F-measure for Relevance Prediction.

learning method, the model with MMP features is always the best. Between the two classifiers, the logistic regression models are consistently better than the decision tree ones. The results show that MMP features are very helpful to the relevance model.

5 End-to-End System Results

The question-answering system is used in the 2012 BOLT IR evaluation (IR, 2012). The task is to answer questions against a corpus of posts collected from Internet discussion forums in 3 languages: Arabic, Chinese and English. There are 499K, 449K and 262K threads in each of these languages. The Arabic and Chinese posts were first translated into English before being processed. We now describe our experiments on the set of 59 questions developed internally and demonstrate the effectiveness of an MMP based relevance model in the end-to-end system. In the next subsection we discuss our performance in the BOLT-IR evaluation done by NIST for DARPA.

We now briefly describe the question-answering system we developed for the DARPA BOLT IR task, where we applied the MMP classifier and its features. Users submit questions to the system in natural language; the BOLT program mandates that these questions comply with the restrictions described in Section 3.1. Questions are analyzed by a query preprocessing stage that includes our MMP extraction classifier. The preprocessed queries are converted to search queries. These are sent to an Indri-based search engine (Strohman et al., 2005), which returns candidate passages, typically spanning numerous sentences. Each sentence of the retrieved passages is analyzed by a relevance detection module, consisting of a statistical classifier that uses, among others, features computed from the MMPs extracted from the questions. Sentences or spans that are deemed relevant to the question by the relevance de-

tection module are further grouped into equivalence classes that provide different information about the answers. The system generates a single answer for each equivalence class, since elements of the same class are redundant with respect to each other. The elements of each equivalence class are converted into citations that support the corresponding answer.

The ultimate goal of the MMP model is to improve the performance of our question-answering system. To test the effectiveness of the MMP model, we contrast the model trained in Section 3 with an IDF baseline, where each non-stop word in a question is an MMP and its score is the corpus IDF. The IDF baseline is what a typical question answering system would do in absence of deep question analysis. To have a fair comparison, the two systems are tested on the same set of 59 questions as the relevance model.

The results of the IDF baseline and MMP system are tabulated in Table 4. Note that the recalls are less than 1.0 because (1) annotated snippets come from both systems; (2) the annotation is done for all snippets in a window surrounding system snippets.

As can be seen from Table 4, the MMP system is about 5 points better than the baseline system. The precision is notably better by 2 points, and the recall is far better (by 7.7%) than that of the baseline. We also compute the question-level F-measures and conduct a Wilcoxon signed-rank test for paired samples. The test indicates that the MMP system is better than the baseline system at $p < 0.00066$. Therefore, the MMP system has a clear advantage over the baseline system.

System	Prec	Recall	F1
baseline	.4228	.3679	.3935
MMP	.4425	.4452	.4438

Table 4: End-to-End system result on 59 questions.

5.1 BOLT Evaluation Results

The BOLT evaluation consists of 146 questions, mostly event- or topic-related, e.g., “What are people saying about the ending of NASA’s space shuttle program?”. A system answer, if correct, is mapped manually to a facet, which is one semantic unit that answers the question. For each question, facets are collected across all participants’ submission. A

facet-based F-measure is computed for each participating site. The recall from which the official F-measure is computed is weighted by snippet citations (a citation is a reference to the original document that supports the correct facet). In other words, a snippet with more citations leads to a higher recall than one with less citations. The performances of 4 participating sites are listed in Table 5. Note that the F-measure is weighted and is not necessarily a number between the precision and the recall.

Site	Facet Metric		
	Precision	Recall	(Weighted) F
SITE 1	0.2713	0.1595	0.1713
SITE 2	0.1500	0.1316	0.1109
SITE 3	0.1935	0.2481	0.1734
Ours	0.2729	0.2195	0.2046

Table 5: Official BOLT 2012 IR evaluation results.

Among 4 participating sites, our system has the highest performance. SITE 1 has about the same level of precision, with lower recall, while SITE 3 has the best recall, but lower precision. The results validate that the MMP question analysis technique presented in this paper is quite effective.

6 Conclusions

We propose a framework to select and rank mandatory matching phrases (MMP) for question answering. The framework makes full use of the lexical, syntactic and semantic information in a question and does not require answer data.

The proposed MMP framework is tested at 3 levels in a full QA system and is shown to be very effective to improve its performance: first, we show that it is possible to reliably predict MMPs from questions alone: the MMP classifier can achieve an F-measure as high as 88.6%; second, phrases proposed by the MMP model are incorporated into a snippet relevance model and we show that it improves its performance; third, the MMP framework is used in an question answering system which achieved the best performance in the official 2012 BOLT IR (IR, 2012) evaluation.

Abstract

In a meeting, it is often desirable to extract keywords from each utterance as soon as it is spoken. Thus, this paper proposes a just-in-time keyword extraction from meeting transcripts. The proposed method considers two major factors that make it different from keyword extraction from normal texts. The first factor is the temporal history of preceding utterances that grants higher importance to recent utterances than old ones, and the second is topic relevance that forces only the preceding utterances relevant to the current utterance to be considered in keyword extraction. Our experiments on two data sets in English and Korean show that the consideration of the factors results in performance improvement in keyword extraction from meeting transcripts.

1 Introduction

A meeting is generally accomplished by a number of participants and a wide range of subjects are discussed. Therefore, it would be helpful to meeting participants to provide them with some additional information related to the current subject. For instance, assume that a participant is discussing a specific topic with other participants at a meeting. The summary of previous meetings on the topic is then one of the most important resources for her discussion.

In order to provide information on a topic to participants, keywords should be first generated for the topic since keywords are often representatives of a topic. A number of techniques have been proposed

for automatic keyword extraction (Frank et al., 1999; Turney, 2000; Mihalcea and Tarau, 2004; Wan et al., 2007), and they are designed to extract keywords from a written document. However, they are not suitable for meeting transcripts. In a meeting, it is often desirable to extract keywords at the time at which a new utterance is made for just-in-time service of additional information. Otherwise, the extracted keywords become just the important words at the end of the meeting.

Two key factors for just-in-time keyword extraction from meeting transcripts are time of preceding utterances and topic of current utterance. First, current utterance is affected by temporal history of preceding utterances. That is, when a new utterance is made it is likely to be related more closely with latest utterances than old ones. Second, the preceding utterances which carry similar topics to current utterance are more important than irrelevant utterances. Since a meeting consists of several topics, the utterances that have nothing to do with current utterance are inappropriate as a history of the current utterance.

This paper proposes a graph-based keyword extraction to reflect these factors. The proposed method represents an utterance as a graph of which nodes are candidate keywords. The preceding utterances are also expressed as a history graph in which the weight of an edge is the temporal importance of the keywords connected by the edge. To reflect the temporal history of utterances, *forgetting curve* (Wozniak, 1999) is adopted in updating the weights of edges in the history graph. It expresses effectively not only the reciprocal relation between memory re-

tention and time, but also active recall that makes frequent words more consequential in keyword extraction. Then, a subgraph that is relevant to the current utterance is derived from the history graph, and used as an actual history of the current utterance. The keywords of the current utterance are extracted by TextRank (Mihalcea and Tarau, 2004) from the merged graph of the current utterance and the history graphs.

The proposed method is evaluated with two kinds of data sets: the National Assembly transcripts in Korean and the ICSI meeting corpus (Janin et al., 2003) in English. The experimental results show that it outperforms both the TFIDF framework (Frank et al., 1999; Liu et al., 2009) and the PageRank-based graph model (Wan et al., 2007). One thing to note is that the proposed method improves even the supervised methods that do not reflect utterance time and topic relevance for the ICSI corpus. This proves that it is critical to consider time and content of utterances simultaneously in keyword extraction from meeting transcripts.

The rest of the paper is organized as follows. Section 2 reviews the related studies on keyword extraction. Section 3 explains the overall process of the proposed method, and Section 4 addresses its detailed description how to reflect meeting characteristics. Experimental results are presented in Section 5. Finally, Section 6 draws some conclusions.

2 Related Work

Keyword extraction has been of interest for a long time in various fields such as information retrieval, document clustering, summarization, and so on. Thus, there have been many studies on automatic keyword extraction. The frequency-based keyword extraction with TFIDF weighting (Frank et al., 1999) and the graph-based keyword extraction (Mihalcea and Tarau, 2004) are two base models for this task. Many studies recently tried to extend them by incorporating specific information such as linguistic knowledge (Hulth, 2003), web-based resource (Turney, 2003), and semantic knowledge (Chen et al., 2010). As a result, they show good performance on written text. However, it is difficult to use them directly for spoken genres, since spoken genres have significantly different characteristics from written

text.

There have been a few studies focused on keyword extraction from spoken genres. Among them, the extraction from meetings has attracted more concern, since the need for grasping important points of a meeting or an opinion of each participant has increased. The studies on meetings focused on the exterior features of meeting dialogues such as unstructured and ill-formed sentences. Liu et al. (2009) used some knowledge sources such as Part-of-Speech (POS) filtering, word clustering, and sentence salience to reflect dialogue features, and they found out that a simple TFIDF-based keyword extraction using these knowledge sources works reasonably well. They also extended their work by adopting various features such as decision making sentence features, speech-related features, and summary features that reflect meeting transcripts better (Liu et al., 2011). Chen et al. (2010) extracted keywords from spoken course lectures. In this study, they considered prosodic information from HKT forced alignment and topics in a lecture generated by Probabilistic Latent Semantic Analysis (pLSA). These studies focused on the exterior characteristics of spoken genres, since they assumed that entire scripts are given in advance and then they extracted keywords that best describe the scripts. However, to the best of our knowledge, there is no previous study considered time of utterances which is an intrinsic element of spoken genres.

The relevance between current utterance and preceding utterances is also a critical feature in keyword extraction from meeting transcripts. The study that considers this relevance explicitly is *CollabRank* proposed by Wan and Xiao (2008). This is collaborative approach to extract keywords in a document. In this study, it is assumed that a few neighbor documents close to a current document can help extract keywords. Therefore, they applied a clustering algorithm to a document set and then extracted words that are reinforced by the documents within a cluster. However, this method also does not consider the utterance time, since it is designed to extract keywords from normal documents. As a result, if it is applied to meeting transcripts, all preceding utterances would affect the current utterance uniformly, which leads to a poor performance.

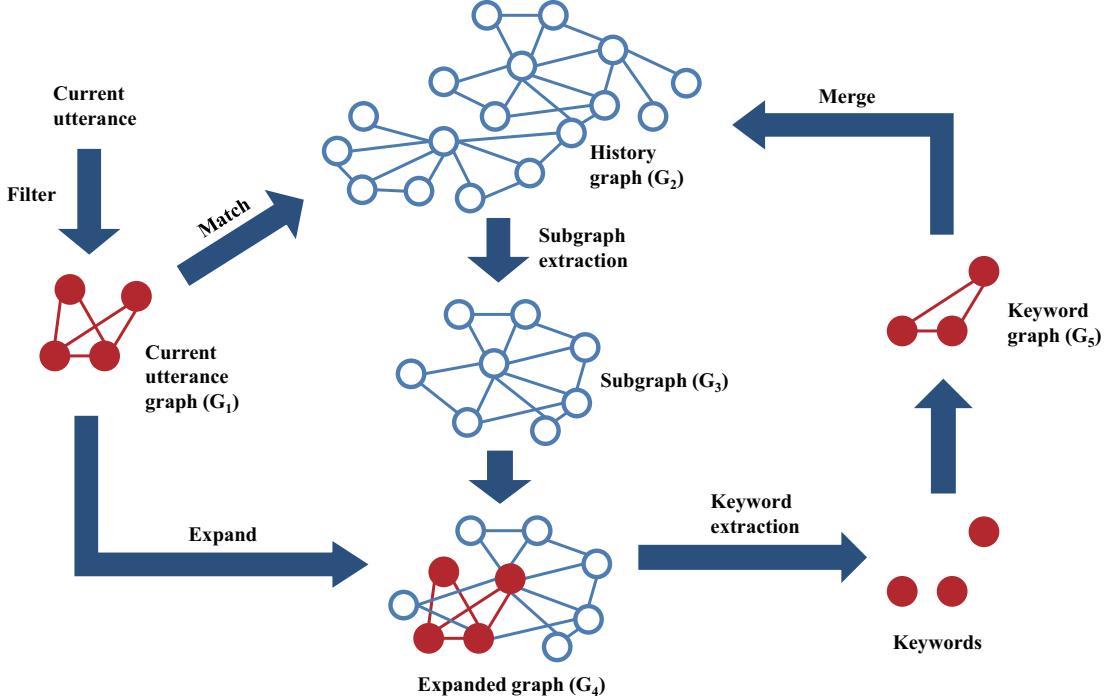

Figure 1: The overall process of the just-in-time keyword extraction from meeting transcripts.

3 Just-In-Time Keyword Extraction for a Meeting

Figure 1 depicts the overall process of extracting keywords from an utterance as soon as it is spoken. We represent all the components in a meeting as graphs. This is because graphs are effective to express the relationship between words, and the graph operations that are required for keyword extraction are also efficiently performed. That is, whenever an utterance is spoken, it is represented as a graph (G_1) of which nodes are the potential keywords in the utterance. This graph is named as *current utterance graph*.

The summary of all preceding utterances is also represented as a *history graph* (G_2). We assume that only the preceding utterances that are directly related with the current utterance are important for extracting keywords from the current utterance. Therefore, a subgraph of G_2 that maximally covers the current utterance graph (G_1) is extracted. This subgraph is labeled as G_3 in Figure 1. Then, the current utterance graph G_1 is expanded by merging it and G_3 . This expanded graph (G_4) is a combined representation of the current and preceding utterances,

and then the keywords of the current utterance is extracted from this graph. The keywords are so-called hub nodes of G_4 .

After keywords are extracted from the current utterance, the current utterance becomes a part of the history graph for the next utterance. For this, the extracted keywords are also represented as a graph (G_5), and it is merged into the current history G_2 . This merged graph becomes a new history graph for the next utterance. In merging two graphs, the weight of each edge in G_2 is updated to reflect the temporal history. If an edge is connecting two nouns from an old utterance, its weight becomes small. In the same way, the weights for the edges from recent utterances get large. The weights of the edges from G_5 are 1, the largest possible value.

4 Graph Representation and Weight Update

4.1 Current Utterance Graph and History Graph

Current utterance graph is a graph-representation of the current utterance. When current utterance consists of m words, we first extract the potential key-

words from the current utterance. Since all words within the current utterance are not keywords, some words are filtered out. For this filtering out, we follow the POS filtering approach proposed by Liu et al. (2009). This approach filters out non-keywords using a stop-word list and POS tags of the words. Assume that n words remain after the filtering out, where $n \leq m$. These n words become the vertices of the current utterance graph.

Formally, the *current utterance graph* $G_1 = (V_1, E_1)$ is an undirected graph, where $|V_1| = n$. E_1 is a set of edges and each edge implies that the nouns connected by the edge co-occur within a window sized W . For each $e_{ij}^1 \in E_1$ that connects nodes v_i^1 and v_j^1 , its weight is given by

$$w_{ij}^1 = \begin{cases} 1 & \text{if } v_i^1 \& v_j^1 \text{ cooccur within the window,} \\ 0 & \text{otherwise.} \end{cases} \quad (1)$$

In a meeting, preceding utterances affect the current utterance. We assume that only the keywords of preceding utterances are effective. Therefore, the *history graph* $G_2 = (V_2, E_2)$ is an undirected graph of keywords in the preceding utterances. That is, all vertices in V_2 are keywords extracted from one or more previous utterances, and the edge between two keywords implies that they co-occurred at least once. Every edge in E_2 has a weight that represents its temporal importance.

The history graph is updated whenever keywords are extracted from a new utterance. This is because the current utterance becomes a part of the history graph for the next utterance. As a history, old utterances are less important than recent ones. Thus, the temporal importance should decrease gradually according to the passage of time. In addition, the keywords which occur frequently at a meeting are more important than those mentioned just once or twice. Since the frequently-mentioned keywords are normally major topics of the meeting, their influence should last for a long time.

To model these characteristics, the *forgetting curve* (Wozniak, 1999) is adopted in updating the history graph. It models the decline of memory retention in time. Figure 2 shows a typical representation of the forgetting curve. The X-axis of this figure is time and the Y-axis is memory retention. As shown in this figure, memory retention of new

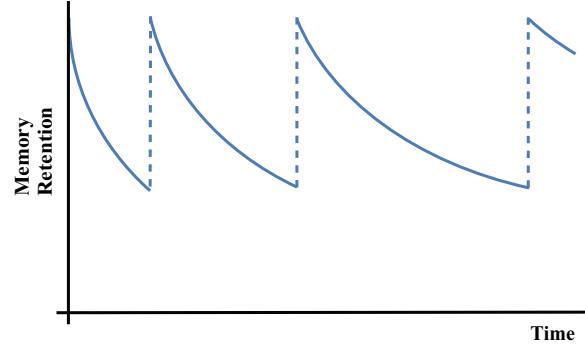

Figure 2: Memory retention according to time.

information decreases gradually by the exponential nature of forgetting. However, whenever the information is repeated, it is recalled longer. This is formulated as

$$R = e^{-\frac{t}{S}},$$

where R is memory retention, t is time, and S is the relative strength of memory.

Based on the forgetting curve, the weight of each edge $e_{ij}^2 \in E_2$ between keywords v_i^2 and v_j^2 is set as

$$w_{ij}^2 = \exp^{-\frac{t}{f(v_i, v_j)}}, \quad (2)$$

where t is the elapse of utterance time and $f(v_i, v_j)$ is the frequency that v_i and v_j co-occur from the beginning of the meeting to now. According to this equation, the temporal importance between keywords decreases gradually as time passes by, but the keyword relations repeated during the meeting are remembered for a long time in the history graph.

4.2 Keyword Extraction by Merging Current Utterance and History Graphs

All words within the history graph are not equally important in extracting keywords from the current utterance. In general, many participants discuss a wide range of topics in a meeting. Therefore, some preceding utterances that shares topics with the current utterance are more significant. We assume that the preceding utterances that contain the nouns in the current utterance share topics with the current utterance. Thus, only a subgraph of G_2 that contain words in G_1 is relevant for keyword extraction from G_1 .

Given the current utterance graph $G_1 = (V_1, E_1)$ and the history graph $G_2 = (V_2, E_2)$, the relevant graph $G_3 = (V_3, E_3)$ is a subgraph of G_2 . Here, $V_3 = (V_1 \cap V_2) \cup \text{adjacency}(V_1)$ and $\text{adjacency}(V_1)$ is a set of vertices from G_2 which are directly connected to the words in V_1 . That is, V_3 contains the words of G_1 and their direct neighbor words in G_2 . E_3 is a subset of E_2 . Only the edges that appear in E_2 are included in E_3 . The weight w_{ij}^3 of each $e_{ij}^3 \in E_3$ is also borrowed from G_2 . That is, $w_{ij}^3 = w_{ij}^2$. Therefore, G_3 is a 1-walk subgraph¹ of G_2 in which words in G_1 and their neighbor words appear.

The keywords of the current utterance should reflect the relevant history as well as the current utterance itself. For this purpose, G_1 is expanded with respect to G_3 . The expanded graph $G_4 = (V_4, E_4)$ of G_1 is defined as

$$\begin{aligned} V_4 &= V_1 \cup V_3, \\ E_4 &= E_1 \cup E_3. \end{aligned}$$

For each edge $e_{ij}^4 \in E_4$, its weight w_{ij}^4 is determined to be the larger value between w_{ij}^1 and w_{ij}^3 if it appears in both G_1 and G_3 . When it appears in only one of the graphs, w_{ij}^4 is set to be the weight of its corresponding graph. That is,

$$w_{ij}^4 = \begin{cases} \max(w_{ij}^1, w_{ij}^3) & \text{if } e_{ij}^4 \in E_1 \text{ and } e_{ij}^4 \in E_3, \\ w_{ij}^1 & \text{if } e_{ij}^4 \in E_1 \text{ and } e_{ij}^4 \notin E_3, \\ w_{ij}^3 & \text{otherwise.} \end{cases}$$

From this expanded graph G_4 , the keywords are extracted by TextRank (Mihalcea and Tarau, 2004). TextRank is an unsupervised graph-based method for keyword extraction. It singles out the key vertices of a graph by providing a ranking mechanism. In order to rank the vertices, it computes the score of each vertex $v_i^4 \in V_4$ by

$$S(v_i^4) = (1 - d) + d \cdot \sum_{v_j^4 \in \text{adj}(v_i^4)} \frac{w_{ji}^4}{\sum_{v_k^4 \in \text{adj}(v_j^4)} w_{jk}^4} S(v_j^4), \quad (3)$$

¹If a m -walk subgraph ($m > 1$) is used, more affluent history is used. However, this graph contains some words irrelevant to the current utterance. According to our experiments, 1-walk subgraph outperforms other m -walk subgraphs where $m > 1$. In addition, extracting G_3 becomes expensive for large m .

where $0 \leq d \leq 1$ is a damping factor and $\text{adj}(v_i)$ denotes v_i 's neighbors. Finally, the words whose score is larger than a specific threshold θ are chosen as keywords. Especially when the current utterance is the first utterance of a meeting, the history graph does not exist. In this case, the current utterance graph becomes the expanded graph ($G_4 = G_1$), and keywords are extracted from the current utterance graph.

The proposed method extracts keywords whenever an utterance is spoken. Thus, it tries to extract keywords even if the current utterance is not related to the topics of a meeting or is too short. However, if the current utterance is irrelevant to the meeting, it has just a few connections with other previous utterances, and thus the potential keywords in this utterance are apt to have a low score. The proposed method, however, does not select the words whose score is smaller than the threshold θ as keywords. As a result, it extracts only the relevant keywords during the meeting.

Since the keywords for the current utterance should be the history for the next utterance, they have to be reflected into the history graph. Therefore, a *keyword graph* $G_5 = (V_5, E_5)$ is constructed from the keywords. Here, V_5 is a set of keywords extracted from G_4 , and E_5 is a subset of E_4 that corresponds to V_5 . The weights of edges in E_5 are same with those in E_4 . That is, $w_{ij}^5 = w_{ij}^4$. The keyword graph G_5 is then merged into the history graph G_2 in the same way that G_1 and G_3 are merged. As stated above, the weights of the edges in the history graph G_2 are updated by Equation (2). Therefore, before merging G_5 and G_2 , all weights of G_2 are updated by increasing t as $t + 1$ to reflect temporal importance of preceding utterances.

5 Experiments

The proposed method is evaluated with two kinds of data sets: the *National Assembly transcripts* in Korean and the *ICSI meeting corpus* in English. Both data sets are the records of meetings that are manually dictated by human transcribers.

Table 1: Simple statistics of the National Assembly transcripts

	the first meeting	the second meeting
No. of utterances	1,280	573
Average No. of words per utterance	7.22	10.17

5.1 National Assembly Transcripts in Korean

The first corpus used to evaluate our method is the National Assembly transcripts². This corpus is obtained from the Knowledge Management System of the National Assembly of KoreaIt is transcribed from the 305th assembly record of the Knowledge Economy Committee in 2012. Table 1 summarizes simple statistics of the National Assembly transcripts. The 305th assembly record actually consists of two meetings. The first meeting contains 1,280 utterances and the second has 573 utterances. The average number of words per utterance in the first meeting is 7.22 while the second meeting contains 10.17 words per utterance on average. The second meeting transcript is used as a development data set to determine window size W of Equation (1), the damping factor d of Equation (3), and the threshold θ . For all experiments below, d is set 0.85, W is 10, and θ is 0.28. The remaining first meeting transcript is used as a data set to extract keywords since this transcript contains more utterances. Only nouns are considered as potential keywords. That is, only the words whose POS tag is NNG (common noun) or NNP (proper noun) can be a keyword.

Three annotators are engaged to extract keywords manually for each utterance in the first meeting transcript, since the Knowledge Management System does not provide the keywords³. The average number of keywords per utterance is 2.58. To see the inter-judge agreement among the annotators, the Kappa coefficient (Carletta, 1996) was investigated. The kappa agreement of the National Assembly transcript is 0.31 that falls under the category of ‘Fair’. Even though all congressmen in the transcript belong to the same committee, they discussed various topics at the meeting. As a result, the keywords are difficult to be agreed unanimously by all three

²The data set is available: <http://ml.knu.ac.kr/dataset/keywordextraction.html>

³A guideline was given to the annotators that keywords must be a single word and the maximum number of keywords per utterance is five.

annotators. Therefore, in this paper the words that are recommended by more than two annotators are chosen as keywords.

The evaluation is done with two metrics: F-measure and the weighted relative score (WRS). Since the previous work by Liu et al. (2009) reported only F-measure and WRS, F-measure instead of precision/recall are used for the comparison with their method. The weighted relative score is derived from *Pyramid* metric (Nenkova and Passonneau, 2004). When a keyword extraction system generates keywords which many annotators agree, a higher score is given to it. On the other hand, a lower score is given if fewer annotators agree.

The proposed method is compared with two baseline models to see its relative performance. One is the frequency-based keyword extraction with TFIDF weighting (Frank et al., 1999) and the other is TextRank in which the weight of edges is mutual information between vertices (Wan et al., 2007). In TFIDF, each utterance is considered as a *document*, and thus all utterances including the current one are regarded as *whole documents*. The frequency-based TFIDF chooses top- K words according to their TFIDF value from the set of words appearing in the meeting transcript. Since the human annotators are restricted to extract up to five keywords, the keyword extraction systems including our method are also requested to select top-5 keywords when more than five keywords are produced.

In order to see the effect of preceding utterances in baseline models, the performances are measured according to the number of preceding utterances used. Figure 3 shows the results. The X-axis of this figure is the number of preceding utterances and the Y-axis represents F-measures. As shown in this figure, the performance of the baseline models improves monotonically at first as the number of preceding utterances increases. However, the performance improvement stops when many preceding utterances are involved, and the performance begins to drop

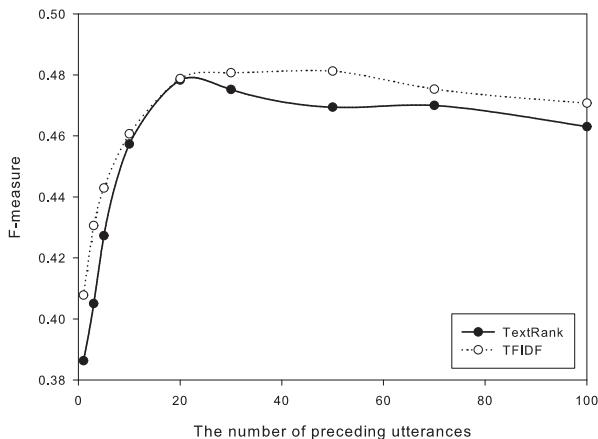

Figure 3: The performance of baseline models according to the number of preceding utterances

Table 2: The experimental results on the National Assembly transcripts

Methods	F-measure	WRS
TextRank	0.478	0.387
TFIDF	0.481	0.394
Proposed method	0.533	0.421

when too many utterances are considered. The performance of TextRank model drops from 20 preceding utterances, while that of TFIDF model begins to drop at 50 utterances. When too many preceding utterances are taken into account, it is highly possible that some of their topics are irrelevant to the current utterance, which leads to performance drop.

Table 2 compares our method with the baseline models on the National Assembly transcripts. The performances of baseline models are obtained when they show the best performance for various number of preceding utterances. TextRank model achieves F-measure of 0.478 and weighted relative score of 0.387, while TFIDF reports its best F-measure of 0.481 and weighted relative score of 0.394. Thus, the difference between TFIDF and TextRank is not significant. However, F-measure and weighted relative score of the proposed method are 0.533 and 0.421 respectively, and they are much higher than those of baseline models. In addition, our method achieves precision of 0.543 and recall of 0.523 and

Table 3: The importance of temporal history

	F-measure	WRS
With Temporal History	0.533	0.421
Without Temporal History	0.518	0.413

this is much higher performance than TextRank whose precision is just 0.510. Since the proposed method uses, as history, the preceding utterances relevant to the current utterance, its performance is kept high even if whole utterances are used. Therefore, it could be inferred that it is important to adopt only the relevant history in keyword extraction from meeting transcripts.

One of the key factors of our method is the temporal history. Its importance is given in Table 3. As explained above, the temporal history is achieved by Equation (2). Thus, the proposed model does not reflect the temporal importance of preceding utterances if $w_{ij}^2 = 1$ always. That is, under $w_{ij}^2 = 1$, old utterances are regarded as important as recent utterances. Without temporal history, F-measure and weighted relative score are just 0.518 and 0.413 respectively. These poor performances prove the importance of the temporal history in keyword extraction from meeting transcripts.

5.2 ICSI Meeting Corpus in English

The proposed method is also evaluated on the ICSI meeting corpus (Janin et al., 2003) which consists of naturally occurring meetings recordings. This corpus is widely used for summarizing and extracting keywords of meetings. We followed all the experimental settings proposed by Liu et al. (2009) for this corpus. Among 26 meeting transcripts chosen by Liu et al. from 161 transcripts of the ICSI meeting corpus, 6 transcripts are used as development data and the remaining transcripts are used as data to extract keywords. The parameters for the ICSI meeting corpus are set to be $d = 0.85$, $W = 10$, and $\theta = 0.20$. Each meeting of the corpus consists of several topic segments, and every topic segment contains three sets of keywords that are annotated by three annotators. Up to five keywords are annotated for a topic segment.

Table 4 shows simple statistics of the ICSI meeting data. Total number of topic segments in the 26 meetings is originally 201, but some of them do not

Table 4: Simple statistics of the ICSI meeting data

Information	Value
# of meetings	26
# of topic segments	201
# of topic segments used actually	140
Average # of utterances per topic segment	260
Average # of words per utterance	7.22

Table 5: The experimental results on the ICSI corpus

Methods	F-measure	WRS
TFIDF-Liu	0.290	0.404
TextRank-Liu	0.277	0.380
ME model	0.312	0.401
Proposed method	0.334	0.533

have keywords. Such segments are discarded, and the remaining 140 topic segments are actually used. The average number of utterances in a topic segment is 260 and the average number of words per utterance is 7.22.

Unlike the National Assembly transcripts, the keywords of the ICSI meeting corpus are annotated at the topic segment level, not the utterance level. Therefore, the proposed method which extracts keywords at the utterance level can not be applied directly to this corpus. In order to obtain keywords for a topic segment with the proposed method, the keywords are first extracted from each utterance in the segment by the proposed method and then they are all accumulated. The proposed method extracts keywords for a topic segment from these accumulated utterance-level keywords as follows. Assume that a topic segment consists of l utterances. Since our method can extract up to 5 keywords for each utterance, the number of keywords for the segment can reach to $5 \cdot l$. From these keywords, we select top-5 keywords ranked by Equation (3).

The proposed method is compared with three previous studies. The first two are the methods proposed by Liu et al. (2009) One is the frequency-based method of TFIDF weighting with the features such as POS filtering, word clustering, and sentence salience score, and the other is the graph-based method with POS filtering. The last method is a maximum entropy model applied to this task (Liu et al., 2008). Note that the maximum entropy is a supervised learning model.

Table 6: The effect of considering topic relevance

Methods	F-measure	WRS
With topic relevance	0.334	0.533
Without topic relevance	0.291	0.458

Table 5 summarizes the comparison results. As shown in this table, the proposed method outperforms all previous methods. Our method achieves precision of 0.311 and recall of 0.361, and thus the F-score is 0.334. The weight relative score of the proposed method is 0.533. This is the improvement of up to 0.044 in F-measure and 0.129 in weighted relative score over other unsupervised methods (TFIDF-Liu and TextRank-Liu). It should be also noted that the proposed method outperforms even the supervised method (ME model). The difference between our method and the maximum entropy model in weighted relative score is 0.132.

One possible variant of the proposed method for the ICSI corpus is to simply merge the current utterance graph (G_1) with the history graph (G_2) rather than to extract keywords from each utterance. After the current utterance graph of the last utterance in a topic segment is merged into the history graph, the keywords for the segment are extracted from the history graph. This variant and the proposed method both rely on the temporal history, but the difference is that the history graph of the variant accumulates all information within the topic segment. Thus, the keywords extracted from the history graph by this variant are those without consideration of topic relevance.

Table 6 compares the proposed method with the variant. The performance of the variant is higher than those of TFIDF-Liu and TextRank-Liu. This proves the importance of the temporal history in keyword extraction from meeting transcripts. However, the proposed method still outperforms the variant, and it demonstrates the importance of topic relevance. Therefore, it can be concluded that the consideration of temporal history and topic relevance is critical in keyword extraction from meeting transcripts.

6 Conclusion

In this paper, we have proposed a just-in-time keyword extraction from meeting transcripts. Whenever an utterance is spoken, the proposed method extracts keywords from the utterance that best describe the utterance. Based on the graph representation of all components in a meeting, the proposed method extracts keywords by TextRank with some graph operations.

Temporal history and topic of the current utterance are two major factors especially in keyword extraction from meeting transcripts. This is because recent utterances are more important than old ones and only the preceding utterances of which topic is relevant to the current utterance are important. To model the temporal importance of the preceding utterances, the concept of forgetting curve is used in updating the history graph of preceding utterances. In addition, the subgraph of the history graph that shares words appearing in the current utterance graph is used to extract keywords rather than whole history graph. The proposed method was evaluated with the National Assembly transcripts and the ICSI meeting corpus. According to our experimental results on these data sets, the performance of keyword extraction is improved when we consider temporal history and topic relevance.

Same Referent, Different Words: Unsupervised Mining of Opaque Coreferent Mentions

Marta Recasens*, Matthew Can†, and Dan Jurafsky*

Abstract

Coreference resolution systems rely heavily on string overlap (e.g., *Google Inc.* and *Google*), performing badly on mentions with very different words (**opaque** mentions) like *Google* and *the search giant*. Yet prior attempts to resolve opaque pairs using ontologies or distributional semantics hurt precision more than improved recall. We present a new unsupervised method for mining opaque pairs. Our intuition is to *restrict* distributional semantics to articles about the same event, thus promoting referential match. Using an English comparable corpus of tech news, we built a dictionary of opaque coreferent mentions (only 3% are in WordNet). Our dictionary can be integrated into any coreference system (it increases the performance of a state-of-the-art system by 1% F1 on all measures) and is easily extendable by using news aggregators.

1 Introduction

Repetition is one of the most common coreferential devices in written text, making string-match features important to all coreference resolution systems. In fact, the scores achieved by just head match and a rudimentary form of pronominal resolution¹ are not far from that of state-of-the-art systems (Recasens and Hovy, 2010). This suggests that **opaque** mentions (i.e., lexically different) such as *iPad* and *the Cupertino slate* are a serious problem for modern systems: they comprise 65% of the non-pronominal

errors made by the Stanford system on the CoNLL-2011 data. Solving this problem is critical for overcoming the recall gap of state-of-the-art systems (Haghighi and Klein, 2010; Stoyanov et al., 2009).

Previous systems have turned either to ontologies (Ponzetto and Strube, 2006; Uryupina et al., 2011; Rahman and Ng, 2011) or distributional semantics (Yang and Su, 2007; Kobdani et al., 2011; Bansal and Klein, 2012) to help solve these errors. But neither semantic similarity nor hypernymy are the same as coreference: *Microsoft* and *Google* are distributionally similar but not coreferent; *people* is a hypernym of both *voters* and *scientists*, but *the people* can corefer with *the voters*, but is less likely to corefer with *the scientists*. Thus ontologies lead to precision problems, and to recall problems like missing NE descriptions (e.g., *Apple* and *the iPhone maker*) and metonymies (e.g., *agreement* and *wording*), while distributional systems lead to precision problems like coreferring *Microsoft* and *the Mountain View giant* because of their similar vector representation (*release*, *software*, *update*).

We increase precision by drawing on the intuition that referents that are *both* similar *and* participate in the same event are likely to corefer. We restrict distributional similarity to collections of articles that discuss the same event. In the following two documents on the Nexus One from different sources, we take the subjects of the identical verb *release*—*Google* and *the Mountain View giant*—as coreferent.

Document 1: Google has released a software update.

Document 2: The Mountain View giant released an update.

Based on this idea, we introduce a new unsupervised method that uses verbs in comparable corpora

¹Closest NP with the same gender and number.

as pivots for extracting the hard cases of coreference resolution, and build a dictionary of opaque coreferent mentions (i.e., the dictionary entries are pairs of mentions). This dictionary is then integrated into the Stanford coreference system (Lee et al., 2011), resulting in an average 1% improvement in the F1 score of all the evaluation measures.

Our work points out the importance of context to decide whether a specific mention pair is coreferent. On the one hand, we need to know what semantic relations are potentially coreferent (e.g., *content* and *video*). On the other, we need to distinguish contexts that are compatible for coreference—(1) and (2-a)—from those that are not—(1) and (2-b).

- (1) Elemental helps those big media entities process content across a full slate of mobile devices.
- (2)
 - a. Elemental provides the picks and shovels to make video work across multiple devices.
 - b. Elemental is powering **the video** for HBO Go.

Our dictionary of opaque coreferent pairs is our solution to the first problem, and we report on some preliminary work on context compatibility to address the second problem.

2 Building a Dictionary for Coreference

To build a dictionary of semantic relations that are appropriate for coreference we will use a cluster of documents about the same news event, which we call a **story**. Consider as an example the story *Sprint blocks out vacation days for employees*. We determine using tf-idf the representative verbs for this story, the main actions and events of the story (e.g., *block out*). Since these verbs are representative of the story, different instances across documents in the cluster are likely to refer to the same events (*Sprint blocks out...* and *the carrier blocks out...*). By the same logic, the subjects and objects of the verbs are also likely to be coreferent (*Sprint* and *the carrier*).

2.1 Comparable corpus

To build our dictionary, we require a monolingual **comparable corpus**, containing clusters of documents from different sources that discuss the same story. To ensure likely coreference, the story must be the very same; documents that are merely clustered by (general) topic do not suffice. The corpus

does not need to be parallel in the sense that documents in the same cluster do not need to be sentence aligned.

We used Techmeme,² a news aggregator for technology news, to construct a comparable corpus. Its website lists the major tech stories, each with links to several articles from different sources. We used the Readability API³ to download and extract the article text for each document. We scraped two years worth of data from Techmeme and only took stories containing at least 5 documents. Our corpus contains approximately 160 million words, 25k stories, and 375k documents. Using a corpus from Techmeme means that our current coreference dictionary is focused on the technological domain. Our method can be easily extended to other domains, however, since getting comparable corpora is relatively simple from the many similar news aggregator sites.

2.2 Extraction

After building our corpus, we used Stanford’s CoreNLP tools⁴ to tokenize the text and annotate it with POS tags and named entity types. We parsed the text using the MaltParser 1.7, a linear time dependency parser (Nivre et al., 2004).⁵

We then extracted the representative verbs of each story by ranking the verbs in each story according to their tf-idf scores. We took the top ten to be the representative set. For each of these verbs, we clustered together its subjects and objects (separately) across instances of the verb in the document cluster, excluding pronouns and NPs headed by the same noun. For example, suppose that *crawl* is a representative verb and that in one document we have *Google crawls web pages* and *The search giant crawls sites* in another document. We will create the clusters {*Google, the search giant*} and {*web pages, sites*}.

When detecting representative verbs, we kept phrasal verbs as a unit (e.g., *give up*) and excluded auxiliary and copular verbs,⁶ light verbs,⁷ and report

²<http://www.techmeme.com>

³<http://www.readability.com/developers/api>

⁴<http://nlp.stanford.edu/software/corenlp.shtml>

⁵<http://www.maltparser.org>

⁶Auxiliary and copular verbs include *appear, be, become, do, have, seem*.

⁷Light verbs include *do, get, give, go, have, keep, make, put, set, take*.

verbs,⁸ as they are rarely representative of a story and tend to add noise to our dictionary. To increase recall, we also considered the synonyms from WordNet and nominalizations from NomBank of the representative verbs, thus clustering together the subjects and objects of any synonym as well as the arguments of nominalizations.⁹ We used syntactic relations instead of semantic roles because the MaltParser is faster than any SRL system, but we checked for frequent syntactic structures in which the agent and patient are inverted, such as passive and ergative constructions.¹⁰

From each cluster of subject or object mentions, we generated all pairs of mentions. This forms the initial version of our dictionary. The next sections describe how we filter and generalize these pairs.

2.3 Filtering

We manually analyzed 200 random pairs and classified them into coreference and spurious relations. The spurious relations were caused by errors due to the parser, the text extraction, and violations of our algorithm assumption (i.e., the representative verb does not refer to a unique event). We employed a filtering strategy to improve the precision of the dictionary. We used a total of thirteen simple rules, which are shown in Table 1. For instance, we sometimes get the same verb with non-coreferent arguments, especially in tech news that compare companies or products. In these cases, NEs are often used, and so we can get rid of a large number of errors by automatically removing pairs in which both mentions are NEs (e.g., *Google* and *Samsung*).

Before filtering, 53% of all relations were good coreference relations versus 47% spurious ones. Of the relations that remained after filtering, 74% were

Both mentions are NEs
Both mentions appear in the same document
Object of a negated verb
Enumeration or list environment
Sentence is ill-formed
Number NE
Temporal NE
Quantifying noun
Coordinated
Verb is preceded by a determiner or an adjective
Head is not nominal
Sentence length ≥ 100
Mention length $\geq 70\%$ of sentence length

Table 1: Filters to improve the dictionary precision. Unless otherwise noted, the filter was applied if either mention in the relation satisfied the condition.

coreferent and only 26% were spurious. In total, about half of the dictionary relations were removed in the filtering process, resulting in a total of 128,492 coreferent pairs.

2.4 Generalization

The final step of generating our dictionary is to process the opaque mention pairs so that they generalize better. We strip mentions of any determiners, relative clauses, and -ing and -ed clauses. However, we retain adjectives and prepositional modifiers because they are sometimes necessary for coreference to hold (e.g., *online piracy* and *distribution of pirated material*). We also generalize NEs to their types so that our dictionary entries can function as templates (e.g., *Cook's departure* becomes *<person>'s departure*), but we keep NE tokens that are in the head position as these are pairs containing world knowledge (e.g., *iPad* and *slate*). Finally, we replace all tokens with their lemmas. Table 2 shows a snapshot of the dictionary.

2.5 Semantics of coreference

From manually classifying a sample of 200 dictionary pairs (e.g., Table 2), we find that our dictionary includes many synonymy (e.g., *IPO* and *offering*) and hypernymy relations (e.g., *phone* and *device*), which are the relations that are typically extracted from ontologies for coreference resolution. However, not all synonyms and hypernyms are valid for coreference (recall the *voters-people* vs. *scientists-people* example in the introduction), so our dic-

⁸Report verbs include *argue*, *claim*, *say*, *suggest*, *tell*, etc.

⁹As a general rule, we extract possessive phrases as subjects (e.g. *Samsung's plan*) and *of*-phrases as objects (e.g. *development of the new logo*).

¹⁰We can easily detect passive subjects (i-b) as they have their own dependency label, and ergative subjects (ii-b) using a list of ergative verbs extracted from Levin (1993).

- (i) a. Developers hacked **the device**.
 b. **The device** was hacked.

- (ii) a. Police scattered **the crowds**.
 b. **The crowds** scattered.

Table 2: Coreference relations in our dictionary.

tionary only includes the ones that are relevant for coreference (e.g., *update* and *change*). Furthermore, only 3% of our 128,492 opaque pairs are related in WordNet, confirming that our method is introducing a large number of new semantic relations.

We also discover other semantic relations that are relevant for coreference, such as various metonymy relations like mentioning the part for the whole. Again though, we can use some part-whole relations coreferentially (e.g., *car* and *engine*) but not others (e.g., *car* and *window*). Our dictionary includes part-whole relations that have been observed as coreferent at least once (e.g., *company* and *site*). We also extract world-knowledge descriptions for NEs (e.g., *Google* and *the Internet giant*).

3 Integration into a Coreference System

We next integrated our dictionary into an existing coreference resolution system to see if it improves resolution.

3.1 Stanford coreference resolution system

Our baseline is the Stanford coreference resolution system (Lee et al., 2011) which was the highest-scoring system in the CoNLL-2011 Shared Task,

Sieve number	Sieve name
1	Discourse processing
2	Exact string match
3	Relaxed string match
4	Precise constructs
5–7	Strict head match
8	Proper head noun match
9	Relaxed head match
10	Pronoun match

Table 3: Rules of the baseline system.

and was also part of the highest-scoring system in the CoNLL-2012 Shared Task (Fernandes et al., 2012). It is a rule-based system that includes a total of ten rules (or “sieves”) for entity coreference, shown in Table 3. The sieves are applied from highest to lowest precision, each rule extending entities (i.e., mention clusters) built by the previous tiers, but never modifying links previously made. The majority of the sieves rely on string overlap.¹¹

The highly modular architecture made it easy for us to integrate additional sieves using our dictionary to increase recall.

3.2 Dictionary sieves

We propose four new sieves, each one using a different granularity level from our dictionary, with each consecutive sieve using higher precision relations than the previous one. The Dict 1 sieve uses only the heads of mentions in each relation (e.g., *devices*). Dict 2 uses the heads and one premodifier, if it exists (e.g., *iOS devices*). Dict 3 uses the heads and up to two premodifiers (e.g., *new iOS devices*). Dict 4 uses the full mentions, including any postmodifiers (e.g., *new iOS devices for businesses*).

We take advantage of frequency counts to get rid of low-precision coreference pairs and only keep (i) pairs that have been seen more than 75 times (Dict 1) or 15 times (Dict 2, Dict 3, Dict 4); and (ii) pairs with a frequency count larger than 8 (Dict 1) or 2 (Dict 2, Dict 3, Dict 4) and a normalized PMI score larger than 0.18. We use the normalized PMI score (Bouma, 2009) as a measure of association between the mentions m_i and m_j of a

¹¹Exceptions: sieve 1 links first-person pronouns inside a quotation with the speaker; sieve 4 links mention pairs that appear in an appositive, copular, acronym, etc., construction; sieve 10 implements generic pronominal coreference resolution.

dictionary pair, computed as

$$(\ln \frac{p(m_i, m_j)}{p(m_i)p(m_j)}) / -\ln p(m_i, m_j)$$

These thresholds were set on the development set.

Since the different coreference rules in the Stanford system are arranged in decreasing order of precision, we start by applying the sieve that uses the highest-precision relations in the dictionary (Dict 4), followed by Dict 3, Dict 2, and Dict 1. We add these new sieves right before the last sieve, as the pronominal sieve can perform better if opaque mentions have been successfully linked. The current sieves only use the dictionary for linking singular mentions, as the experiments on the dev showed that plural mentions brought too much noise.

For any mention pair under analysis, each sieve checks whether it is supported by the dictionary as well as whether basic constraints are satisfied, such as number, animacy and NE-type agreement, and NE-common noun order (not the opposite).

4 Experiments

4.1 Data

Although our dictionary creation technology can apply across domains, our current coreference dictionary is focused on the technical domain, so we created a coreference labeled corpus in this domain for evaluation. We extracted new data from Techmeme (different from that used to extract the dictionary) to create a development and a test set. It is important to note that we do not need comparable data at this stage. A massive comparable corpus is only needed for mining the coreference dictionary (Section 2); once it is built, it can be used for solving coreference within and across documents.

The annotation was performed by two experts, using the Callisto annotation tool. The development and test sets were annotated with coreference relations following the OntoNotes guidelines (Pradhan et al., 2007). We annotated full NPs (with all modifiers), excluding appositive phrases and predicate nominals. Only premodifiers that were proper nouns or possessive phrases were annotated. We extended the OntoNotes guidelines by also annotating singletons. Table 4 shows the dataset statistics.

Dataset	Stories	Docs	Tokens	Entities	Mentions
Dev	4	27	7837	1360	2279
Test	24	24	8547	1341	2452

Table 4: Dataset statistics: development (dev) and test.

4.2 Evaluation measures

We evaluated using six coreference measures, as they sometimes provide different results and there is no agreement on a standard. We used the scorer of the CoNLL-2011 Shared Task (Pradhan et al., 2011).

- MUC (Vilain et al., 1995). Link-based metric that measures how many links the true and system partitions have in common.
- B^3 (Bagga and Baldwin, 1998). Mention-based metric that measures the proportion of mention overlap between gold and predicted entities.
- CEAF- ϕ_3 (Luo, 2005). Mention-based metric that, unlike B^3 , enforces a one-to-one alignment between gold and predicted entities.
- CEAF- ϕ_4 (Luo, 2005). The entity-based version of the above metric.
- BLANC (Recasens and Hovy, 2011). Link-based metric that considers both coreference and non-coreference links.
- CoNLL (Denis and Baldridge, 2009). Average of MUC, B^3 and CEAF- ϕ_4 . It was the official metric of the CoNLL-2011 Shared Task.

4.3 Results

We always start from the baseline, which corresponds to the Stanford system with the sieves listed in Table 3. This is the set of sieves that won the CoNLL-2011 Shared Task (Pradhan et al., 2011), and they exclude WordNet.

Table 5 shows the incremental scores, on the development set, for the four sieves that use the dictionary, corresponding to the different granularity levels, from the highest precision one (Dict 4) to the lowest one (Dict 1). The largest improvement is achieved by Dict 4 and Dict 3, as they improve recall (R) without hurting precision (P). R is equivalent to P for CEAF- ϕ_4 , and vice versa. The other two sieves increase R further, especially Dict 1, but also decrease P, although the trade-off for the F-score (F1) is still positive. It is the best score, with the exception of B^3 .

System	MUC			B^3			CEAF- ϕ_3			CEAF- ϕ_4			BLANC			CoNLL F1
	R	P	F1	R	P	F1	R	P	F1	R	P	F1	R	P	B	
Baseline	55.9	72.8	63.3	74.1	89.8	81.2	74.6	85.2	73.6	79.0	66.6	87.1	72.6	74.5		
+Dict 4	57.0	72.8	63.9	75.1	89.4	81.6	75.3	85.2	74.3	79.4	68.2	87.3	74.2	75.0		
+Dict 3	57.6	72.8	64.3	75.4	89.3	81.7	75.5	85.1	74.6	79.5	68.4	87.2	74.4	75.2		
+Dict 2	57.6	72.5	64.2	75.4	89.1	81.7	75.4	85.0	74.6	79.5	68.4	87.0	74.3	75.1		
+Dict 1	58.4	71.9	64.5	75.7	88.5	81.6	75.5	84.6	75.1	79.6	68.6	86.6	74.4	75.2		

Table 5: Incremental results for the four sieves using our dictionary on the development set. Baseline is the Stanford system without the WordNet sieves. Scores are on gold mentions.

System	MUC			B^3			CEAF- ϕ_3			CEAF- ϕ_4			BLANC			CoNLL F1
	R	P	F1	R	P	F1	R	P	F1	R	P	F1	R	P	B	
Baseline	62.4	78.2	69.4	73.7	89.5	80.8	75.1	86.2	73.8	79.5	71.4	88.6	77.3	76.6		
w/ WN	63.5	75.3	68.9	74.2	87.5	80.3	74.1	83.7	74.1	78.6	71.8	87.3	77.3	75.9		
w/ Dict	64.7*	77.6*	70.6*	75.7*	88.5*	81.6*	76.5*	85.3*	75.0*	79.9*	74.6*	88.6	79.9*	77.3*		
w/ Dict + Context	64.8*	77.8*	70.7*	75.7*	88.6*	81.7*	76.5*	85.5*	75.1*	80.0*	74.6*	88.7	79.9*	77.5*		

Table 6: Performance on the test set. Scores are on gold mentions. Stars indicate a statistically significant difference with respect to the baseline.

Table 6 reports the scores on the test set and compares the scores obtained by adding the WordNet sieves to the baseline (w/ WN) with those obtained by adding the dictionary sieves (w/ Dict). Whereas adding WordNet only brings a small improvement in R that is much lower than the loss in P, the dictionary sieves succeed in increasing R by a larger amount and at a smaller cost to P, resulting in a significant improvement in F1: 1.2 points according to MUC, 0.8 points according to B^3 , 1.4 points according to CEAF- ϕ_3 , 0.4 points according to CEAF- ϕ_4 , 2.6 points according to BLANC, and 0.7 points according to CoNLL. Section 5.2 presents the last line (w/ Dict + Context).

5 Discussion

5.1 Error analysis

Thanks to the dictionary, the coreference system improves the baseline by establishing coreference links between the bolded mentions in (3) and (4).

- (3) With **Groupon Inc.**’s stock down by half from its IPO price and **the company** heading into its first earnings report since an accounting blowup [...] outlining opportunity ahead and the promise of new products for **the daily-deals company**.

(4) Thompson revealed the diagnosis as evidence arose that seemed to contradict his story about why he was not responsible for a degree listed on his resume that he does not have, the newspaper reports, citing anonymous sources familiar with **the situation** [...] a Yahoo board committee appointed to investigate **the matter**.

The first case requires world knowledge and the second case, semantic knowledge.

We manually analyzed 40 false positive errors caused by the dictionary sieves. Only a small number of them were due to noise in the dictionary. The majority of errors were due to the discourse context: the two mentions could be coreferent, but not in the given context. For example, *Apple* and *company* are potentially coreferent—which is successfully captured by our dictionary—and while they are coreferent in (5), they are not in (6).¹²

- (5) It will only get better as **Apple** will be updating it with iOS6, an operating system that **the company** will likely be showing off this summer.

- (6) Since *Apple* reinvented the segment, **Microsoft** is the latest entrant into the tablet market, banking on its Windows 8 products to bridge the gap between PCs and tablets. [...] **The company** showed off Windows 8 last September.

¹²Examples in this section show gold coreference relations in bold and incorrectly predicted coreferent mentions in italics.

In these cases it does not suffice to check whether the opaque mention pair is included in the coreference dictionary, but we need a method for taking the surrounding context into account. In the next section we present our preliminary work in this direction.

5.2 Context fit

To help the coreference system choose the right antecedent in examples like (6), we exploit the fact that *the company* is closely followed by *Windows 8*, which is a clue for selecting *Microsoft* instead of *Apple* as the antecedent. We devise a contextual constraint that rules out a mention pair if the contexts are incompatible. To check for context compatibility, we borrow the idea of topic signatures from Lin and Hovy (2000) and that Agirre et al. (2001) used for Word Sense Disambiguation. Instead of identifying the keywords of a topic, we find the NEs that tend to co-occur with another NE. For example, the signature for *Apple* should include terms like *iPhone*, *MacBook*, *iOS*, *Steve Jobs*, etc. This is what we call the **NE signature** for *Apple*.

To construct NE signatures, we first compute the log-likelihood ratio (LLR) statistic between NEs in our corpus (the same one used to build the dictionary). Then, the signature for a NE, w , is the list of k other NEs that have the highest LLR with w . The LLR between two NEs, w_1 and w_2 , is $-2 \ln \frac{L(H_1)}{L(H_2)}$, where H_1 is the hypothesis that

$$P(w_1 \in \text{sent} | w_2 \in \text{sent}) = P(w_1 \in \text{sent} | w_2 \notin \text{sent}),$$

H_2 is the hypothesis that

$$P(w_1 \in \text{sent} | w_2 \in \text{sent}) \neq P(w_1 \in \text{sent} | w_2 \notin \text{sent}),$$

and $L(\cdot)$ is the likelihood. We assume a binomial distribution for the likelihood.

Once we have NE signatures, we determine the context fit as follows. When the system compares a NE antecedent with a (non-NE) anaphor, we check whether any NEs in the anaphor’s sentence are in the antecedent’s signature. We also check whether the antecedent is in the signature list of any NE’s in the anaphor’s sentence. If neither of these is true, we do not allow the system to link the antecedent and the anaphor. In (6), *Apple* is not linked with *the company* because it is not in Windows’ signature, and *Windows* is not in Apple’s signature either (but *Microsoft* is in Windows’ signature).

The last two lines in Table 6 compare the scores without using this contextual feature (w/ Dict) with

those using context (w/ Dict + Context). Our feature for context compatibility leads to a small but positive improvement, taking the final improvement of the dictionary sieves to be about 1 percentage point above the baseline according to all six evaluation measures. We leave as future work to test this idea on a larger test set and refine it further so as to address more challenging cases where comparing NEs is not enough, like in (7).

- (7) **Snapchat** will notify users [...] The program is available for free in *Apple*’s App Store [...] While **the company** “attempts to delete image data as soon as possible after the message is transmitted,” it cannot guarantee messages will always be deleted.

To resolve (7), it would be helpful to know that Snapchat is a picture messaging platform, as the context mentions *image data* and *messages*.

6 Related Work

Existing ontologies are not optimal for solving opaque coreferent mentions because of both a precision and a recall problem (Lee et al., 2011; Uryupina et al., 2011). On the other hand, using data-driven methods such as distributional semantics for coreference resolution suffers especially from a precision problem (Ng, 2007). Our work combines ideas from distributional semantics and paraphrase acquisition methods in order to efficiently use contextual information to extract coreference relations.

The main idea that we borrow from paraphrase acquisition is the use of monolingual (non-parallel) comparable corpora, which have been exploited to extract both sentence-level (Barzilay and McKeown, 2001) and sub-sentential-level paraphrases (Shinyama and Sekine, 2003; Wang and Callison-Burch, 2011). To ensure that the NPs are coreferent, we limit the meaning of *comparable corpora* to collections of documents that report on the very same story, as opposed to collections of documents that are about the same (general) topic. However, the distinguishing factor is that while most paraphrasing studies, including Lin and Pantel (2001), use NEs—or nouns in general—as pivots to learn paraphrases of their surrounding context, we use verbs as pivots to learn coreference relations at the NP level.

There are many similarities between paraphrase and coreference, and our work is most similar to

that by Wang and Callison-Burch (2011). However, some paraphrases that might not be considered to be valid (e.g., *under \$200* and *around \$200*) can be acceptable coreference relations. Unlike Wang and Callison-Burch (2011), we do not work on document pairs but on sets of at least five (comparable) documents, and we do not require sentence alignment, but just verb alignment.

Another source of inspiration is the work by Bean and Riloff (2004). They use contextual roles (i.e., the role that an NP plays in an event) for extracting patterns that can be used in coreference resolution, showing the relevance of verbs in deciding on coreference between their arguments. However, they use a very small corpus (two domains) and do not aim to build a dictionary. The idea of creating a repository of extracted concept-instance relations appears in Fleischman et al. (2003), but restricted to person-role pairs, e.g. *Yasser Arafat* and *leader*. Although it was originally designed for answering who-is questions, Daumé III and Marcu (2005) successfully used it for coreference resolution.

The coreference relations that we extract might overlap but go beyond those detected by Bansal and Klein (2012)'s Web-based features. First, they focus on NP headwords, while we extract full NPs, including multi-word mentions. Second, the fact that they use the Google n -gram corpus means that the two headwords must appear at most four words apart, thus ruling out coreferent mentions that can only appear far from each other. Finally, while their extraction patterns focus on synonymy and hypernymy relations, we discover other types of semantic relations that are relevant for coreference (Section 2.5).

7 Conclusions

We have pointed out an important problem with current coreference resolution systems: their heavy reliance on string overlap. Pronouns aside, opaque mentions account for 65% of the errors made by state-of-the-art systems. To improve coreference scores beyond 60-70%, we therefore need to make better use of semantic and world knowledge to deal with non-identical-string coreference. But, as we have also shown, coreference is not the same as semantic similarity or hypernymy. Only certain semantic relations in certain contexts are good cues for

coreference. We therefore need semantic resources specifically targeted at coreference.

We proposed a new solution for detecting opaque mention pairs: restricting distributional similarity to a comparable corpus of articles about the very same story, thus ensuring that similar mentions will also likely be coreferent. We used this corpus to build a dictionary focused on coreference, and successfully extracted the specific semantic and world knowledge relevant for coreference. The resulting dictionary can be added on top of any coreference system to increase recall at a minimum cost to precision. Integrated into the Stanford coreference resolution system, which won the CoNLL-2011 shared task, the F-score increases about 1 percentage point according to all of the six evaluation measures. The dictionary and NE signatures are available on the Web.¹³

We showed that apart from the need for extracting coreference-specific semantic and world knowledge, we need to take into account the context surrounding the mentions. The results from our preliminary work for identifying incompatible contexts is promising.

Our unsupervised method for extracting opaque coreference relations can be easily extended to other domains by using online news aggregators, and trained on more data to build a more comprehensive dictionary that can increase recall even further. We integrated the dictionary into a rule-based coreference system, but it remains for future work to integrate it into a learning-based architecture, where the system can combine the dictionary features with other features. This can also make it easier to include contextual features that take into account how well a dictionary pair fits in a specific context.

Abstract

We present the first work on antecedent selection for bridging resolution without restrictions on anaphor or relation types. Our model integrates global constraints on top of a rich local feature set in the framework of Markov logic networks. The global model improves over the local one and both strongly outperform a reimplementations of prior work.

1 Introduction

Identity coreference is a relatively well understood and well-studied instance of entity coherence. However, entity coherence can rely on more complex, lexico-semantic, frame or encyclopedic relations than identity. Anaphora linking distinct entities or events this way are called *bridging* or *associative anaphora* and have been widely discussed in the linguistic literature (Clark, 1975; Prince, 1981; Gundel et al., 1993).¹ In Example 1, the phrases *the windows*, *the carpets* and *walls* can be felicitously used because they are semantically related via a part-of relation to their antecedent *the Polish center*.²

(1) ...as much as possible of *the Polish center* will be made from aluminum, steel and glass recycled from Warsaw’s abundant rubble. ...**The windows** will open. **The carpets** won’t be glued down and **walls** will be coated with non-toxic finishes.

¹Poesio and Vieira (1998) include cases where antecedent and anaphor are coreferent but do not share the same head noun. We restrict *bridging* to non-coreferential cases. We also exclude *comparative anaphora* (Modjeska et al., 2003)

²Examples are from OntoNotes (Weischedel et al., 2011). Bridging anaphora are typed in boldface; antecedents in italics.

Bridging is frequent amounting to between 5% (Gardent and Manuélian, 2005) and 20% (Caselli and Prodanof, 2006) of definite descriptions (both studies limited to NPs starting with *the* or non-English equivalents). Bridging resolution is needed to fill gaps in entity grids based on coreference only (Barzilay and Lapata, 2008). Example 1 does not exhibit any coreferential entity coherence. Coherence can only be established when the bridging anaphora are resolved. Bridging resolution may also be important for textual entailment (Mirkin et al., 2010).

Bridging resolution can be divided into two tasks, recognizing that a bridging anaphor is present and finding the correct antecedent among a list of candidates. These two tasks have frequently been handled in a pipeline with most research concentrating on antecedent selection only. We also handle only the task of antecedent selection.

Previous work on antecedent selection for bridging anaphora is restricted. It makes strong untested assumptions about bridging anaphora types or relations, limiting it to definite NPs (Poesio and Vieira, 1998; Poesio et al., 2004; Lassalle and Denis, 2011) or to part-of relations between anaphor and antecedent (Poesio et al., 2004; Markert et al., 2003; Lassalle and Denis, 2011). We break new ground by considering all relations and anaphora/antecedent types and show that the variety of bridging anaphora is much higher than reported previously.

Following work on coreference resolution, we apply a *local* pairwise model (Soon et al., 2001) for antecedent selection. We then develop novel semantic, syntactic and salience features for this task, showing strong improvements over one of the best known

prior models (Poesio et al., 2004).

However, this local model classifies each anaphor-antecedent candidate pair in isolation. Thus, it neglects that bridging anaphora referring to a single antecedent often occur in clusters (see Example 1). It also neglects that once an entity is an antecedent for a bridging anaphor it is more likely to be used again as antecedent. In addition, such local models construct the list of possible antecedent candidates normally relying on a window size constraint to restrict the set of candidates: is the window too small, we miss too many correct antecedents; is it too large, we include so many incorrect antecedents as to lead to severe data imbalance in learning.

To remedy these flaws we change to a *global* Markov logic model that allows us to:

- model constraints that certain anaphora are likely to share the same antecedent;
- model the global semantic connectivity of a salient potential antecedent to all anaphora in a text;
- consider the union of potential antecedents for all anaphora instead of a static window-sized constraint.

We show that this global model with the same local features but enhanced with global constraints improves significantly over the local model.

2 Related Work

Prior corpus-linguistic studies on bridging are beset by three main problems. First, reliability is not measured or low (Fraurud, 1990; Poesio, 2003; Gardent and Manuélian, 2005; Riester et al., 2010).³ Second, annotated corpora are small (Poesio et al., 2004; Korzen and Buch-Kromann, 2011). Third, they are often based on strong untested assumptions about bridging anaphora types, antecedent types or relations, such as limiting it to definite NP anaphora (Poesio and Vieira, 1998; Poesio et al., 2004; Gardent and Manuélian, 2005; Caselli and Prodanof, 2006; Riester et al., 2010; Lassalle and Denis, 2011), to NP antecedents (all prior work) or to part-

³Although the overall information status scheme in Riester et al. (2010) achieved high agreement, their confusion matrix shows that the anaphoric bridging category (BRI) is frequently confused with other categories so that the two annotators agreed on only less than a third of bridging anaphors.

of relations between anaphor and antecedent (Markert et al., 2003; Poesio et al., 2004). In our own work (Markert et al., 2012) we established a corpus that circumvents these problems, i.e. human bridging recognition was reliable, it contains a medium number of bridging cases that allows generalisable statistics and we did not limit bridging anaphora or antecedents according to their syntactic type or relations between them. However, we only discussed human agreement on bridging recognition in Markert et al. (2012), disregarding antecedent annotation. We also did not discuss the different types of bridging in the corpus. We will remedy this in Section 3.

Automatic work on bridging distinguishes between recognition (Vieira and Poesio, 2000; Rahman and Ng, 2012; Cahill and Riester, 2012; Markert et al., 2012) and antecedent selection. Work on antecedent selection suffers from focusing on subproblems, e.g. only part-of bridging (Poesio et al., 2004; Markert et al., 2003) or definite NP anaphora (Lassalle and Denis, 2011). Most relevant for us is Lassalle and Denis (2011) who restrict anaphora to definite descriptions but have no other restrictions on relations or antecedent NPs (in a French corpus) with an accuracy of 23%. Also the evaluation set-up is sometimes not clear: The high results in Poesio et al. (2004) cannot be used for comparison as they test unrealistically: they distinguish only between the correct antecedent and *one* or *three* false candidates (baseline of 50% for the former). They also restrict the phenomenon to part-of relations.

There is a partial overlap between bridging and implicit noun roles (Ruppenhofer et al., 2010). However, work on implicit noun roles is mostly focused on few predicates (e.g. Gerber and Chai (2012)). We consider all bridging anaphors in running text. The closest work to ours interpreting implicit role filling as anaphora resolution is Silberer and Frank (2012).

3 Corpus for Bridging: An Overview

We use the dataset we created in Markert et al. (2012) with almost 11,000 NPs annotated for information status including 663 bridging NPs and their antecedents in 50 texts taken from the WSJ portion of the OntoNotes corpus (Weischedel et al., 2011). Bridging anaphora can be any noun phrase. They

are not limited to definite NPs as in previous work. In contrast to Nissim et al. (2004), antecedents are annotated and can be noun phrases, verb phrases or even clauses. Our bridging annotation is also not limited with regards to semantic relations between anaphor and antecedent.

In Markert et al. (2012) we achieved high agreement for the overall information status annotation scheme between three annotators (κ between 75 and 80, dependent on annotator pairs) as well as for all subcategories, including bridging (κ over 60 for all annotator pairings, over 70 for two expert annotators). Here, we add the following new results:

- Agreement for selecting bridging antecedents was around 80% for all annotator pairings.
- Surprisingly, only 255 of the 663 (38%) bridging anaphors are definite NPs, which calls into question the strategy of prior approaches to limit themselves to these types of bridging.
- NPs are the most frequent antecedents by far with only 42 of 663 (6%) bridging anaphora having a non-NP antecedent (mostly verb phrases).
- Bridging is a relatively local phenomenon with 71% of NP antecedents occurring in the same or up to 2 sentences prior to the anaphor. However, farther away antecedents are common when the antecedent is the global focus of a document.
- The semantic relations between anaphor and antecedent are extremely diverse with only 92 of 663 (14%) anaphors having a part-of/attribute-of antecedent (see Example 1) and only 45 (7%) anaphors standing in a set relationship to the antecedent (see Example 2). This contrasts with Gardent and Manuélian's (2005) finding that 52% of bridging cases had meronymic relations. We find many different types of relations in our corpus, including encyclopedic relations such as *restaurant – the waiter* as well as, frequently, relational person nouns as bridging anaphors such as *friend, husband, president*.
- There are only a few cases of bridging where surface cues may indicate the antecedent. First, some bridging anaphors are modified by a small number of adjectives that have more than one role filler, with the bridging relation often being temporal or spatial sequence between two enti-

ties of the same semantic type as in Example 3 (see also Lassalle and Denis (2011) for a discussion of such cases). Second, some anaphors are compounds where the nominal premodifier matches the antecedent head as in Example 4.

- (2) Still *employees* do occasionally try to smuggle out a gem or two. **One man** wrapped several diamonds in the knot of his tie. **Another** poked a hole in the heel of his shoe. **None** made it past the body searches ...
- (3) *His truck* is parked across the field ... The farmer at **the next truck** shouts ...
- (4) ...it doesn't make *the equipment needed to produce those chips*. And IBM worries that the Japanese will take over **that equipment market**.

4 Models for Bridging Resolution

4.1 Pairwise mention-entity model

The pairwise model is widely used in coreference resolution (Soon et al., 2001). We adapt it for bridging resolution⁴: Given an anaphor mention m and the set of antecedent candidate entities E_m which appear before m , we create a pairwise instance (m, e) for every $e \in E_m$. A binary decision whether m is bridged to e is made for each instance (m, e) separately. A post-processing step to choose one antecedent is necessary (closest first or best first are common strategies). This model causes three problems for bridging resolution: First, the ratio between positive and negative instances is 1 to 17 even if only antecedent candidates from the current and the immediately preceding two sentences are considered. The ratio will be even worse with a larger window size. Therefore, usually a fixed window size is used restricting the set of candidates. This, however, causes a second problem: antecedents which are beyond the window cannot be found. In our data, only 81% of NP antecedents appear within the previous 5 sentences, and only 71% of NP antecedents appear within the previous 2 sentences. The third problem is a shortcoming of the pairwise model itself: decisions are made for each instance separately, ignoring

⁴Different from coreference, we treat an anaphor as a mention and an antecedent as an entity. The anaphor is the first mention of the corresponding entity in the document.

relations between instances. We resolve these problems by employing a global model based on Markov logic networks.

4.2 Markov Logic Networks

Bridging can be considered a document global phenomenon, where globally salient entities are preferred as antecedents and two or more anaphors having the same antecedent should be related or similar. Motivated by this observation, we explore Markov logic networks (Domingos and Lowd, 2009, MLNs) to model bridging resolution on the global discourse level.

MLNs are a powerful representation for joint inference with uncertainty. An MLN consists of a set of pairs (F_i, w_i) , where F_i is a formula in first-order logic and w_i is its associated real numbered weight. It can be viewed as a template for constructing Markov networks. Given different sets of constants, an MLN will produce different ground Markov networks which may vary in size but have the same structure and parameters. For a ground Markov network, the probability distribution over possible worlds x is given by

$$P(X = x) = \frac{1}{Z} \exp \left(\sum_i w_i n_i(x) \right) \quad (1)$$

where $n_i(x)$ is the number of true groundings of F_i in x . The normalization factor Z is the partition function.

MLNs have been applied to many NLP tasks and achieved good performance by leveraging rich relations among objects (Poon and Domingos, 2008; Meza-Ruiz and Riedel, 2009; Fahrni and Strube, 2012, *inter alia*). We use *thebeast*⁵ to learn weights for the formulas and to perform inference. *thebeast* employs cutting plane inference (Riedel, 2008) to improve the accuracy and efficiency of MAP inference for Markov logic.

With MLNs, we model bridging resolution globally on the discourse level: given the set M of all anaphors and sets of local antecedent candidates E_m for each anaphor $m \in M$, we select antecedents for all anaphors from $E = \bigcup_{m \in M} E_m$ at the same time. Table 1 shows the hidden predicates and formulas used. Each formula is associated with a weight. The

polarity of the weights is indicated by the leading $+$ or $-$. The weight value (except for hard constraints) is learned from training data. For some formulas the final weight consists of a learned weight w multiplied by a score d (e.g. inverse distance between antecedent and anaphor). In these cases the final weight for a formula in a ground Markov network does not just depend on the respective formula, but also on the specific constants. We indicate such combined weights by the term $w \cdot d$.

We tackle the previously mentioned problems of the pairwise model: (1) We construct hard constraints to specify that each anaphor has at most one antecedent entity (Table 1: f1) and that the antecedent must precede the anaphor (f2). This eliminates the need for the post-processing step in the pairwise model. (2) We select the antecedent entity for each anaphor from the antecedent candidate entities pool E which alleviates the missing true antecedent problem in the pairwise model. Based on (1) and (2), MLNs allow us to express relations between anaphor-anaphor and anaphor-antecedent pairs $((m,n)$ or $(m,e))$ on the global discourse level improving accuracy by performing joint inference.

5 Features

5.1 Local features

5.1.1 Poesio et al.'s feature set

Table 2 shows the feature set proposed by Poesio et al. (2004) for part-of bridging. Google distance is the inverse value of Google hit counts for the *ofPattern* query (e.g. *the windows of the center*). WordNet distance is the inverse value of the shortest path length between an anaphor and an antecedent candidate among all synset combinations. These features are supposed to capture the meronymy relation between anaphor and antecedent. The other ones measure the salience of the antecedent candidate.

Group	Feature	Value
lexical	Google distance	numeric
	WordNet distance	numeric
salience	utterance distance	numeric
	local first mention	boolean
	global first mention	boolean

Table 2: Poesio et al.'s feature set

-

Table 1: Hidden predicates and formulas used for bridging resolution (m, n, l represent mentions, M the set of bridging anaphora mentions in the whole document, e the antecedent candidate entity, E_m the set of local antecedent candidate entities for m , and $E = \bigcup_{m \in M} E_m$)

5.1.2 Other features

Since Poesio et al. (2004) deal exclusively with meronymy bridging, we have to extend the feature set to capture more diverse relations between anaphor and antecedent. All numeric features in Table 3 are normalized among all antecedent candidates of one anaphor. For anaphor m_i and its antecedent candidates E_{m_i} ($e_{ij} \in E_{m_i}$), the numeric score for pair $\{m_i, e_{ik}\}$ is S_{ik} . Then the value $NormS_{ik}$ for this pair is normalized (set to values between 0 and 1) as below:

$$NormS_{ik} = \frac{S_{ik} - \min_j S_{ij}}{\max_j S_{ij} - \min_j S_{ij}} \quad (2)$$

A second variant of numeric features tells whether the score of an anaphor-antecedent candidate pair is the highest among all pairs for this anaphor.

Group	Feature	Value
semantic	$feat1$ preposition pattern	numeric
	$feat2$ verb pattern	numeric
	$feat3$ WordNet partOf	boolean
	$feat4$ semantic class	nominal
salience	$feat5$ document span	numeric
surface	$feat6$ isSameHead	boolean
	$feat7$ isPremodOverlap	boolean
syntactic	$feat8$ isCoArgument	boolean

Table 3: Local features we developed

Preposition pattern ($feat1$). The *ofPattern* proposed by Poesio et al. (2004) is useful for part-of and attribute-of relations but cannot cover all bridging relations (such as *sanctions against a country*). We extend the *ofPattern* to a generalised *preposition pattern* by using the Gigaword (Parker et al., 2011) and the Tipster (Harman and Liberman, 1993) corpora (both automatically POS tagged and NP chunked for improving query match precision).

First, we extract the three most highly associated prepositions for each anaphor. Then for each anaphor-antecedent candidate pair, we use their head words to create the query "*anaphor preposition antecedent*". To improve recall, we take lowercase, uppercase, singular and plural forms of the head word into account, and replace proper names by fine-grained named entity types (using a gazetteer). All raw hit counts are converted into the Dunning

Root Loglikelihood association measure,⁶ then normalized using Formula 2 within all antecedent candidates of one anaphor.

Verb pattern ($feat2$). A set-membership relation between anaphor and antecedent is often hard to capture by the *preposition pattern* because the anaphor often has no common noun head (see Example 2 in Section 3). Hence, we measure the compatibility of the antecedent candidates with the verb the anaphor depends on.

First, we hypothesise that anaphors whose lexical head is a pronoun or a number are potential set bridging cases and then extract the verb the anaphor depends on. In example 2, for the set anaphor **Another**, *poked* is the verb. Then for each antecedent candidate, subject-verb or verb-object queries are applied to the Web 1T 5-gram corpus (Brants and Franz, 2006). In this case, *employees poked* and *diamonds poked* are example queries. The hit counts are transformed into PMI and all pairs for one anaphor are normalized as described in Formula 2.

WordNet partOf relation ($feat3$). To capture part-of bridging, we extract whether the anaphor is part of the antecedent candidate in WordNet. To improve recall, we use hyponym information of the antecedent. If an antecedent e is a hypernym of x and an anaphor m is a meronym of x , then m is a meronym of e .

Semantic class ($feat4$). The anaphor and the antecedent candidate are assigned one of 16 coarse-grained semantic classes, e.g. location, organization, GPE, roleperson, relativePerson, otherPerson⁷, product, language, NORP (nationalities, religious or political groups) and several classes for numbers (such as date, money or percent).

Salience feature ($feat5$). Salient entities are preferred as antecedents. We capture salience superficially by computing the "*antecedent document span*" of an antecedent candidate. We compute the

⁶<http://tdunning.blogspot.de/2008/03/surprise-and-coincidence.html>

⁷We use WordNet to extract lists for *rolePerson* (persons like *president* or *teacher* playing a role in an organization) and *relativePerson* (persons like *father* or *son* indicating that they have a relation with another person). Persons not in these two lists are counted as *otherPerson*.

span of text (measured in sentences) in which the antecedent candidate entity is mentioned. This is divided by the number of sentences in the whole document. This score is normalized using Formula 2 for all antecedent candidates of one anaphor.

Surface features (*feat6-feat7*). *isSameHead* (*feat6*) checks whether antecedent candidates have the same head as the anaphor: this is rarely the case in bridging anaphora (except in some cases of set bridging and spatial/temporal sequence, see Example 3) and can therefore be used to exclude antecedent candidates. *isPremodOverlap* (*feat7*) determines the antecedent for compound noun anaphors whose head is prenominally modified by the antecedent head (see Example 4).

Syntactic feature (*feat8*) The *isCoArgument* feature is based on the intuition that the subject cannot be the bridging antecedent of the object in the same clause. This feature excludes (some) close antecedent candidates. In Example 4, the antecedent candidate *the Japanese* isCoArgument with the anaphor **that equipment market**.

5.2 Global features for MLNs

f1-f13 in Table 1 are discourse level constraints. All antecedent candidates come from the antecedent candidates pool E in the whole document.

Global salience (Table 1: *f3-f10*). The salience feature in the pairwise model only measures the salience for candidates within the local window. However, globally salient antecedents are preferred even if they are far away from the anaphor. We model this from two perspectives:

f7 models the preference for globally salient antecedents, which we derive for each document. For $m \in M$ and $e \in E$, let $score(m, e)$ be the preposition pattern score for pair (m, e) . Calculate pattern semantic salience score e_{sal} for each $e \in E$ as

$$e_{sal} = \sum_{m \in M} score(m, e) \quad (3)$$

If e appears in the title and also has the highest pattern semantic salience score e_{sal} among all e in E , then e is the predicted globally salient antecedent for this document. Note that global salience here is based on semantic connectivity to all anaphors in the

document and that not every document has a globally salient antecedent.

f3-f6 and *f8-f10* model that similar or related anaphors in one document are likely to have the same antecedent. To make the ground Markov network more sparse for more efficient inference, we add the hidden predicate (*p2*) and hard constraints (*f3-f6*) specifying relations among similar/related anaphors m , n and l (reflexivity and transitivity). Formulas *f8-f10* explore three different ways (syntactic and semantic) to compute the similarity between two anaphors. In *f10*, we use SVM^{light} (similarity scores from WordNet plus sentence distance as features) to predict whether two anaphors not sharing the same head are similar or not.

Frequent bridging relations (Table 1: *f11-f13*).

Three common bridging relations are restricted by semantic class of anaphor and antecedent (see also Section 3). It is worth noting that in formula *f11* (modeling that a role person mention like *president* or *chairman* prefers organization or GPE antecedents), we do not penalize the antecedents far away from the anaphor. In formula *f12* (modeling that a relativePerson mention such as *mother* or *husband* prefers close person antecedents) and *f13*, we prefer close antecedents by including the distance between antecedent and anaphor into the weights.

MLN formulation of local features (Table 1: *f14-f20*). Corresponding to features of the pairwise model (Table 3) – we exclude only semantic class as this is modelled globally via features *f11-f13*. These local features are only used for an anaphor m and its local antecedent candidate e from E_m .

6 Experiments and Results

6.1 Experimental setup

We perform experiments on our gold standard corpus via 10-fold cross-validation on documents. We use gold standard mentions, true coreference information, and the OntoNotes named entity and syntactic annotation layers for feature extraction.

6.2 Improved baseline

We reimplement the algorithm from Poesio et al. (2004) as baseline. Since they did not explain

whether they used the mention-mention or mention-entity model, we assume they treated antecedents as entities and use a 2 and 5 sentence window for candidates⁸. Since the GoogleAPI is not available any more, we use the Web 1T 5-gram corpus (Brants and Franz, 2006) to extract the Google distance feature. We improve it by taking all information about entities via coreference into account as well as by replacing proper names. All other features (Table 2 in Section 5.1.1) are extracted as Poesio et al. did. A Naive Bayes classifier with standard settings in WEKA (Witten and Frank, 2005) is used. In order to evaluate their model in the more realistic setting of our experiment, we apply the *best first* strategy to select the antecedent for each anaphor.

6.3 Pairwise models

Pairwise model I: We use the *preposition pattern* feature (*feat1*) plus Poesio et al.’s salience features (Table 2). We use a 2 sentence window as it performed on a par with the 5 sentence window in the baseline. We replace Naive Bayes with SVM^{light} because it can deal better with imbalanced data⁹.

Pairwise model II: Based on *Pairwise model I*. Local features *feat2-ffeat8* from Table 2 are added.

Pairwise model III: Based on *Pairwise model II*. We apply a more advanced antecedent candidate selection strategy, which allows to include 77% of NP antecedents compared to 71% in *Pairwise model II*. For each anaphor, we add the top k salient entities measured through the length of the coreference chains (k is set to 10%) as additional antecedent candidates. For potential set anaphors (as automatically determined by pronoun or number heads), singular antecedent candidates are filtered out. We compiled a small set of adjectives (using FrameNet and thesauri) that indicate spatial or temporal sequences (see Example 3). For anaphors modified by such adjectives we consider only antecedent candidates that have the same semantic class as the anaphor.

⁸They use a 5 sentence window, because all antecedents in their corpus are within the previous 5 sentences.

⁹The SVM^{light} parameter is set according to the ratio between positive and negative instances in the training set.

6.4 MLN models

MLN model I: MLN system using local formulas $f1-f2$ and $f14-f20$. The same strategy as in *Pairwise model III* is used to select local antecedent candidates E_m for each anaphor m .

MLN model II: Based on *MLN model I*, all formulas in Table 1 are used.

6.5 Results

Table 4 shows the comparison of our models to baselines. Significance tests are conducted using McNemar’s test on overall accuracy at the level of 1%.

		acc
<i>improved baseline</i>	2 sent. + NB	18.85
	5 sent. + NB	18.40
<i>pairwise model</i>	<i>pairwise model I</i>	29.11
	<i>pairwise model II</i>	33.94
	<i>pairwise model III</i>	36.35
<i>MLN model</i>	<i>MLN model I</i>	35.60
	<i>MLN model II</i>	41.32

Table 4: Results for MLN models compared to pairwise models and baselines.

MLN model II, which is inspired by the linguistic observation that globally salient entities are preferred as antecedents, performs significantly better than all other systems. The gains come from three aspects. First, by selecting the antecedent for each anaphor from the antecedent candidate pool E in the whole document 91% of NP antecedents are accessible compared to 77% in *pairwise model III*. Second, we leverage semantics and salience by using local formulas and discourse level formulas. Local formulas are used to capture semantic relations for bridging pairs as well as surface and syntactic constraints. Global formulas resolve several bridging anaphors together, often to a globally salient antecedent beyond the local window. Third, the model allows us to express specific relations among bridging anaphors and their antecedents ($f11-f13$).

However, our *pairwise model I* already outperforms *improved baselines* by about 10%, which suggests that our *preposition pattern* feature can capture more diverse semantic relations. The continuous improvements shown in *pairwise model II* and *pairwise model III* verify the contribution of our other

features and advanced antecedent candidate selection strategy. *pairwise model III* would become too complex if we tried to integrate discourse level formulas $f7, f11-f13$ into antecedent candidate selection. *MLN model II* solves this task elegantly.

6.6 Discussion and error analysis

We analyse our best model (*MLN model II*) and compare it to the best local one (*pairwise model III*).

Anaphors with long distance antecedents are harder to resolve. Table 5 shows the comparison of correctly resolved anaphors with regard to anaphor-antecedent distance. We can see that the global model is equal or better to the local model for all anaphor types but that the difference is especially large for anaphora with antecedents that are 3 or more sentences away due to the use of global salience and accessibility of possible antecedents beyond a fixed window-size.

	# pairs	<i>MLN II</i>	<i>pairwise III</i>
sent. distance			
0	175	48.57	45.14
1	260	34.62	35
2	90	47.78	43.33
≥ 3	158	35.44	16.46

Table 5: Comparison of the percentage of correctly resolved anaphors with regard to anaphor-antecedent distance. Significance tests are conducted using McNemar’s test at the level of 1%.

We now distinguish between "sibling anaphors" (anaphors that share an antecedent with other bridging anaphors) and "non-siblings" (anaphors that do not share an antecedent with any other anaphor). The performance of our *MLN model II* is 54% on sibling anaphors but only 24% on non-sibling anaphors. This shows that our use of global salience and links between related anaphors does indeed help to capture the behaviour of sibling anaphors.

However, our global model is good at predicting the right antecedent for sibling anaphors where the antecedent is globally salient but not as good for sibling anaphors where the (shared) antecedent is a locally salient subtopic. Thus, in the future we need to model equivalent constraints for local salience of antecedents, taking into account topic segmentation/shifts to improve over the 54% for sibling

anaphors.

The semantic knowledge we employ is still insufficient. Typical cases where we have problems are: (i) cases with very context-specific bridging relations. For example, in one text about the stealing of Sago Palms in California we found *the thieves* as a bridging anaphor with the antecedent *palms*, which is not a very usual semantic link. (ii) more frequently, we have cases where several good antecedents from a semantic perspective can be found. For example, two laws are discussed and a later anaphor *the veto* could be the veto of either bills. Integration of the wider context apart from the two NPs is necessary in these cases. This includes the semantics of modification, whereas we currently consider only head noun knowledge. An example is that the anaphor *the local council* would preferably be interpreted as *the council of a village* instead of *the council of a state* due to the occurrence of *local*.

Finally, 6% of the anaphors in our corpus have a non-NP antecedent. These cases are not correctly resolved in our current model as we only extract NP phrases as potential candidate antecedents.

7 Conclusions

We provide the first reasonably sized and reliably annotated English corpus for bridging resolution. It covers a diverse set of relations between anaphor and antecedent as well as all anaphor/antecedent types. We developed novel semantic, syntactic and salience features based on linguistic intuition. Inspired by the observation that salient entities are preferred as antecedents, we implemented a global model for antecedent selection within the framework of Markov logic networks. We show that our global model significantly outperforms other local models and baselines. This work is – to our knowledge – the first bridging resolution algorithm that tackles the unrestricted phenomenon in a real setting.

Abstract

We examine the task of temporal relation classification. Unlike existing approaches to this task, we (1) classify an event-event or event-time pair as one of the 14 temporal relations defined in the TimeBank corpus, rather than as one of the six relations collapsed from the original 14; (2) employ sophisticated linguistic knowledge derived from a variety of semantic and discourse relations, rather than focusing on morpho-syntactic knowledge; and (3) leverage a novel combination of rule-based and learning-based approaches, rather than relying solely on one or the other. Experiments with the TimeBank corpus demonstrate that our knowledge-rich, hybrid approach yields a 15–16% relative reduction in error over a state-of-the-art learning-based baseline system.

1 Introduction

Recent years have seen a surge of interest in temporal information extraction (IE). Temporal relation classification, one of the most important temporal IE tasks, involves classifying a given event-event pair or event-time pair as one of a set of predefined temporal relations. The creation of the TimeBank corpus (Pustejovsky et al., 2003) and the organization of the TempEval-1 (Verhagen et al., 2007) and TempEval-2 (Verhagen et al., 2010) evaluation exercises have facilitated the development and evaluation of temporal relation classification systems.

Our goal in this paper is to advance the state of the art in temporal relation classification. Our work differs from existing work with respect to both the

complexity of the task we are addressing and the *approach* we adopt. Regarding task complexity, rather than focus on six temporal relations as is typically done in previous work (see Section 2 for more information), we address an arguably more challenging version of the task where we consider all the 14 relations originally defined in the TimeBank corpus.

Our approach to temporal relation classification can be distinguished from existing approaches in two respects. The first involves a large-scale expansion of the linguistic features made available to the classification system. Recall that existing approaches have relied primarily on morpho-syntactic features as well as a few semantic features extracted from WordNet synsets and VerbOcean’s (Chklovski and Pantel, 2004) semantic relations. On the other hand, we propose not only novel lexical and grammatical features, but also sophisticated features involving semantics and discourse. Most notably, we propose (1) semantic features encoding a variety of semantic relations, including PropBank-style predicate-argument relations as well as those extracted from the Merriam-Webster dictionary, and (2) discourse features encoding automatically computed Penn Discourse TreeBank (PDTB) style (Prasad et al., 2008) discourse relations.

Second, while the vast majority of existing approaches to temporal relation classification are learning-based, we propose a system architecture in which we combine a learning-based approach and a rule-based approach. Our motivation behind adopting a hybrid approach stems from two hypotheses. First, a rule-based method could better handle the skewed class distribution underlying the dataset for

our 14-class classification problem. Second, better decision rules could be formed by leveraging human insights to combine the available linguistic features than by using fully automatic machine learning methods. Note that while rule-based approaches have been shown to underperform learning-based approaches on this task (Mani et al., 2006), to our knowledge they have not been used in combination with learning-based approaches. Moreover, while the rules employed in previous work are created based on intuition (e.g., Mani et al. (2006), Puşcaşu (2007)), our rules are created in a *data-driven* manner via a manual inspection of the annotated temporal relations in the TimeBank corpus.

Experiments on the TimeBank corpus demonstrate the effectiveness of our knowledge-rich, hybrid approach to temporal relation classification: it yields a 15–16% relative reduction in error over a state-of-the-art learning-based baseline system.

To our knowledge, we are the first to (1) report results for the 14-class temporal relation classification task on the TimeBank (v1.2) corpus; (2) successfully employ automatically computed PDTB-style discourse relations to improve performance on this task; and (3) show that a hybrid approach to this task can yield better results than either a rule-based or learning-based approach. Note that hybrid approaches in this spirit were popular in the natural language processing community back in the mid-90s (Klavans and Resnik, 1994). We believe that they are among the most competitive approaches to language processing tasks that require complex reasoning and should be given more attention in the community. We release the complete set of rules that we mined from the TimeBank corpus and used in our rule-based approach in hopes that our insights into how features can be combined as decision rules can benefit researchers interested in this task.

The rest of the paper is organized as follows. Section 2 provides an overview of the TimeBank corpus. Sections 3 and 4 describe the baseline system and our approach, respectively. We present evaluation results in Section 5 and conclude in Section 6.

2 Corpus

For evaluation, we use the TimeBank (v1.2) corpus, which consists of 183 newswire articles. In

each article, the *events*, *times*, and their *temporal relations* are marked up. An event, which can be a tensed verb, adjective, or nominal, contains various attributes, including the *class* of event, *tense*, *aspect*, *polarity*, and *modality*. A time expression has a *class* attribute, which specifies whether it is a date, time, duration, or set, and its value is normalized based on TIMEX3. A temporal relation can be an *order* relation, which orders two events (as in sentence (1)), or an *anchor* relation, which anchors an event to a time expression (as in sentence (2)).

- (1) A steep *rise* in world oil prices followed the Kuwait *invasion*.
- (2) We are there to *stay* for a long *period*.

Each temporal relation has a *type*. For example, the relation defined on *rise* and *invasion* in (1) has type **After**, whereas the relation defined on *stay* and *period* in (2) has type **During**. Note that a temporal relation is defined on an *ordered* pair. For example, in (1), the pair (*rise*, *invasion*) has type **After**, whereas the pair (*invasion*, *rise*) has type **Before**.

14 relation types are defined and used to annotate the temporal relations in the TimeBank corpus. Table 1 provides a brief description of these relation types and the relevant statistics.

In our experiments, we assume that our temporal relation classification system is given an event-event or event-time pair that is known to belong to one of the 14 relation types defined in TimeBank and aims to determine its relation type. Following previous evaluations of the temporal relation classification task on the TimeBank corpus (e.g., Mani et al. (2006), Chambers et al. (2007)) and in TempEval-1/2, we assume as input gold events and time expressions.

Unlike Mani et al. (2006) and Chambers et al. (2007), who focus on six relation types (**Simultaneous**, **Before**, **IBefore**, **Begins**, **Ends**, and **Includes**), we report results on 14 relation types. Note that the aforementioned six relation types are chosen by (1) discarding **During**, **During_Inv**, and **Identity**, and (2) combining the two relation types in each of the five pairs, namely (**Before**, **After**), (**IBefore**, **IAfter**), (**Includes**, **Is_Included**), (**Begins**, **Begun_By**), and (**Ends**, **Ended_By**), into a single type because they are inverses of each other. In other words, if a relation instance (e_1, e_2) is anno-

Id	Relation	Description	Total	%	E-E	E-T
1	Simultaneous	e_1 and e_2 happen at the same time or are temporally distinguishable	660 (13.3)	599	61	
2	Identity	e_1 and e_2 are coreferent	702 (14.1)	696	6	
3	Before	e_1 happens before e_2 in time	689 (13.9)	639	50	
4	After	e_1 happens after e_2 in time	744 (15)	681	63	
5	IBefore	e_1 happens immediately before e_2 in time	39 (0.8)	38	1	
6	IAfter	e_1 happens immediately after e_2 in time	28 (0.6)	25	3	
7	Includes	As in <i>Ed arrived in Seoul last Sunday</i> (e_1 =last Sunday; e_2 =arrived)	758 (15.3)	318	440	
8	Is_Included	As in <i>Ed arrived in Seoul last Sunday</i> (e_1 =arrived; e_2 =last Sunday)	762 (15.3)	201	561	
9	During	e_1 persists throughout duration e_2	102 (2.1)	19	83	
10	During_Inv	e_2 persists throughout duration e_1	124 (2.5)	44	80	
11	Begins	e_1 marks the beginning of e_2	66 (1.3)	44	22	
12	Begun_By	e_2 marks the beginning of e_1	61 (1.2)	32	29	
13	Ends	e_1 marks the end of e_2	66 (1.3)	21	45	
14	Ended_By	e_2 marks the end of e_1	170 (3.42)	93	77	

Table 1: The 14 temporal relations and their frequency of occurrences in TimeBank (v1.2). Each relation is defined on an ordered event-event or event-time pair (e_1, e_2). The “Total” and “%” columns show the number and percentage of instances annotated with the corresponding relation in the corpus, respectively, and the “E-E” and “E-T” columns show the breakdown by the number of event-event pairs and event-time pairs.

tated as **After**, it is replaced with the instance (e_2, e_1) with class **Before**, and subsequently a relation classifier is presented with (e_2, e_1) but not (e_1, e_2). On the other hand, our 14-class task is arguably more challenging since our system has to further distinguish a relation type from its inverse given an instance in which the two elements are in arbitrary order.

3 Baseline Temporal Relation Classifier

Since the currently best-performing systems for temporal relation classification are learning-based, we will employ a learning-based system as our baseline. Below we describe how we train this baseline.

Without loss of generality, assume that (e_1, e_2) is an event-event/event-time pair such that (1) e_1 precedes e_2 in the associated text and (2) (e_1, e_2) belongs to one of the 14 TimeBank temporal relation types. We create one training instance for each event-event/event-time pair in a training document that satisfies the two conditions above, labeling it with the relation type that exists between e_1 and e_2 .

To build a strong baseline, we represent each instance using 68 linguistic features modeled after the top-performing temporal relation classification systems on TimeBank (e.g., Mani et al. (2006), Chambers et al. (2007)) and in the TempEval shared tasks (e.g., Min et al. (2007), Puşcaşu (2007), Ha et al. (2010), Llorens et al. (2010), Mirroshandel and

Ghassem-Sani (2011)).¹ These features can be divided into six categories, as described below.

Lexical (5). The strings of e_1 and e_2 , the head words of e_1 and e_2 , and a binary feature indicating whether e_1 and e_2 have the same string.

Grammatical (33). The POS tags of the head words of e_1 and e_2 , the POS tags of the five tokens preceding and following e_1 and e_2 , the POS bigram formed from the head word of e_1 and its preceding token, the POS bigram formed from the head word of e_2 and its preceding token, the POS tag pair formed from the head words of e_1 and e_2 , the prepositional lexeme of the prepositional phrase (PP) if e_1 is headed by a PP (Chambers et al., 2007), the prepositional lexeme of the PP if e_2 is headed by a PP, the prepositional lexeme of the PP if e_1 is governed by a PP (Mirroshandel and Ghassem-Sani, 2011), the prepositional lexeme of the PP if e_2 is governed by a PP, the POS of the head of the verb phrase (VP) if e_1 is governed by a VP, the POS of the head of the VP if e_2 is governed by a VP, whether e_1 syntactically dominates e_2 (Chambers et al., 2007), and the shortest path from e_1 to e_2 in the associated syntactic parse tree. We obtain parse trees and POS tags using the Stanford CoreNLP tool.²

¹Note, however, that these features were designed for the arguably simpler 6-class temporal relation classification tasks.

²<http://nlp.stanford.edu/software/corenlp.shtml>

Entity attributes (13). The tense, aspect, modality, polarity, and event type of e_1 and e_2 if they are events (if one of them is a time expression, then the class attribute will be set to its class and the rest of them will have the value NULL), pairwise features formed by pairing up the tense values, the aspect values, and the class values of e_1 and e_2 .

Semantic (7). The subordinating temporal role token of e_1 if it appears within a temporal semantic role argument (Llorens et al., 2010), the subordinating temporal role token of e_2 if it appears within a temporal semantic role argument, the first WordNet synset to which e_1 belongs, the first WordNet synset to which e_2 belongs, and whether e_1 and e_2 are in the *happens-before*, *happens-after*, and *similar* relation according to VerbOcean.³

Distance (1). Are e_1 and e_2 in the same sentence?

DCT related (3). The temporal relation type between e_1 and the document creation time (DCT) [its value can be one of the 14 relation types, or NULL if no relation exists], the temporal relation type between e_2 and the DCT, and whether e_1 and e_2 have different relation types with the DCT.

After creating the training instances, we train a 14-class classifier on them using SVM^{*multiclass*} (Tschantaridis et al., 2004).⁴ We then use it to make predictions on the test instances, which are generated in the same way as the training instances.

4 Our Hybrid Approach

In this section, we describe our hybrid learning-based and rule-based approach to temporal relation classification. Section 4.1 describes our novel features, which will be used to augment the baseline feature set (see Section 3) to train a temporal relation classifier. Section 4.2 outlines our manual rule creation process. Section 4.3 discusses how we combine our hand-crafted rules and the learned classifier to make predictions in our hybrid approach.

³*happens-after* is not a relation in VerbOcean: we create this relation simply by inverting the *happens-before* relation.

⁴For all the experiments involving SVM^{*multiclass*}, we set C, the regularization parameter, to 10,000, since preliminary experiments indicate that preferring generalization to overfitting (by setting C to a small value) tends to yield poorer classification performance. The remaining learning parameters are set to their default values.

4.1 Six Types of New Features

4.1.1 Pairwise Features

Recall that some of the features in the baseline feature set are computed based on either e_1 or e_2 but not both. Since our task is to predict the *relation* between them, we hypothesize that *pairwise* features, which are computed based on both elements, could better capture the relationship between them.

Specifically, we introduce pairwise versions of the head word feature and the two prepositional lexeme-based features in the baseline. In addition, we create two quadruple-wise features, one by pairing up the tense and class attribute values of e_1 with those of e_2 , and the other by pairing up their tense and aspect values. Next, we create two *trace* features, one based on prepositions and the other on verbs, since prepositions and verb tenses have been shown to play an important role in temporal relation classification. The *preposition trace* feature is computed by (1) collecting the list of prepositions along the path from e_1/e_2 to the root of its syntactic parse trees, and (2) concatenating the resulting lists computed from e_1 and e_2 . The *verb trace* feature is computed in a similar manner, except that we collect the POS tags of the verbs appearing in the corresponding paths.

4.1.2 Dependency Relations

We introduce features computed based on dependency parse trees obtained via the Stanford CoreNLP tool, motivated by our observation that some dependency relation types are more closely associated with certain temporal relation types than with others. Let us illustrate with an example:

- (3) Ed *changed* his plans as the mood *took* him.

In (3), there is a adverbial clause modifier dependency between *changed* and *took*, because *took* appears in an adverbial clause (headed by *as*) modifying *changed*. Intuitively, if the two events participate in this type of dependency relation and the adverbial clause is headed by *as* and there is a temporal relation between them, then it is likely that this temporal relation is **Simultaneous**. While the temporal relation type is dependent on the connective heading the adverbial clause, in general an adverbial clause modifier dependency between two events implies that their temporal relation is likely to be **Si-**

multaneous, Before, or After.

Given the potential usefulness of dependency relations for temporal relation classification, we create dependency-based features as follows. For each of the 25 dependency relation types produced by the Stanford parser, we create four binary features: whether e_1/e_2 is the governing entity in the relation, and whether e_1/e_2 is the dependent in the relation.

4.1.3 Webster Relations

Some events are not connected by a dependency relation but by a *lexical* relation. We hypothesize that some of these lexical relations could be useful for temporal relation classification. Consider the following example.

- (4) The phony war has *finished* and the real referendum campaign has *begun*.

In this sentence, the two events, *finished* and *begun*, are connected by an antonym relation. Statistically speaking, if (1) two events are in two clauses connected by a coordinating conjunction (e.g., *and*), (2) one is an antonym of the other, and (3) there is a temporal relation between them, then the temporal relation is likely to be **Simultaneous**.

Given the potential usefulness of lexical relations for temporal relation classification, we create features based on four types of lexical relations present in Webster’s online thesaurus⁵, namely synonyms, related-words, near-antonyms, and antonyms. Specifically, for each event e appearing in TimeBank, we first use the head word of e to retrieve four lists, which are the lists corresponding to the synonyms, related words, near-antonyms, and antonyms of e . Then, given a training/test instance involving e_1 and e_2 , we create eight binary features: whether e_1 appears in e_2 ’s list of synonyms/related words/near-antonyms/antonyms, and whether e_2 appears in e_1 ’s list of synonyms/related words/near-antonyms/antonyms.

4.1.4 WordNet Relations

Previous uses of WordNet for temporal relation classification are limited to synsets (e.g., Llorens et al. (2010)). We hypothesize that other WordNet lexical relations could also be useful for the task. Specifically, we employ four types of WordNet relations,

namely hypernyms, hyponyms, troponyms, and similar, to create eight binary features for temporal relation classification. These eight features are created from the four WordNet relations in the same way as the eight features were created from the four Webster relations in the previous subsection.

4.1.5 Predicate-Argument Relations

So far we have exploited lexical and dependency relations for temporal relation classification. We hypothesize that semantic relations, in particular predicate-argument relations, could be useful for the task. Consider the following example.

- (5) “What sector is *stepping forward* to pick up the slack?” he asked.

Using SENNA (Collobert et al., 2011), a PropBank-style semantic role labeler, we know that *forward* is in the directional argument of the predicate *stepping*. This enables us to infer that an **Includes** relation exists between *stepping* and *forward* since intuitively an action includes a direction.

As another example, consider another PropBank-style predicate-argument relation, *cause*. Assuming that e_2 is in e_1 ’s cause argument, we can infer that e_2 occurs **Before** e_1 since intuitively the cause of an action precedes the action.

Consequently, we create features for temporal relation classification based on four types of PropBank-style predicate-argument relations, namely directional, manner, temporal, and cause. Specifically, using SENNA’s output, we create four binary features that encode whether argument e_2 is related to predicate e_1 through the four types of relations, and we create another four binary features that encode whether argument e_1 is related to predicate e_2 through the four types of relations.

4.1.6 Discourse Relations

Rhetorical relations such as causation, elaboration and enablement could aid in tracking the temporal progression of the discourse (Hitzeman et al., 1995). Hence, unlike syntactic dependencies and predicate-argument relations through which we can identify *intra-sentential* temporal relations, discourse relations can potentially be exploited to discover both *inter-sentential* and *intra-sentential* temporal relations. However, no recent work has attempted to use discourse relations for temporal relation clas-

-

Table 2: Examples illustrating the usefulness of discourse relations for temporal relation classification.

sification. In this subsection, we examine whether we can improve a temporal relation identifier via *explicit* and *implicit* PDTB-style discourse relations automatically extracted by Lin et al.’s (2013) end-to-end discourse parser.

Let us first review PDTB-style discourse relations. Each relation is represented by a triple (*Arg1*, *sense*, *Arg2*), where *Arg1* and *Arg2* are the two arguments of the relation and *sense* is the sense/type of the relation. A discourse relation can be explicit or implicit. An explicit relation is triggered by a discourse connective. On the other hand, an implicit relation is not triggered by a discourse connective, and may exist only between two consecutive sentences. Generally, implicit relations are much harder to identify than their explicit counterparts.

Next, to motivate why discourse relations can be useful for temporal relation classification, we use two examples (see Table 2), one involving an implicit relation (Example (6)) and the other an explicit relation (Example (7)). For convenience, both sentences are also annotated using Lin et al.’s (2013) discourse parser, which marks up the two arguments with the _Arg1 and _Arg2 tags and outputs the relation sense next to the beginning of Arg2.

In (6), we aim to determine the order relation between the reporting event *said* and the occurrence event *filing*. The parser determines that a RESTATEMENT implicit relation exists between the two sentences. Intuitively, if no asynchronous relations can be found among the events in two discourse units connected by the RESTATEMENT relation, then the temporal relation between two temporally linked events within these units is likely to be either **Identity** or **Simultaneous**. In this case, we can rule out **Identity**: since *said* and *filing* belong to different event classes, they are not coreferent.

In (7), we aim to determine the anchor relation

between the reporting event *said* and the date *Thursday*. The parser determines that a SYNCHRONY explicit relation triggered by *Meanwhile* exists between the two sentences. Intuitively, if a temporally related reporting event and date occur within different discourse units connected by the SYNCHRONY relation, then it is likely that the event **IsIncluded** in the date. Note that without this discourse relation, it could be difficult for a machine to confidently associate a reporting event with a date occurring in a different discourse segment.

Given the potential usefulness of discourse relations for temporal relation classification, we create four features based on discourse relations. In the first feature, if e_1 is in *Arg1*, e_2 is in *Arg2*, and *Arg1* and *Arg2* possess an explicit relation with sense s , then its feature value is s ; otherwise its value is NULL. In the second feature, if e_2 is in *Arg1*, e_1 is in *Arg2*, and *Arg1* and *Arg2* possess an explicit relation with sense s , then its feature value is s ; otherwise its value is NULL. The third and fourth features are computed in the same way as the first two features, except that they are computed over implicit rather than explicit relations.

4.2 Manual Rule Creation

As noted before, we adopt a hybrid learning-based and rule-based approach to temporal relation classification. Hence, in addition to training a temporal relation classifier, we also manually design a set of rules in which each rule returns a temporal relation type for a given test instance. We hypothesize that a rule-based approach can complement a purely learning-based approach, since a human could combine the available linguistic features into rules using commonsense knowledge that may not be accessible to a learning algorithm.

The design of the rules is partly based on intu-

ition and partly data-driven: we first use our intuition to come up with a rule and then manually refine it based on the observations we made on the TimeBank data. For this purpose, we partition the TimeBank documents into five folds of roughly the same size, reserving three folds for developing our rules and using the remaining two folds for evaluating final system performance. We order these rules in decreasing order of accuracy, where the accuracy of a rule is defined as the number of times the rule yields the correct temporal relation type divided by the number of times it is applied, as measured on the three development folds. A new instance is classified using the first applicable rule in the ruleset.

Some of these rules were shown in the previous subsection when we motivated each feature type with examples. The complete set of rules can be accessed via our website.⁶

4.3 Combining Rules and Machine Learning

We investigate three ways to combine the hand-crafted rules and the machine-learned classifier.

In the first method, we employ all of the rules as additional features for training the classifier. The value of each such feature is the temporal relation type predicted by the corresponding rule.

The second method can be viewed as an extension of the first one. Given a test instance, we first apply to it the ruleset composed only of rules that are at least 80% accurate. If none of the rules is applicable, we classify it using the classifier employed in the first method.⁷

The third method is essentially the same as the second, except we do not employ the rules as features when training the classifier.

5 Evaluation

5.1 Experimental Setup

Dataset. As mentioned before, we partition the 183 documents in the TimeBank (v1.2) corpus into five folds of roughly the same size, reserving three folds (say Folds 1–3) for manual rule development

⁶<http://www.hlt.utdallas.edu/~jld082000/temporal-relations/>

⁷Although this classifier is applied to only those test instances that the rules cannot handle, we did not retrain it on only those training instances that the rules cannot handle.

and using the remaining two folds (say Folds 4–5) for testing. We perform two-fold cross-validation experiments using the two test folds. In the first fold experiment, we train a temporal relation classifier on Folds 1–4 and test on Fold 5; and in the second fold experiment, we train the classifier on all but Fold 4 and test on Fold 4. The results reported in the rest of the paper are averaged over the two test folds.

Evaluation metrics. We employ *accuracy* (Acc) and *macro F-score* (F^{ma}). Accuracy is the percentage of correctly classified test instances, and is the standard evaluation metric for temporal relation classification. Since each test instance belongs to one of the 14 temporal relation types, accuracy is the same as micro F-score. On the other hand, macro F-score is rarely used to evaluate this task. We chose it because it could provide insights into how well our approach performs on the minority classes.

5.2 Results and Discussion

Table 3 shows the two-fold cross-validation results for our 14-class temporal relation classification task. The six columns of the table correspond to six different system architectures. The “Feature” column corresponds to a purely learning-based architecture where the results are obtained simply by training a temporal relation classifier using the available features. The next two columns correspond to two purely rule-based architectures, differing by whether all rules are used regardless of their accuracy or whether only high-accuracy rules (i.e., those that are at least 80% accurate) are used. The rightmost three columns correspond to the three ways of combining rules and machine learning described in Section 4.3.

On the other hand, the rows of the table differ in terms of what features are available to a system. In row 1, only the baseline features are available. In the subsequent rows, the six types of features discussed in Section 4 are added incrementally to the baseline feature set. This means that the last row corresponds to the case where all feature types are used.

A point merits clarification. It may not be immediately clear how to interpret the results under, for instance, the “All Rules” column. In other words, it may not be clear what it means to add the six types of features incrementally to a rule-based system. Recall that one of our goals is to compare a purely learning-based system with a purely rule-

Feature Type	Features		All Rules		All Rules with accuracy ≥ 0.8		Features + Rules as Features		Rules + Features		Rules + Features + Rules as Features	
	Acc	F ^{ma}	Acc	F ^{ma}	Acc	F ^{ma}	Acc	F ^{ma}	Acc	F ^{ma}	Acc	F ^{ma}
1 Baseline	45.3	24.9	—	—	—	—	—	—	—	—	—	—
2 + Pairwise	46.5	25.8	37.6	26.5	5.1	13.9	46.7	26.5	48.0	31.9	48.2	32.1
3 + Dependencies	47.0	25.9	39.0	27.8	6.9	15.7	47.2	26.7	49.2	32.3	49.2	32.6
4 + WordNet	46.9	26.0	43.5	30.4	6.9	15.7	47.5	26.8	49.2	32.3	49.5	32.8
5 + Webster	46.9	25.8	43.3	29.9	6.9	15.7	48.1	26.8	49.2	32.0	50.1	33.1
6 + PropBank	47.2	26.0	44.3	30.5	8.1	16.6	48.0	26.8	49.5	32.2	50.0	33.0
7 + Discourse	48.1	26.6	47.5	35.1	12.8	23.3	48.9	27.5	53.0	36.0	53.4	36.6

Table 3: Two-fold cross-validation accuracies and macro F-scores as features are added incrementally to the baseline.

based system, since we hypothesized that humans may be better at combining the available features to form rules than a learning algorithm would be. To facilitate this comparison, all and only those features that are available to a learning-based system in a given row can be used in hand-crafting the rules of the rule-based system in the same row. The other columns involving the use of rules can be interpreted in a similar manner.

The highest accuracy and macro F-score are achieved when all types of features are used in combination with the “Rules + Features + Rules as Features” architecture. Specifically, this system achieves an accuracy of 53.4% and a macro F-score of 36.6% on the 2000-instance test set. This translates to a relative error reduction of 15–16% in comparison to the baseline result shown in row 1. A closer examination of these results reveals that the hand-crafted rules used by the system correctly classify 239 of the 305 test instances to which they are applicable. In other words, the rules achieve a precision of 78.3% and a recall of 15.3% on the test data.

Our results suggest that the rules are effective at improving performance when they are used to make classification decisions prior to the application of the classifier, as the performance of the “Rules + Features + Rules as Features” architecture is significantly better than that of the “Features + Rules as Features” architecture.⁸ On the other hand, the “Rules + Features + Rules as Features” architecture does not benefit from the use of rules as features, as its performance is statistically indistinguishable from that of the “Rules + Features” architecture. Nevertheless, both “Rules + Features + Rules as Features” and “Rules + Features” are significantly

better than the remaining four architectures. This suggests that the best-performing approach for our 14-class temporal relation classification task is the hybrid approach where high-accuracy rules are first applied and then the learned classifier is used to classify those cases that cannot be handled by the rules.

Among the remaining four architectures, “All Rules with accuracy ≥ 0.8 ”, the version of the rule-based architecture where only the high-accuracy rules are used, performs significantly worse than the others, presumably because the coverage of the rule-set is low. The results of the two feature-based architectures, “Features” and “Features + Rules as Features”, are statistically indistinguishable from each other at the $p < 0.01$ level. At the $p < 0.05$ level, however, their results are mixed: “Features + Rules as Features” is better than “Features” according to accuracy, whereas the reverse is true according to macro F-score. Combining these results with those we discussed above concerning the “Rules + Features” and “Rules + Features + Rules as Features” architectures, we can conclude that the features encoding the hand-crafted rules are (mildly) useful only when used in combination with a weak-performing system. Finally, comparing the “Features” architecture and the “All Rules” architecture, we also see mixed results: “Features” is better than “All Rules” according to accuracy, whereas the reverse is true according to macro F-score. These results confirm our earlier hypothesis that the rule-based system is indeed better at identifying instances of minority relation types.

Next, to determine whether the addition of a particular type of features to the feature set is useful, we apply the paired t -test to each pair of adjacent rows in Table 3. We found that adding pairwise features, dependency relations, and most

⁸Unless otherwise stated, all statistical significance tests are paired t -tests, with $p < 0.05$.

	Feature Type	Event-Event		Event-Time	
		Acc	F ^{ma}	Acc	F ^{ma}
1	Baseline	36.7	15.6	63.3	19.2
2	+ Pairwise	40.4	25.4	64.7	24.2
3	+ Dependencies	42.4	28.4	64.9	25.4
4	+ WordNet	42.6	28.1	64.7	25.3
5	+ Webster	43.0	29.7	64.6	25.3
6	+ PropBank	43.2	28.6	64.3	25.1
7	+ Discourse	46.8	36.3	65.4	26.4

Table 4: Event-event and event-time classification results of our best system (Rules + Features+ Rules as features).

importantly, discourse relations significantly improves both accuracy and macro F-score ($p < 0.05$). Adding the Webster relations improves accuracy at a slightly lower significance level ($p < 0.07$) but does not significantly improve macro F-score. Somewhat counter-intuitively, the WordNet and predicate-argument relations are not useful. We speculate that their failure to improve performance could be attributed to the fact that these relations are extracted by imperfect analyzers. Additional experiments involving the use of gold-standard quality features are needed to precisely determine the reason.

Recall that the results shown in Table 3 were computed over both the order (i.e., event-event) and anchor (i.e., event-time) temporal relations. To gain additional insights into our best-performing system, we show in Table 4 its performance on classifying event-event and event-time relations separately. In comparison to the baseline, both accuracy and macro F-score increase significantly when our system is used in combination with all feature types. In particular, our system yields a relative error reduction of 16–25% for event-event classification and 6–9% for event-time classification over the baseline. The pairwise features, as well as dependency relations and discourse relations, contribute significantly to the classification of both event-event and event-time relations.

Finally, we show in Table 5 the per-class results of the baseline system and our best-performing system. As we can see, our system performs significantly better than the baseline on all relation types, owing to a simultaneous rise in recall and precision.

6 Conclusions

We have investigated a knowledge-rich, hybrid approach to the 14-class temporal relation classifica-

Relation	Baseline			Our System

tion task. Results on the TimeBank corpus show that our approach achieves a relative error reduction of 15–16% over a learning-based baseline that employs a state-of-the-art feature set. Our results suggest that (1) the pairwise features, dependency relations, and discourse relations are useful for temporal relation classification; and (2) hand-crafted rules can better handle the skewed class distribution underlying our dataset via improving minority class prediction. To our knowledge, we are the first to (1) report results for the 14-class temporal relation classification task on TimeBank; (2) successfully employ PDTB-style discourse relations to improve this task; and (3) show that a hybrid approach to this task can yield better results than either a rule-based or learning-based approach. To stimulate research on this task, we make our complete set of hand-crafted rules available to other researchers. We believe that hybrid rule-based and learning-based approaches are promising approaches to language processing tasks that require complex reasoning and hope that they will be given more attention in the community.

Abstract

Inferring the information structure of scientific documents is useful for many downstream applications. Existing feature-based machine learning approaches to this task require substantial training data and suffer from limited performance. Our idea is to guide feature-based models with declarative domain knowledge encoded as posterior distribution constraints. We explore a rich set of discourse and lexical constraints which we incorporate through the Generalized Expectation (GE) criterion. Our constrained model improves the performance of existing fully and lightly supervised models. Even a fully unsupervised version of this model outperforms lightly supervised feature-based models, showing that our approach can be useful even when no labeled data is available.

1 Introduction

Techniques that enable automatic analysis of the information structure of scientific articles can help scientists identify information of interest in the growing volume of scientific literature. For example, classification of sentences according to argumentative zones (AZ) – an information structure scheme that is applicable across scientific domains (Teufel et al., 2009) – can support information retrieval, information extraction and summarization (Teufel and Moens, 2002; Tbahriti et al., 2006; Ruch et al., 2007; Liakata et al., 2012; Contractor et al., 2012).

Previous work on sentence-based classification of scientific literature according to categories of information structure has mostly used feature-based ma-

chine learning, such as Support Vector Machines (SVM) and Conditional Random Fields (CRF) (e.g. (Teufel and Moens, 2002; Lin et al., 2006; Hirohata et al., 2008; Shatkay et al., 2008; Guo et al., 2010; Liakata et al., 2012)). Unfortunately, the performance of these methods is rather limited, as indicated e.g. by the relatively low numbers reported by Liakata et al. (2012) in biochemistry and chemistry with per-class F-scores ranging from .18 to .76.

We propose a novel approach to this task in which traditional feature-based models are augmented with explicit declarative expert and domain knowledge, and apply it to sentence-based AZ. We explore two sources of declarative knowledge for our task - *discourse* and *lexical*. One way to utilize discourse knowledge is to guide the model predictions by encoding a desired predicted class (i.e. information category) distribution in a given position in the document. Consider, for example, sentence (1) from the first paragraph of the *Discussion* section in a paper:

(1) *In time, this will prove to be most suitable for detailed analysis of the role of these hormones in mammary cancer development.*

Although the future tense and cue phrases such as “*in time*” can indicate that authors are discussing future work (i.e. the “Future work” class in the AZ scheme), in this case they refer to their own contribution (i.e. the “Conclusion” class in AZ). As most authors discuss their own contribution in the beginning of the *Discussion* section and future directions in the end, encoding the desired class distribution as a function of the position in this section can guide the model to the right decision.

Likewise, lexical knowledge can guide the model

through predicted class distributions for sentences that contain specific vocabulary. Consider, for example, sentence (2):

(2) *The values calculated for lungs include the presumed DNA adduct of BA and might thus be slightly overestimated.*

The verb “*calculated*” usually indicates the “Method” class, but, when accompanied by the modal verb “*might*”, it is more likely to imply that authors are interpreting their own results (i.e. the “Conclusion” class in AZ). This can be explicitly encoded in the model through a target distribution for sentences containing certain modal verbs.

Recent work has shown that explicit declaration of domain and expert knowledge can be highly useful for structured NLP tasks such as parsing, POS tagging and information extraction (Chang et al., 2007; Mann and McCallum, 2008; Ganchev et al., 2010). These works have encoded expert knowledge through constraints, with different frameworks differing in the type of constraints and the inference and learning algorithms used. We build on the Generalized Expectation (GE) framework (Mann and McCallum, 2007) which encodes expert knowledge through a preference (i.e. soft) constraints for parameter settings for which the predicted label distribution matches a target distribution.

In order to integrate domain knowledge with a features-based model, we develop a simple taxonomy of constraints (i.e. desired class distributions) and employ a top-down classification algorithm on top of a Maximum Entropy Model augmented with GE constraints. This algorithm enables us to break the multi-class prediction into a pipeline of consecutive, simpler predictions which can be better assisted by the encoded knowledge.

We experiment in the biological domain with the eight-category AZ scheme (Table 1) adapted from (Mizuta et al., 2006) and described in (Contractor et al., 2012). The results show that our constrained model substantially outperforms a baseline unconstrained Maximum Entropy Model. While this type of constrained models have previously improved the feature-based model performance mostly in the weakly supervised and domain adaptation scenarios (e.g. (Mann and McCallum, 2007; Mann and McCallum, 2008; Ganchev et al., 2010)), we demonstrate substantial gains both when the Maximum En-

tropy Model is fully trained and when its training data is sparse. This demonstrates the importance of expert knowledge for our task and supports our modeling decision that combines feature-based methods with domain knowledge encoded via constraints.

2 Previous work

Information structure analysis The information structure of scientific documents (e.g. journal articles, abstracts, essays) can be analyzed in terms of patterns of topics, functions or relations observed in multi-sentence scientific text. Computational approaches have mainly focused on analysis based on argumentative zones (Teufel and Moens, 2002; Mizuta et al., 2006; Hachey and Grover, 2006; Teufel et al., 2009), discourse structure (Burstein et al., 2003; Webber et al., 2011), qualitative dimensions (Shatkay et al., 2008), scientific claims (Blake, 2009), scientific concepts (Liakata et al., 2010) and information status (Markert et al., 2012).

Most existing methods for analyzing scientific text according to information structure use full supervision in the form of thousands of manually annotated sentences (Teufel and Moens, 2002; Burstein et al., 2003; Mizuta et al., 2006; Shatkay et al., 2008; Guo et al., 2010; Liakata et al., 2012; Markert et al., 2012). Because manual annotation is prohibitively expensive, approaches based on light supervision are now emerging for the task, including those based on active learning and self-training (Guo et al., 2011) and unsupervised methods (Varga et al., 2012; Reichart and Korhonen, 2012). Unfortunately, these approaches do not reach the performance level of fully supervised models, let alone exceed it. Our novel method addresses this problem.

Declarative knowledge and constraints Previous work has shown that incorporating declarative constraints into feature-based machine learning

models works well in many NLP tasks (Chang et al., 2007; Mann and McCallum, 2008; Druck et al., 2008; Bellare et al., 2009; Ganchev et al., 2010). Such constraints can be used in a semi-supervised or unsupervised fashion. For example, (Mann and McCallum, 2008) shows that using CRF in conjunction with auxiliary constraints on unlabeled data significantly outperforms traditional CRF in information extraction, and (Druck et al., 2008) shows that using declarative constraints alone for unsupervised learning achieves good results in text classification. We show that declarative constraints can be highly useful for the identification of information structure of scientific documents. In contrast with most previous works, we show that such constraints can improve the performance of a fully supervised model. The constraints are particularly helpful for identifying low-frequency information categories, but still yield high performance on high-frequency categories.

3 Maximum-Entropy Estimation and Generalized Expectation (GE)

In this section we describe the Generalized Expectation method for declarative knowledge encoding.

Maximum Entropy (ME) The idea of Generalized Expectation (Dudík, 2007; Mann and McCallum, 2008; Druck et al., 2008) stems from the principle of maximum entropy (Jaynes, 1957; Pietra and Pietra, 1993) which raises the following constrained optimization problem:

$$\begin{aligned} & \max_p H(\cdot) \\ \text{subject to } & E_p[\mathbf{f}(\cdot)] = E_{\tilde{p}}[\mathbf{f}(\cdot)] \\ & p(\cdot) \geq 0 \\ & \sum p(\cdot) = 1, \end{aligned} \quad (1)$$

where $\tilde{p}(\cdot)$ is the empirical distribution, $p(\cdot)$ is a probability distribution in the model and $H(\cdot)$ is the corresponding information entropy, $\mathbf{f}(\cdot)$ is a collection of feature functions, and $E_p[\mathbf{f}(\cdot)]$ and $E_{\tilde{p}}[\mathbf{f}(\cdot)]$ are the expectations of \mathbf{f} with respect to $p(\cdot)$ and $\tilde{p}(\cdot)$. An example of $p(\cdot)$ could be a conditional probability distribution $p(y|x)$, and $H(\cdot)$ could be a conditional entropy $H(y|x)$. The optimal $p(y|x)$ will take on an exponential form:

$$p_\lambda(y|x) = \frac{1}{Z_\lambda} \exp(\lambda \cdot \mathbf{f}(x, y)), \quad (2)$$

where λ is the Lagrange multipliers in the corresponding unconstrained objective function, and Z_λ

is the partition function. The dual problem becomes maximizing the conditional log-likelihood of labeled data \mathcal{L} (Berger et al., 1996):

$$\max_\lambda \sum_{(x_i, y_i) \in \mathcal{L}} \log(p_\lambda(y_i|x_i)), \quad (3)$$

which is usually known as a Log-linear or Maximum Entropy Model (MaxEnt).

ME with Generalized Expectation The objective function and the constraints on **expectations** in (1) can be **generalized** to:

$$\begin{aligned} & \max_\lambda - \sum_x \tilde{p}(x) D(p_\lambda(y|x) || p_0(y|x)) \\ & - g(E_{\tilde{p}(x)}[E_{p_\lambda(y|x)}[\mathbf{f}(x, y)|x]]), \end{aligned} \quad (4)$$

where $D(p_\lambda || p_0)$ is the divergence from p_λ to a base distribution p_0 , and $g(\cdot)$ is a constraint/penalty function that takes empirical evidence $E_{\tilde{p}(x,y)}[\mathbf{f}(x, y)]$ as a reference point (Pietra and Pietra, 1993; Chen et al., 2000; Dudík, 2007). Note that a special case of this is MaxEnt where p_0 is set to be a uniform distribution, $D(\cdot)$ to be the KL divergence, and $g(\cdot)$ to be an equality constraint.

The constraint $g(\cdot)$ can be set in a relaxed manner:

$$\sum_k \frac{1}{2\rho_k^2} (E_{\tilde{p}(x)}[E_{p_\lambda(y|x)}[f_k(x, y)|x]] - E_{\tilde{p}(x,y)}[f_k(x, y)])^2,$$

which is the logarithm of a Gaussian distribution centered at the reference values with a diagonal covariance matrix (Pietra and Pietra, 1993), and the dual problem will become a regularized MaxEnt with a Gaussian prior ($\mu_k = 0$, $\sigma_k^2 = \frac{1}{\rho_k^2}$) over the parameters:

$$\max_\lambda \sum_{(x_i, y_i) \in \mathcal{L}} \log(p_\lambda(y_i|x_i)) - \sum_k \frac{\lambda_k^2}{2\sigma_k^2} \quad (5)$$

Such a model can be further extended to include expert knowledge or auxiliary constraints on unlabeled data \mathcal{U} (Mann and McCallum, 2008; Druck et al., 2008; Bellare et al., 2009):

$$\begin{aligned} & \max_\lambda \sum_{(x_i, y_i) \in \mathcal{L}} \log(p_\lambda(y_i|x_i)) - \sum_k \frac{\lambda_k^2}{2\sigma_k^2} \\ & - \gamma g^*(E_{p_\lambda(y|x)}[\mathbf{f}^*(x, y)]) \end{aligned} \quad (6)$$

where $\mathbf{f}^*(\cdot)$ is a collection of auxiliary feature functions on \mathcal{U} , $g^*(\cdot)$ is a constraint function that takes expert/declarative knowledge $E_{p^*(y|x)}[\mathbf{f}^*(x, y)]$ as a reference point, and γ is the weight of the auxiliary GE term.

The auxiliary constraint $g^*(\cdot)$ can take on many forms and the one we used in this work is an L^2 penalty function (Dudík, 2007). We trained the model with L-BFGS (Nocedal, 1980) in supervised, semi-supervised and unsupervised fashions on labeled and/or unlabeled data, using the Mallet software (McCallum, 2002).

4 Incorporating Expert Knowledge into GE constraints

We defined the auxiliary feature functions – the expert knowledge on unlabeled data as¹:

$$f_k^*(x, y) = \mathbb{1}_{(x_k, y_k)}(x, y), \\ \text{such that } E_{p^*(y|x)}[f_k(x, y)] = p^*(y_k|x_k), \quad (7)$$

where $\mathbb{1}_{(x_k, y_k)}(x, y)$ is an indicator function, and $p^*(y_k|x_k)$ is a conditional probability specified in the form of

$$p^*(y_k|x_k) \in [a_k, b_k] \quad (8)$$

by experts. In particular, we took

$$p^*(y_k|x_k) = \begin{cases} a_k & \text{if } p_\lambda(y_k|x_k) < a \\ b_k & \text{if } p_\lambda(y_k|x_k) > b \\ p_\lambda(y_k|x_k) & \text{if } a \leq p_\lambda(y_k|x_k) \leq b \end{cases} \quad (9)$$

as the reference point when calculating $g^*(\cdot)$.

We defined two types of constraints: those based on *discourse* properties such as the location of a sentence in a particular section or paragraph, and those based on *lexical* properties such as citations, references to tables and figures, word lists, tenses, and so on. Note that the word lists actually contain both lexical and semantic information.

To make an efficient use of the declarative knowledge we build a taxonomy of information structure categories centered around the distinction between categories that describe the authors' OWN work and those that describe OTHER work (see Section 5). In practice, our model labels every sentence with an AZ category augmented by one of the two categories, OWN or OTHER. In evaluation we consider only the standard AZ categories which are part of the annotation scheme of (Contractor et al., 2012).

Table 2: Discourse and lexical constraints for identifying information categories at different levels of the information structure taxonomy.

(a) OWN / OTHER	
OWN	Discourse (1) Target(last part of paragraph) = 1 (2) Target(last part of section) = 1 Lexical (3) Target(tables/figures) ≥ 1 (4) $\exists x \in \{w w \sim we\}$ Target(x) = 1 $\wedge \forall y \in \{w w \sim previous\}$ Target(y) = 0 (5) $\exists x \in \{w w \sim thus\}$ Target(x) = 1
OTHER	Lexical (6) Target(cite) = 1 (7) Target(cite) > 1 (8) Backward(cite) = 1 $\wedge \exists x \in \{w w \sim in_addition\}$ Target(x) = 1
(b) PROB / METH / RES / CON / FUT	
PROB	Discourse (1) Target(last part in section) = 1 Lexical (2) $\exists x \in \{w w \sim aim\}$ Target(x) = 1 (3) $\exists x \in \{w w \sim question\}$ Target(x) = 1 (4) $\exists x \in \{w w \sim investigate\}$ Target(x) = 1
METH	Lexical (5) $\exists x \in \{w w \sim \{use, method\}\}$ Target(x) = 1
RES	Lexical (6) Target(articles/figures) ≥ 1 (7) $\exists x \in \{w w \sim observe\}$ Target(x) = 1
CON	Lexical (8) Target(cite) ≥ 1 (9) $\exists x \in \{w w \sim conclude\}$ Target(x) = 1 (10) $\exists x \in \{w w \sim \{suggest, thus, because, likely\}\}$ \wedge Target(x) = 1
FUT	Discourse (11) Target(first part in section) = 1 (12) Target(last part in section) = 1 $\wedge \exists x \in \{w w \sim \{will, need, future\}\}$ Target(x) = 1 Lexical (13) $\exists x \in \{w w \sim will, future\}$ Target(x) = 1 (14) Target(present continuous tense) = 1
(c) BKG / CN / DIFF	
BKG	Discourse (1) Target(first part in paragraph) = 1 (2) Target(first part in section) = 1 Lexical (3) $\exists x \in \{w w \sim we\}$ Target(x) = 1 $\wedge \forall y \in \{w w \sim previous\}$ Target(y) = 0 (4) Forward(cite) = 1 $\wedge \forall x \in \{w w \sim \{consistent, inconsistent, than\}\}$ $(Target(x) = 0 \wedge Forward(x) = 0)$
CN	Lexical (5) $\exists x \in \{w w \sim consistent\}$ Target(x) = 1 (6) $\exists x \in \{w w \sim inconsistent\}$ Forward(x) = 1
DIFF	Lexical (7) $\exists x \in \{w w \sim inconsistent\}$ Target(x) = 1 (8) $\exists x \in \{w w \sim inconsistent\}$ Forward(x) = 1 (9) $\exists x \in \{w w \sim \{inconsistent, than, however\}\}$ $Forward(x) = 1 \wedge \exists y \in \{w w \sim we\}$ Forward(y) = 1 $\wedge \forall z \in \{w w \sim previous\}$ Forward(z) = 0

¹Accordingly, $E_{p_\lambda(y|x)}[f_k(x, y)] = p_\lambda(y_k|x_k)$

Table 3: The lexical sets used as properties in the constraints.

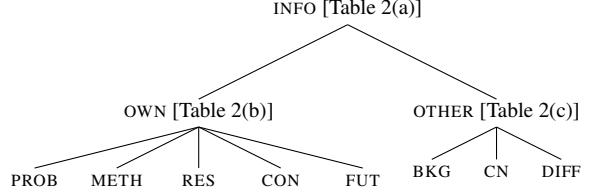

Cue	Synonyms
we	our, present_study
previous	previously, recent, recently
thus	therefore
aim	objective, goal, purpose
question	hypothesis, ?
investigate	explore, study, test, examine, evaluate, assess, determine, characterize, analyze, report, present
use	employ
method	algorithm, assay
observe	see, find, show
conclude	conclusion, summarize, summary
suggest	illustrate, demonstrate, imply, indicate, confirm, reflect, support, prove, reveal
because	result_from, attribute_to
likely	probable, probably, possible, possibly, may, could
need	remain
future	further
consistent	match, agree, support, in_line, in_agreement, similar, same, analogous
inconsistent	conflicting, conflict, contrast, contrary, differ, different, difference
than	compare
however	other_hand, although, though, but

The constraints in Table 2(a) refer to the top level of this taxonomy: distinction between the authors' own work and the work of others, and the constraints in Tables 2(b)-(c) refer to the bottom level of the taxonomy: distinction between AZ categories related to the authors' own work (Table 2(b)) and other's work (Table 2(c)).

The first and second columns in each table refer to the y and x variables in Equation (8), respectively. The functions Target(\cdot), Forward(\cdot) and Backward(\cdot) refer to the property value for the target, next and preceding sentence, respectively. If their value is 1 then the property holds for the respective sentence, if it is 0, the property does not hold. In some cases the value of such functions can be greater than 1, meaning that the property appears multiple times in the sentence. Terms of the form $\{w|w\sim\{w_i\}\}$ refer to any word/bi-grams that have the same sense as w_i , where the actual word set we use with every example word in Table 2 is described in Table 3.

For example, take constraints (1) and (4) in Table 2(a). The former is a standard discourse constraint that refers to the probability that the target sentence describes the authors' own work given that it appears in the last of the ten parts in the paragraph. The latter is a standard lexical constraint that refers to the probability that a sentence presents other people's work given that it contains any words in $\{we, our, present_study\}$ and that it doesn't contain any words

Figure 1: The constraint taxonomy for top-down modeling.

in $\{previous, previously, recent, recently\}$. Our constraint set further includes constraints that combine both types of information. For example, constraint (12) in Table 2(b) refers to the probability that a sentence discusses future work given that it appears in the last of the ten parts of the section (discourse) and that it contains at least one word in $\{will, future, further, need, remain\}$ (lexical).

5 Top-Down Model

An interesting property of our task and domain is that the available expert knowledge does not directly support the distinctions between AZ categories, but it does provide valuable indirect guidance. For example, the number of citations in a sentence is only useful for separating the authors' work from other people's work, but not for further fine grained distinctions between zone categories. Moreover, those constraints that are useful for making fine grained distinctions between AZ categories are usually useful only for a particular subset of the categories only. For example, all the constraints in Table 2(b) are conditioned on the assumption that the sentence describes the authors' own work.

To make the best use of the domain knowledge, we developed a simple constraint taxonomy, and apply a top-down classification approach which utilizes it. The taxonomy is presented in Figure 1. For classification we trained three MaxEnt models augmented with GE constraints: one for distinguishing between OWN and OTHER², one for distinguishing between the AZ categories under the OWN auxiliary category and one for distinguishing between the AZ categories under the OTHER auxiliary category. At test time we first apply the first classifier and based on its prediction we apply either the classifier that distinguishes between OWN categories or the one that distinguishes between OTHER categories.

²For the training of this model, each training data AZ category is mapped to its respective auxiliary class.

6 Experiments

Data We used the full paper corpus used by Contractor et al. (2012) which contains 8171 sentences from 50 biomedical journal articles. The corpus is annotated according to the AZ scheme described in Table 1. AZ describes the logical structure, scientific argumentation and intellectual attribution of a scientific paper. It was originally introduced by Teufel and Moens (2002) and applied to computational linguistics papers, and later adapted to other domains such as biology (Mizuta et al., 2006) – which we used in this work – and chemistry (Teufel et al., 2009).

Table 4 shows the AZ class distribution in full articles as well as in individual sections. Since section names vary across scientific articles, we grouped similar sections before calculating the statistics (e.g. *Discussion* and *Conclusions* sections were grouped under *Discussion*). We can see that although there is a major category in each section (e.g. CON in *Discussion*), up to 36.5% of the sentences in each section still belong to other categories.

Features We extracted the following features from each sentence and used them in the feature-based classifiers: (1) Discourse features: location in the article/section/paragraph. For this feature each text batch was divided to ten equal size parts and the corresponding feature value identifies the relevant part; (2) Lexical features: number of citations and references to tables and figures (0, 1, or more), word, bi-gram, verb, and verb class (obtained by spectral clustering (Sun and Korhonen, 2009)); (3) Syntactic features: tense and voice (POS tags of main and auxiliary verbs), grammatical relation, subject and object. The lexical and the syntactic features were extracted for the represented sentence as well as for its surrounding sentences. We used the C&C POS tagger and parser (Curran et al., 2007) for extracting the lexical and the syntactic features. Note that all the information encoded into our constraints is also encoded in the features and is thus available to the feature-based model. This enables us to properly evaluate the impact of our modeling decision which augments a feature-based model with constraints.

Baselines We compared our model against four baselines, two with full supervision: Support Vector Machines (SVM) and Maximum Entropy Models (MaxEnt), and two with light supervision: Trans-

Table 4: Class distribution (shown in percentages) in articles and their individual sections in the AZ-annotated corpus.

	BKG	PROB	METH	RES	CON	CN	DIFF	FUT

ductive SVM (TSVM) and semi-supervised MaxEnt based on Entropy Regularization (ER) (Vapnik, 1998; Jiao et al., 2006). SVM and MaxEnt have proved successful in information structure analysis (e.g. (Merity et al., 2009; Guo et al., 2011)) but, to the best of our knowledge, their semi-supervised versions have not been used for AZ of full articles.

Parameter tuning The boundaries of the reference probabilities (a_k and b_k in Equation (8)) were defined and optimized on the development data which consists of one third of the corpus. We considered six types of boundaries: Fairly High for 1, High for [0.9,1), Medium High for [0.5,0.9), Medium Low for [0.1,0.5), Low for [0,0.1), and Fairly Low for 0.

Evaluation We evaluated the precision, recall and F-score for each category, using a standard ten-fold cross-validation scheme. The models were tested on each of the ten folds and trained on the rest of them, and the results were averaged across the ten folds.

7 Results

We report results at two levels of granularity. We first provide detailed results for the *Discussion* section which should be, as is clearly evident from Table 4, the most difficult section for AZ prediction as only 63.5% of its sentences take its most dominant class (CON). As we show below, this is also where our constrained model is most effective. We then show the advantages of our model for other sections.

Results for the *Discussion* section To get a bet-

Table 6: *Discussion* section performance of MaxEnt, MaxEnt+GE and a MaxEnt+GE model that does not include our top-down classification scheme. Results are presented for different amounts of labeled training data. The MaxEnt+GE (Top-down) model outperforms the MaxEnt in 44 out of 48 cases, and MaxEnt+GE (Flat) in 39 out of 48 cases.

ter understanding of the nature of the challenge we face, Table 5 shows the F-scores of fully- and semi-supervised SVM and MaxEnt on the *Discussion* section. The dominant zone category CON, which accounts for 63.5% of the section sentences, has the highest F-scores for all methods and scenarios. Most of the methods also identify the second and the third most frequent zones BKG and CN, but with relatively lower F-scores. Other low-frequency categories can hardly be identified by any of the methods regardless of the amount of labeled data available for training. Note that the compared models perform quite similarly. We therefore use the MaxEnt model, which

Table 8: Analysis of the impact of the different constraint types for the lightly supervised and the fully supervised cases. Results are presented for the *Discussion* section. Using only the lexical constraints is generally preferable in the fully supervised case. Combining the different constraint types is preferable for the lightly supervised case.

	Discourse		Lexical		Discourse+Lexical	
	150	Full	150	Full	150	Full
BKG	.29	.55	.46	.58	.48	.57
PROB	0	0	.37	.40	.29	.41

CN	.12	.34	.35	.42	.33	.39
DIFF	0	0	.21	.21	.25	.21
FUT	0	0	0	.29	.31	.31

is most naturally augmented with GE constraints, as the baseline unconstrained model.

When adding the GE constraints we observe a substantial performance gain, in both the fully and the lightly supervised cases, especially for the low-frequency categories. Table 6 presents the F-scores of MaxEnt with and without GE constraints (“MaxEnt+GE (Top-down)” and “MaxEnt”) in the light and full supervision scenarios. Incorporating GE into MaxEnt results in a substantial F-score improvement for all AZ categories except for the major category CON for which the performance is kept very similar. In total, MaxEnt+GE (Top-down) is

better in 44 out of the 48 cases presented in the table. Importantly, the constrained model provides substantial improvements for both the relatively high-frequency classes (BKG and CN which together label 30.2% of the sentences) and for the low-frequency classes (which together label 6.4% of the sentences).

The table also clearly demonstrates the impact of our tree-based top-down classification scheme, by comparing the Top-down version of MaxEnt+GE to the standard “Flat” version. In 39 out of 48 cases, the Top-down model performs better. In some cases, especially for high-frequency categories and when the amount of training data increases, unconstrained MaxEnt even outperforms the flat MaxEnt+GE model. The results presented in the rest of the paper for the MaxEnt+GE model therefore refer to its Top-down version.

All sections We next turn to the performance of our model on the three other sections. Our experiments show that augmenting the MaxEnt model with domain knowledge constraints improves performance for all the categories (either low or high frequency), except the major section category, and keep the performance for the latter on the same level. Figure 2 demonstrates this pattern for the lightly supervised case with 150 training sentences but the same pattern applies to all other amounts of training data, including the fully supervised case. Naturally, we cannot demonstrate all these cases due to space limitations. The result patterns are very similar to those presented above for the *Discussion* section.

Unsupervised GE We next explore the quality of the domain knowledge constraints when used in isolation from a feature-based model. The objective function of this model is identical to Equation (6) except that the first (likelihood) term is omitted. Our experiments reveal that this unsupervised GE model outperforms standard MaxEnt for all the categories except the major category of the section, when up to 150 training sentences are used. Table 7 demonstrates this for the *Discussion* section. This pattern holds for the other scientific article sections. Even when more than 150 labeled sentences are used, the unsupervised model better detects the low frequency categories (i.e. those that label less than 10% of the sentences) for all sections. These results provide strong evidence for the usefulness of our constraints even when they are used with no labeled data.

Model component analysis We finally analyze the impact of the different types of constraints on the performance of our model. Table 8 presents the *Discussion* section performance of the constrained model with only one or the full set of constraints. Interestingly, when the feature-based model is fully trained the application of the lexical constraints alone results in a very similar performance to the application of the full set of lexical and discourse constraints. It is only in the lightly supervised case where the full set of constraints is required and results in the best performing model.

8 Conclusions and Future Work

We have explored the application of posterior discourse and lexical constraints for the analysis of the information structure of scientific documents. Our results are strong. Our constrained model outperforms standard feature-based models by a large margin in both the fully and the lightly supervised cases. Even an unsupervised model based on these constraints provides substantial gains over feature-based models for most AZ categories.

We provide a detailed analysis of the results which reveals a number of interesting properties of our model which may be useful for future research. First, the constrained model significantly outperforms its unconstrained counterpart for low-medium frequency categories while keeping the performance on the major section category very similar to that of the baseline model. Improved modeling of the major category is one direction for future research. Second, our full constraint set is most beneficial in the lightly supervised case while the lexical constraints alone yield equally good performance in the fully supervised case. This calls for better understanding of the role of discourse constraints for our task as well as for the design of additional constraints that can enhance the model performance either in combination with the existing constraints or when separately applied to the task. Finally, we demonstrated that our top-down tree classification scheme provides a substantial portion of our model’s impact. A clear direction for future research is the design of more fine-grained constraint taxonomies which can enable efficient usage of other constraint types and can result in further improvements in performance.

Adaptation of Reordering Models for Statistical Machine Translation

Boxing Chen, George Foster and Roland Kuhn

National Research Council Canada

first.last@nrc-cnrc.gc.ca

Abstract

Previous research on domain adaptation (DA) for statistical machine translation (SMT) has mainly focused on the translation model (TM) and the language model (LM). To the best of our knowledge, there is no previous work on reordering model (RM) adaptation for phrase-based SMT. In this paper, we demonstrate that mixture model adaptation of a lexicalized RM can significantly improve SMT performance, even when the system already contains a domain-adapted TM and LM. We find that, surprisingly, different training corpora can vary widely in their reordering characteristics for particular phrase pairs. Furthermore, particular training corpora may be highly suitable for training the TM or the LM, but unsuitable for training the RM, or vice versa, so mixture weights for these models should be estimated separately. An additional contribution of the paper is to propose two improvements to mixture model adaptation: smoothing the in-domain sample, and weighting instances by document frequency. Applied to mixture RMs in our experiments, these techniques (especially smoothing) yield significant performance improvements.

1 Introduction

A phrase-based statistical machine translation (SMT) system typically has three main components: a translation model (TM) that contains information about how to translate word sequences (phrases) from the source language to the target language, a language model (LM) that contains information

about probable word sequences in the target language, and a reordering model (RM) that indicates how the order of words in the source sentence is likely to influence the order of words in the target sentence. The TM and the RM are trained on parallel data, and the LM is trained on target-language data. Usage of language and therefore the best translation practice differs widely across genres, topics, and dialects, and even depends on a particular author's or publication's style; the word "domain" is often used to indicate a particular combination of all these factors. Unless there is a perfect match between the training data domain and the (test) domain in which the SMT system will be used, one can often get better performance by adapting the system to the test domain.

In offline domain adaptation, the system is provided with a sample of translated sentences from the test domain prior to deployment. In a popular variant of offline adaptation, linear mixture model adaptation, each training corpus is used to generate a separate model component that forms part of a linear combination, and the sample is used to assign a weight to each component (Foster and Kuhn, 2007). If the sample resembles some of the corpora more than others, those corpora will receive higher weights in the combination.

Previous research on domain adaptation for SMT has focused on the TM and the LM. Such research is easily motivated: translations across domains are unreliable. For example, the Chinese translation of the English word "mouse" would most likely be "laoshu 老鼠" if the topic is the animal; if the topic is computer hardware, its translation would most

likely be “shubiao 鼠标”. However, when the translation is for people in Taiwan, even when the topic is computer hardware, its translation would more likely be “huashu 滑鼠”. It is intuitively obvious why TM and LM adaptation would be helpful here.

By contrast, it is not at all obvious that RM model adaptation will improve SMT performance. One would expect reordering behaviour to be characteristic of a particular language pair, but not of particular domains. At most, one might think that reordering is lexicalized—perhaps, (for instance) in translating from Chinese to English, or from Arabic to English, there are certain words whose English translations tend to undergo long-distance movement from their original positions, while others stay close to their original positions. However, one would not expect a particular Chinese adverb or a particular Arabic noun to undergo long-distance movement when being translated into English in one domain, but not in others. Nevertheless, that is what we observe: see section 5 below.

This paper shows that RM adaptation improves the performance of our phrase-based SMT system. In our implementation, the RM is adapted by means of a linear mixture model, but it is likely that other forms of RM adaptation would also work. We obtain even more effective RM adaptation by smoothing the in-domain sample and by weighting orientation counts by the document frequency of the phrase pair. Both improvements could be applied to the TM or the LM as well, though we have not done so.

Finally, the paper analyzes reordering to see why RM adaptation works. There seem to be two factors at work. First, the reordering behaviour of words and phrases often differs dramatically from one bilingual corpus to another. Second, there are corpora (for instance, comparable corpora and bilingual lexicons) which may contain very valuable information for the TM, but which are poor sources of RM information; RM adaptation downweights information from these corpora significantly, and thus improves the overall quality of the RM.

2 Reordering Model

In early SMT systems, such as (Koehn, 2004), changes in word order when a sentence is translated were modeled by means of a penalty that is in-

curred when the decoder chooses, as the next source phrase to be translated, a phrase that does not immediately follow the previously translated source sentence. Thus, the system penalizes deviations from monotone order, with the magnitude of the penalty being proportional to distance in the source sentence between the end of the previously translated source phrase and the start of the newly chosen source phrase.

Many SMT systems, including our own, still use this distance-based penalty as a feature. However, starting with (Tillmann and Zhang, 2005; Koehn et al., 2005), a more sophisticated type of reordering model has often been adopted as well, and has yielded consistent performance gains. This type of RM typically identifies three possible orientations for a newly chosen source phrase: monotone (M), swap (S), and discontinuous (D). The M orientation occurs when the newly chosen phrase is immediately to the right of the previously translated phrase in the source sentence, the S orientation occurs when the new phrase is immediately to the left of the previous phrase, and the D orientation covers all other cases.¹ This type of RM is lexicalized: the estimated probabilities of M, S and D depend on the source-language and target-language words in both the previous phrase pair and the newly chosen one.

Galley and Manning (2008) proposed a “hierarchical” lexicalized RM in which the orientation (M, S, or D) is determined not by individual phrase pairs, but by blocks. A block is the largest contiguous sequence of phrase pairs that satisfies the phrase pair consistency requirement of having no external links. Thus, classification of the orientation of a newly chosen phrase as M, S, or D is carried out as if the decoder always chose the longest possible source phrase in the past, and will choose the longest possible source phrase in the future.

The RM used in this paper is hierarchical and lexicalized. For a given phrase pair (f, e) , we estimate the probabilities that it will be in an M, S, or D orientation o with respect to the previous phrase pair and the following phrase pair (two separate distributions). Orientation counts $c(o, f, e)$ are obtained from a word-aligned corpus using the method de-

¹Some researchers have distinguished between left and right versions of the D orientation, but this 4-orientation scheme has not yielded significant gains over the 3-orientation one.

scribed in (Cherry et al., 2012), and corresponding probabilities $p(o|f, e)$ are estimated using recursive MAP smoothing:

$$\begin{aligned} p(o|f, e) &= \frac{c(o, f, e) + \alpha_f p(o|f) + \alpha_e p(o|e)}{c(f, e) + \alpha_f + \alpha_e} \\ p(o|f) &= \frac{c(o, f) + \alpha_g p(o)}{c(f) + \alpha_g} \\ p(o) &= \frac{c(o) + \alpha_u/3}{c(\cdot) + \alpha_u}, \end{aligned} \quad (1)$$

where $p(o|e)$ is defined analogously to $p(o|f)$, and the four smoothing parameters α_e , α_f , α_g , and α_u are set to values that minimize the perplexity of the resulting model on held-out data.

During decoding, orientations with respect to the previous context are obtained from a shift-reduce parser, and orientations with respect to following context are approximated using the coverage vector (Cherry et al., 2012).

3 RM Adaptation

3.1 Linear mixture model

Following previous work (Foster and Kuhn, 2007; Foster et al., 2010), we adopt the linear mixture model technique for RM adaptation. This technique trains separate models for each training corpus, then learns weights for each of the models and combines the weighted component models into a single model.

If we have N sub-corpora, the global reordering model probabilities $p(o|f, e)$ are computed as in (2):

$$p(o|f, e) = \sum_{i=1}^N \alpha_i p_i(o|f, e) \quad (2)$$

where $p_i(o|f, e)$ is the reordering model trained on sub-corpus i , and α_i is its weight.

Following (Foster et al., 2010), we use the EM algorithm to learn the weights that maximize the probability of phrase-pair orientations in the development set (in-domain data):

$$\hat{\alpha} = \operatorname{argmax}_{\alpha} \sum_{o, f, e} \tilde{p}(o, f, e) \log \sum_{i=1}^N \alpha_i p_i(o|f, e) \quad (3)$$

where $\tilde{p}(o, f, e)$ is the empirical distribution of counts in the dev set (proportional to $c(o, f, e)$). Two

separate sets of mixing weights are learned: one for the distribution with respect to the previous phrase pair, and one for the next phrase pair.

3.2 Development set smoothing

In Equation 3, $\tilde{p}(o, f, e)$ is extracted from the in-domain development set. Since dev sets for SMT systems are typically small (1,000-3,000 sentences), we apply smoothing to this RM. We first obtain a smoothed conditional distribution $p(o|f, e)$ using the MAP technique described above, then multiply by the empirical marginal $\tilde{p}(e, f)$ to obtain a final smoothed joint distribution $p(o, f, e)$.

There is nothing about this idea that limits it to the RM: smoothing could be applied to the statistics in the dev that are used to estimate a mixture TM or LM, in order to mitigate over-fitting. However, we note that, compared to the TM, the over-fitting problem is likely to be more acute for the RM, since it splits counts for each phrase pair into three categories.

3.3 Document-frequency weighting

Mixture models, like the RM in this paper, depend on the existence of multiple training corpora, with each sub-corpus nominally representing a domain. A recent paper suggests that some phrase pairs belong to general language, while others are domain-specific (Foster et al., 2010). If a phrase pair exists in all training corpora, it probably belongs to general language; on the other hand, if it appears in only one or two training corpora, it is more likely to be domain-specific.

We were interested in seeing whether information about domain-specificity could improve the estimation of mixture RM weights. The intuition is that phrase pairs that belong to general language should contribute more to determining sub-corpus weights, since they are the ones whose reordering behaviour is most likely to shift with domain. To capture this intuition, we multiplied the empirical distribution in (3) by the following factor, inspired by the standard document-frequency formula:

$$D(f, e) = \log(DF(f, e) + K), \quad (4)$$

where $DF(f, e)$ is the number of sub-corpora that (f, e) appears in, and K is an empirically-determined smoothing term.

4 Experiments

4.1 Data setting

We carried out experiments in two different settings, both involving data from NIST Open MT 2012.² The first setting uses data from the Chinese to English constrained track, comprising 283M English tokens. We manually identified 14 sub-corpora on the basis of genres and origins. Table 1 summarizes the statistics and genres of all the training corpora and the development and test sets; for the training corpora, we show their size in number of words as a percentage of all training data. Most training corpora consist of parallel sentence pairs. The *isi* and *lex&ne* corpora are exceptions: the former is extracted from comparable data, while the latter is a lexicon that includes many named entities. The development set (*tune*) was taken from the NIST 2005 evaluation set, augmented with some web-genre material reserved from other NIST corpora.

Table 2: NIST Arabic-English data. In the *genres* column: nw=newswire, bc=broadcast conversation, bn=broadcast news, ng=newsgroup, wl=weblog.

The second setting uses NIST 2012 Arabic to English data, but excluding the UN data. There are about 47.8 million English running words in these training data. We manually grouped the training data into 7 groups according to genre and origin. Table 2 summarizes the statistics and genres of all the training corpora and the development and test sets. Note that for this language pair, the comparable *isi* data represent a large proportion of the training data: 72% of the English words. We use the evaluation sets from NIST 2006, 2008, and 2009 as our development set and two test sets, respectively.

4.2 System

Experiments were carried out with an in-house phrase-based system similar to Moses (Koehn et al., 2007). The corpus was word-aligned using IBM2, HMM, and IBM4 models, and the phrase table was the union of phrase pairs extracted from these separate alignments, with a length limit of 7. The translation model was smoothed in both directions with KN smoothing (Chen et al., 2011). The DF smoothing term K in equation 4 was set to 0.1 using held-out optimization. We use the hierarchical lexicalized RM described above, with a distortion limit of 7. Other features include lexical weighting in both directions, word count, a distance-based RM, a 4-gram LM trained on the target side of the parallel data, and a 6-gram English *Gigaword* LM. The sys-

tem was tuned with batch lattice MIRA (Cherry and Foster, 2012).

4.3 Results

For our main baseline, we simply concatenate all training data. We also tried augmenting this with separate log-linear features corresponding to sub-corpus-specific RMs. Our metric is case-insensitvie IBM BLEU-4 (Papineni et al., 2002); we report BLEU scores averaged across both test sets. Following (Koehn, 2004), we use the bootstrap-resampling test to do significance testing. In tables 3 to 5, * and ** denote significant gains over the baseline at $p < 0.05$ and $p < 0.01$ levels, respectively.

Table 3 shows that reordering model adaptation helps in both data settings. Adding either document-frequency weighting (equation 4) or dev-set smoothing makes the improvement significant in both settings. Using both techniques together yields highly significant improvements.

Our second experiment measures the improvement from RM adaptation over a baseline that includes adapted LMs and TMs. We use the same technique—linear mixtures with EM-tuned weights—to adapt these models. Table 4 shows that adapting the RM gives gains over this strong baseline for both language pairs; improvements are significant in the case of Arabic to English.

The third experiment breaks down the gains in the last line of table 4 by individual adapted model. As shown in table 5, RM adaptation yielded the largest

improvement on Arabic, while TM adaptation did best on Chinese. Surprisingly, both methods significantly outperformed LM adaptation, which only achieved significant gains over the baseline for Chinese.

5 Analysis

Why does RM adaptation work? Intuitively, one would think that reordering behaviour for a given phrase pair should not be much affected by domain, making RM adaptation pointless. That is probably why (as far as we know) no-one has tried it before. In this section, we describe three factors that account for at least part of the observed gains.

5.1 Weighting by corpus quality

One answer to the above question is that some corpora are better for training RMs than others. Furthermore, corpora that are good for training the LM or TM are not necessarily good for training the RM, and vice versa. Tables 6 and 7 illustrate this. These list the weights assigned to various sub-corpora for LM, TM, and RM mixture models.

The weights assigned to the *isi* sub-corpus in particular exhibit a striking pattern. These are high in the LM mixtures, moderate in the TM mixtures, and very low in the RM mixtures. When one considers that *isi* contains 72.6% of the English words in the Arabic training data (see table 2), its weight of 0.01 in the RM mixture is remarkable.

On reflection, it makes sense that EM would assign weights in the order it does. The *isi* corpus consists of comparable data: sentence pairs whose source- and target-language sides are similar, but often not mutual translations. These are a valuable source of in-domain n-grams for the LM; a somewhat noisy source of in-domain phrase pairs for the TM; and an unreliable source of re-ordering patterns for the RM. Figure 1 shows this. Although the two

sides of the comparable data are similar, they give the misleading impression that the phrases labeled 1, 2, 3 in the Chinese source should be reordered as 2, 3, 1 in English. We show a reference translation of the Chinese source (not found in the comparable data) that reorders the phrases as 1, 3, 2.

Thus, RM adaptation allows the RM to learn that certain corpora whose reordering information is of lower quality corpora should have lower weights. The optimal weights for corpora inside an RM may be different from the optimal weights inside a TM or LM.

5.2 Weighting by domain match

So is this all that RM adaptation does: downweight poor-quality data? We believe there is more to RM adaptation than that. Specifically, even if one

Table 8: Orientation frequencies for the phrase pair “立即 immediately”, with respect to the previous phrase.

considers only high-quality data for training RMs (ignoring comparable data, etc.) one sees differences in reordering behaviour between different domains. This isn’t just because of differences in word frequencies between domains, because we observe domain-dependent differences in reordering for the same phrase pair. Two examples are given below: one Chinese-English, one Arabic-English.

Table 8 shows reordering data for the phrase pair “立即 immediately” in various corpora. Notice the strong difference in behaviour between the three Hong Kong corpora—*hkh*, *hkl* and *hkn*—and some of the other corpora, for instance *fbis*. In the

dev	0.75	0.12	0.13	52

Table 9: Orientation frequencies for the phrase pair “work AlEm1” with respect to the previous phrase.

Hong Kong corpora, *immediately* is much less likely (probability of around 0.3) to be associated with a monotone (M) orientation than it is in *fbis* (probability of 0.5). This phrase pair is relatively frequent in both corpora, so this disparity seems too great to be due to chance.

Table 9 shows reordering behaviour for the phrase pair “work AlEm1”³ across different sub-corpora. As in the Chinese example, there appear to be significant differences in reordering patterns for certain corpora. For instance, *gale_bc* swaps this well-attested phrase pair twice as often (probability of 0.27) as *gale_ng* (probability of 0.13).

For Chinese, it is possible that dialect plays a role in reordering behaviour. In theory, Mandarin Chinese is a single language which is quite different, especially in spoken form, from other languages of China such as Cantonese, Hokkien, Shanghainese, and so on. In practice, many speakers of Mandarin may be unconsciously influenced by other languages that they speak, or by other languages that they don’t speak but that have an influence over people they interact with frequently. Word order can be affected by this: the Mandarin of Mainland China, Hong Kong and Taiwan sometimes has slightly different word order. Hong Kong Mandarin can be somewhat influenced by Cantonese, and Taiwan Mandarin by Hokkien. For instance, if a verb is modified by an adverb in Mandarin, the standard word order is “adverb verb”. However, since in Cantonese, “verb adverb” is a more common word order, speakers and writers of Mandarin in Hong Kong may adopt the

³We represent the Arabic word *AlEm1* in its Buckwalter transliteration.

Figure 2: An example of different word ordering in Mandarin from different area.

“verb adverb” order in that language as well. Figure 2 shows how a different word order in the Mandarin source affects reordering when translating into English. Perhaps in situations where different training corpora represent different dialects, RM adaptation involves an element of dialect adaptation. We are eager to test this hypothesis for Arabic—different dialects of Arabic are much more different from each other than dialects of Mandarin, and reordering is often one of the differences—but we do not have access to Arabic training, dev, and test data in which the dialects are clearly separated.

It is possible that RM adaptation also has an element of genre adaptation. We have not yet been able to confirm or refute this hypothesis. However, whatever is causing the corpus-dependent reordering patterns for particular phrase pairs shown in the two tables above, it is clear that they may explain the performance improvements we observe for RM adaptation in our experiments.

5.3 Penalizing highly-specific phrase pairs

In section 3.3 we described our strategy for giving general (high document-frequency) phrase pairs that occur in the dev set more influence in determining mixing weights. An artifact of our implementation applies a similar strategy to the probability estimates for *all* phrase pairs in the model. This is that 0 probabilities are assigned to all orientations whenever a phrase pair is absent from a particular sub-corpus.

Thus, for example, a pair (f, e) that occurs only in sub-corpus i will receive a probability $p(o|f, e) = \alpha_i p_i(o|f, e)$ in the mixture model (equation 2). Since $\alpha_i \leq 1$, this amounts to a penalty on pairs that occur in few sub-corpora, especially ones with low mixture weights.

The resulting mixture model is deficient (non-

normalized), but easy to fix by backing off to a global distribution such as $p(o)$ in equation 1. However, we found that this “fix” caused large drops in performance, for instance from the Arabic BLEU score of 48.3 reported in table 3 to 46.0. We therefore retained the original strategy, which can be seen as a form of instance weighting. Moreover, it is one that is particularly effective in the RM, since, compared to a similar strategy in the TM (which we also employ), it applies to whole phrase pairs and results in much larger penalties.

6 Related work

Domain adaptation is an active topic in the NLP research community. Its application to SMT systems has recently received considerable attention. Previous work on SMT adaptation has mainly focused on translation model (TM) and language model (LM) adaptation. Approaches that have been tried for SMT model adaptation include mixture models, transductive learning, data selection, data weighting, and phrase sense disambiguation.

Research on mixture models has considered both linear and log-linear mixtures. Both were studied in (Foster and Kuhn, 2007), which concluded that the best approach was to combine sub-models of the same type (for instance, several different TMs or several different LMs) linearly, while combining models of different types (for instance, a mixture TM with a mixture LM) log-linearly. (Koehn and Schroeder, 2007), instead, opted for combining the sub-models directly in the SMT log-linear framework.

In transductive learning, an MT system trained on general domain data is used to translate in-domain monolingual data. The resulting bilingual sentence pairs are then used as additional training data (Ueffing et al., 2007; Chen et al., 2008; Schwenk, 2008; Bertoldi and Federico, 2009).

Data selection approaches (Zhao et al., 2004; Lü et al., 2007; Moore and Lewis, 2010; Axelrod et al., 2011) search for bilingual sentence pairs that are similar to the in-domain “dev” data, then add them to the training data. The selection criteria are typically related to the TM, though the newly found data will be used for training not only the TM but also the LM and RM.

Data weighting approaches (Matsoukas et al., 2009; Foster et al., 2010; Huang and Xiang, 2010; Phillips and Brown, 2011; Sennrich, 2012) use a rich feature set to decide on weights for the training data, at the sentence or phrase pair level. For instance, a sentence from a corpus whose domain is far from that of the dev set would typically receive a low weight, but sentences in this corpus that appear to be of a general nature might receive higher weights.

The 2012 JHU workshop on Domain Adaptation for MT⁴ proposed phrase sense disambiguation (PSD) for translation model adaptation. In this approach, the context of a phrase helps the system to find the appropriate translation.

All of the above work focuses on either TM or LM domain adaptation.

7 Conclusions

In this paper, we adapt the lexicalized reordering model (RM) of an SMT system to the domain in which the system will operate using a mixture model approach. Domain adaptation of translation models (TMs) and language models (LMs) has become common for SMT systems, but to our knowledge this is the first attempt in the literature to adapt the RM. Our experiments demonstrate that RM adaptation can significantly improve translation quality, even when the system already has TM and LM adaptation. We also experimented with two modifications to linear mixture model adaptation: dev set smoothing and weighting orientation counts with document frequency of phrase pairs. Both ideas are potentially applicable to TM and LM adaptation. Dev set smoothing, in particular, seems to improve the performance of RM adaptation significantly. Finally, we investigate why RM adaptation helps SMT performance. Three factors seem to be important: downweighting information from corpora that are less suitable for modeling reordering (such as comparable corpora), dialect/genre effects, and implicit instance weighting.

Abstract

This paper examines tuning for statistical machine translation (SMT) with respect to multiple evaluation metrics. We propose several novel methods for tuning towards multiple objectives, including some based on *ensemble decoding* methods. Pareto-optimality is a natural way to think about multi-metric optimization (MMO) and our methods can effectively combine several Pareto-optimal solutions, obviating the need to choose one. Our best performing *ensemble tuning* method is a new algorithm for multi-metric optimization that searches for Pareto-optimal ensemble models. We study the effectiveness of our methods through experiments on multiple as well as single reference(s) datasets. Our experiments show simultaneous gains across several metrics (BLEU, RIBES), without any significant reduction in other metrics. This contrasts the traditional tuning where gains are usually limited to a single metric. Our human evaluation results confirm that in order to produce better MT output, optimizing multiple metrics is better than optimizing only one.

1 Introduction

Tuning algorithms are used to find the weights for a statistical machine translation (MT) model by minimizing error with respect to a single MT evaluation metric. The tuning process improves the performance of an SMT system as measured by this metric; with BLEU (Papineni et al., 2002) being the most popular choice. Minimum error-rate training (MERT) (Och, 2003) was the first approach in MT to directly optimize an evaluation metric. Several alternatives now exist: MIRA (Watanabe et al., 2007; Chiang et al., 2008), PRO (Hopkins and May, 2011), linear regression (Bazrafshan et al., 2012) and ORO (Watanabe, 2012) among others.

However these approaches optimize towards the best score as reported by a single evaluation metric. MT system developers typically use BLEU and

ignore all the other metrics. This is done despite the fact that other metrics model wide-ranging aspects of translation: from measuring the translation edit rate (TER) in matching a translation output to a human reference (Snover et al., 2006), to capturing lexical choices in translation as in METEOR (Lavie and Denkowski, 2009) to modelling semantic similarity through textual entailment (Padó et al., 2009) to RIBES, an evaluation metric that pays attention to long-distance reordering (Isozaki et al., 2010). While some of these metrics such as TER, METEOR are gaining prominence, BLEU enjoys the status of being the *de facto* standard tuning metric as it is often claimed and sometimes observed that optimizing with BLEU produces better translations than other metrics (Callison-Burch et al., 2011).

The gains obtained by the MT system tuned on a particular metric do not improve performance as measured under other metrics (Cer et al., 2010), suggesting that over-fitting to a specific metric might happen without improvements in translation quality. In this paper we propose a new tuning framework for jointly optimizing multiple evaluation metrics.

Pareto-optimality is a natural way to think about multi-metric optimization and multi-metric optimization (MMO) was recently explored using the notion of Pareto optimality in the Pareto-based Multi-objective Optimization (PMO) approach (Duh et al., 2012). PMO provides several equivalent solutions (parameter weights) having different trade-offs between the different MT metrics. In (Duh et al., 2012) the choice of which option to use rests with the MT system developer and in that sense their approach is an *a posteriori* method to specify the preference (Marler and Arora, 2004).

In contrast to this, our tuning framework provides a principled way of using the Pareto optimal options using *ensemble decoding* (Razmara et al., 2012). We also introduce a novel method of *ensemble tuning* for jointly tuning multiple MT evaluation metrics and further combine this with the PMO ap-

proach (Duh et al., 2012). We also introduce three other approaches for multi-metric tuning and compare their performance to the ensemble tuning. Our experiments yield the highest metric scores across many different metrics (that are being optimized), something that has not been possible until now.

Our ensemble tuning method over multiple metrics produced superior translations than single metric tuning as measured by a post-editing task. HTER (Snover et al., 2006) scores in our human evaluation confirm that multi-metric optimization can lead to better MT output.

2 Related Work

In grammar induction and parsing (Spitkovsky et al., 2011; Hall et al., 2011; Auli and Lopez, 2011) have proposed multi-objective methods based on round-robin iteration of single objective optimizations.

Research in SMT parameter tuning has seen a surge of interest recently, including online/batch learning (Watanabe, 2012; Cherry and Foster, 2012), large-scale training (Simianer et al., 2012; He and Deng, 2012), and new discriminative objectives (Gimpel and Smith, 2012; Zheng et al., 2012; Bazrafshan et al., 2012). However, few works have investigated the multi-metric tuning problem in depth. Linear combination of BLEU and TER is reported in (Zaidan, 2009; Dyer et al., 2009; Servan and Schwenk, 2011); an alternative is to optimize on BLEU with MERT while enforcing that TER does not degrade per iteration (He and Way, 2009). Studies on metric tunability (Liu et al., 2011; Callison-Burch et al., 2011; Chen et al., 2012) have found that the metric used for evaluation may not be the best metric used for tuning. For instance, (Mauser et al., 2008; Cer et al., 2010) report that tuning on linear combinations of BLEU-TER is more robust than a single metric like WER.

The approach in (Devlin and Matsoukas, 2012) modifies the optimization function to include traits such as output length so that the hypotheses produced by the decoder have maximal score according to one metric (BLEU) but are subject to an output length constraint, e.g. that the output is 5% shorter. This is done by rescoreing an N-best list (forest) for the metric combined with each trait condition and then the different trait hypothesis are combined using a system combination step. The traits are in-

dependent of the reference (while tuning). In contrast, our method is able to combine multiple metrics (each of which compares to the reference) during the tuning step and we do not depend on N-best list (or forest) rescoring or system combination.

Duh et. al. (2012) proposed a Pareto-based approach to SMT multi-metric tuning, where the linear combination weights do not need to be known in advance. This is advantageous because the optimal weighting may not be known in advance. However, the notion of Pareto optimality implies that multiple “best” solutions may exist, so the MT system developer may be forced to make a choice after tuning.

These approaches require the MT system developer to make a choice either before tuning (e.g. in terms of linear combination weights) or afterwards (e.g. the Pareto approach). Our method here is different in that we do not require any choice. We use *ensemble decoding* (Razmara et al., 2012) (see sec 3) to combine the different solutions resulting from the multi-metric optimization, providing an elegant solution for deployment. We extend this idea further and introduce *ensemble tuning*, where the metrics have separate set of weights. The tuning process alternates between ensemble decoding and the update step where the weights for each metric are optimized separately followed by joint update of metric (meta) weights.

3 Ensemble Decoding

We now briefly review ensemble decoding (Razmara et al., 2012) which is used as a component in the algorithms we present. The prevalent model of statistical MT is a log-linear framework using a vector of feature functions ϕ :

$$p(e|f) \propto \exp(w \cdot \phi) \quad (1)$$

The idea of ensemble decoding is to combine several models dynamically at decode time. Given multiple models, the scores are combined for each partial hypothesis across the different models during decoding using a user-defined mixture operation \otimes .

$$p(e|f) \propto \exp(w_1 \cdot \phi_1 \otimes w_2 \cdot \phi_2 \otimes \dots) \quad (2)$$

(Razmara et al., 2012) propose several mixture operations, such as *log-wsum* (simple linear mixture), *wsum* (log-linear mixture) and *max* (choose lo-

cally best model) among others. The different mixture operations allows the user to encode the beliefs about the relative strengths of the models. It has been applied successfully for domain adaptation setting and shown to perform better approaches that pre-compute linear mixtures of different models.

4 Multi-Metric Optimization

In statistical MT, the multi-metric optimization problem can be expressed as:

$$w^* = \arg \max_w g\left([M_1(H), \dots, M_k(H)]\right) \quad (3)$$

where $H = \mathcal{N}(\mathbf{f}; w)$

where $\mathcal{N}(\mathbf{f}; w)$ is the decoding function generating a set of candidate hypotheses H based on the model parameters w , for the source sentences \mathbf{f} . For each source sentence $f_i \in \mathbf{f}$ there is a set of candidate hypotheses $\{h_i\} \in H$. The goal of the optimization is to find the weights that maximize the function $g(\cdot)$ parameterized by different evaluation metrics M_1, \dots, M_k .

For the Pareto-optimal based approach such as PMO (Duh et al., 2012), we can replace $g(\cdot)$ above with $g_{PMO}(\cdot)$ which returns the points in the Pareto frontier. Alternately a weighted averaging function $g_{wavg}(\cdot)$ would result in a linear combination of the metrics being considered, where the tuning method would maximize the joint metric. This is similar to the (TER-BLEU)/2 optimization (Cer et al., 2010; Servan and Schwenk, 2011).

We introduce four methods based on the above formulation and each method uses a different type of $g(\cdot)$ function for combining different metrics and we compare experimentally with existing methods.

4.1 PMO Ensemble

PMO (Duh et al., 2012) seeks to maximize the number of points in the Pareto frontier of the metrics considered. The inner routine of the PMO-PRO tuning is described in Algorithm 1. This routine is contained within an outer loop that iterates for a fixed number iterations of decoding the tuning set and optimizing the weights.

The tuning process with PMO-PRO is independently repeated with different set of weights for metrics¹ yielding a set of equivalent solutions

¹For example Duh et al. (2012) use five different weight

Algorithm 1 PMO-PRO (Inner routine for tuning)

```

1: Input: Hypotheses  $H = \mathcal{N}(\mathbf{f}; w)$ ; Weights  $w$ 
2: Initialize  $\mathcal{T} = \{\}$ 
3: for each  $f$  in tuning set  $\mathbf{f}$  do
4:    $\{h\} = H(f)$ 
5:    $\{M(\{h\})\} = \text{ComputeMetricScore}(\{h\}, \hat{e})$ 
6:    $\{\mathcal{F}\} = \text{FindParetoFrontier}(\{M(\{h\})\})$ 
7:   for each  $h$  in  $\{h\}$  do
8:     if  $h \in \mathcal{F}$  then add  $(1, h)$  to  $\mathcal{T}$ 
9:     else add  $(\ell, h)$  to  $\mathcal{T}$  (see footnote 1)
10:   $w^p \leftarrow \text{PRO}(\mathcal{T})$  (optimize using PRO)
11: Output: Pareto-optimal weights  $w^p$ 

```

$\{p_{s_1}, \dots, p_{s_n}\}$ which are points on the Pareto frontier. The user then chooses one solution by making a trade-off between the performance gains across different metrics. However, as noted earlier this *a posteriori* choice ignores other solutions that are indistinguishable from the chosen one.

We alleviate this by complementing PMO with ensemble decoding, which we call *PMO ensemble*, in which each point in the Pareto solution is a distinct component in the ensemble decoder. This idea can also be used in other MMO approaches such as linear combination of metrics ($g_{wavg}(\cdot)$) mentioned above. In this view, PMO ensemble is a special case of *ensemble combination*, where the decoding is performed by an ensemble of optimal solutions.

The ensemble combination model introduces new hyperparameters β that are the weights of the ensemble components (meta weights). These ensemble weights could set to be uniform in a naïve implementation. Or the user can encode her beliefs or expectations about the individual solutions $\{p_{s_1}, \dots, p_{s_n}\}$ to set the ensemble weights (based on the relative importance of the components). Finally, one could also include a meta-level tuning step to set the weights β .

The PMO ensemble approach is graphically illustrated in Figure 1; we will also refer to this figure while discussing other methods.² The orig-

settings for metrics (M_1, M_2) , viz. $(0.0, 1.0)$, $(0.3, 0.7)$, $(0.5, 0.5)$, $(0.7, 0.3)$ and $(1.0, 0.0)$. They combine the metric weights q_i with the sentence-level metric scores M_i as $\ell = (\sum_k q_k M_k) / k$ where ℓ is the target value for negative examples (the *else* line in Alg 1) in the optimization step.

²The illustration is based on two metrics, metric-1 and metric-2, but could be applied to any number of metrics. Without loss of generality we assume accuracy metrics, i.e. higher

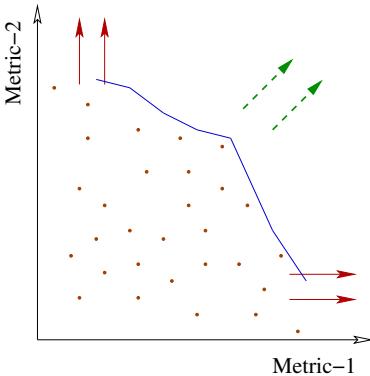

Figure 1: Illustration of different MMO approaches involving two metrics. Solid (red) arrows indicate optimizing two metrics independently and the dashed (green) arrow optimize them jointly. The Pareto frontier is indicated by the curve.

inal PMO-PRO seeks to maximize the points on the Pareto frontier (blue curve in the figure) leading to Pareto-optimal solutions. On the other hand, the PMO ensemble combines the different Pareto-optimal solutions and potentially moving in the direction of dashed (green) arrows to some point that has higher score in either or both dimensions.

4.2 Lateen MMO

Lateen EM has been proposed as a way of jointly optimizing multiple objectives in the context of dependency parsing (Spitkovsky et al., 2011). It uses a secondary hard EM objective to move away, when the primary soft EM objective gets stuck in a local optima. The course correction could be performed under different conditions leading to variations that are based on when and how often to shift from one objective function to another during optimization.

The lateen technique can be applied to the multi-metric optimization in SMT by treating the different metrics as different objective functions. While the several lateen variants are also applicable for our task, our objective here is to improve performance across the different metrics (being optimized). Thus, we restrict ourselves to the style where the search alternates between the metrics (in round-robin fashion) at each iteration. Since the notion of convergence is unclear in lateen setting, we stop after a fixed number of iterations optimizing the tuning set. In terms of Figure 1, lateen MMO corresponds to alternately maximizing the metrics along two dimensions as depicted by the solid arrows.

By the very nature of lateen-alternation, the metric score is better.

weights obtained at each iteration are likely to be best for the metric that was optimized in that iteration. Thus, one could use weights from the last k iterations (for lateen-tuning with as many metrics) and then decode the test set with an ensemble of these weights as in PMO ensemble. However in practice we find the weights to converge and we simply use the weights from the final iteration to decode the test set in our lateen experiments.

4.3 Union of Metrics

At each iteration lateen MMO excludes all but one metric for optimization. An alternative would be to consider all the metrics at each iteration so that the optimizer could try to optimize them jointly. This has been the general motivation for considering the linear combination of metrics (Cer et al., 2010; Servan and Schwenk, 2011) resulting in a joint metric, which is then optimized.

However due to the scaling differences between the scores of different metrics, the linear combination might completely suppress the metric having scores in the lower-range. As an example, the RIBES scores that are typically in the high 0.7-0.8 range, dominate the BLEU scores that is typically around 0.3. While the weighted linear combination tries to address this imbalance, they introduce additional parameters that are manually fixed and not separately tuned.

We avoid this linear combination pitfall by taking the union of the metrics under which we consider the union of training examples from all metrics and optimize them jointly. Mathematically,

$$w^* = \arg \max_w g(M_1(H)) \cup \dots \cup g(M_k(H)) \quad (4)$$

Most of the optimization approaches involve two phases: i) select positive and negative examples and ii) optimize parameters to favour positive examples while penalizing negative ones. In the *union* approach, we independently generate positive and negative sets of examples for all the metrics and take their union. The optimizer now seeks to move towards positive examples from all metrics, while penalizing others.

This is similar to the PMO-PRO approach except that here the optimizer tries to simultaneously maximize the number of high scoring points across all

metrics. Thus, instead of the entire Pareto frontier curve in Figure 1, the union approach optimizes the two dimensions simultaneously in each iteration.

5 Ensemble Tuning

These methods, even though novel, under utilize the power of ensembles as they combine the solution only at the end of the tuning process. We would prefer to tightly integrate the idea of ensembles into the tuning. We thus extend the ensemble decoding to *ensemble tuning*. The feature weights are replicated separately for each evaluation metric, which are treated as components in the ensemble decoding and tuned independently in the optimization step. Initially the ensemble decoder decodes a devset using a weighted ensemble to produce a single N-best list. For the optimization, we employ a two-step approach of optimizing the feature weights (of each ensemble component) followed by a step for tuning the meta (component) weights. The optimized weights are then used for decoding the devset in the next iteration and the process is repeated for a fixed number of iterations.

Modifying the MMO representation in Equation 3, we formulate *ensemble tuning* as:

$$H_{ens} = \mathcal{N}_{ens}(\mathbf{f}; \{w_M\}; \otimes; \boldsymbol{\lambda}) \quad (5)$$

$$\mathbf{w}^* = \left\{ \arg \max_{w_{M_i}} H_{ens} \mid 1 \leq i \leq k \right\} \quad (6)$$

$$\boldsymbol{\lambda} = \arg \max_{\lambda} g(\{M_i(H_{ens}) \mid 1 \leq i \leq k\}; \mathbf{w}^*) \quad (7)$$

Here the ensemble decoder function $\mathcal{N}_{ens}(.)$ is parameterized by an ensemble of weights w_{M_1}, \dots, w_{M_k} (denoted as $\{w_M\}$ in Eq 5) for each metric and a mixture operation (\otimes). $\boldsymbol{\lambda}$ represents the weights of the ensemble components.

Pseudo-code for ensemble tuning is shown in Algorithm 2. In the beginning of each iteration (line 2), the tuning process ensemble decodes (line 4) the tuning set using the weights obtained from the previous iteration. Equation 5 gives the detailed expression for the ensemble decoding, where H_{ens} denotes the N-best list generated by the ensemble decoder.

The method now uses a dual tuning strategy involving two phases to optimize the weights. In the first step it optimizes each of the k metrics independently (lines 6-7) along its respective dimension in

Algorithm 2 Ensemble Tuning Algorithm

```

1: Input: Tuning set  $\mathbf{f}$ ,  

   Metrics  $M_1, \dots, M_k$  (ensemble components)  

   Initial weights  $\{w_M\} \leftarrow w_{M_1}, \dots, w_{M_k}$  and  

   Component (meta) weights  $\boldsymbol{\lambda}$   

2: for  $j = 1, \dots$  do  

3:    $\{w_M^{(j)}\} \leftarrow \{w_M\}$   

4:   Ensemble decode the tuning set  

      $H_{ens} = \mathcal{N}_{ens}(\mathbf{f}; \{w_M^{(j)}\}; \otimes; \boldsymbol{\lambda})$   

5:    $\{w_M\} = \{\}$   

6:   for each metric  $M_i \in \{M\}$  do  

7:      $w_{M_i}^* \leftarrow \text{PRO}(H_{ens}, w_{M_i})$       (use PRO)  

8:     Add  $w_{M_i}^*$  to  $\{w_M\}$   

9:    $\boldsymbol{\lambda} \leftarrow \text{PMO-PRO}(H_{ens}, \{w_M\})$       (Alg 1)  

10:  Output: Optimal weights  $\{w_M\}$  and  $\boldsymbol{\lambda}$ 
```

the multi-metric space (as shown by the solid arrows along the two axes in Figure 1). This yields a new set of weights \mathbf{w}^* for the features in each metric.

The second tuning step (line 9) then optimizes the meta weights ($\boldsymbol{\lambda}$) so as to maximize the multi-metric objective along the joint k -dimensional space as shown in Equation 7. This is illustrated by the dashed arrows in the Figure 1. While $g(.)$ could be any function that combines multiple metrics, we use the PMO-PRO algorithm (Alg. 1) for this step.

The main difference between *ensemble tuning* and *PMO ensemble* is that the former is an ensemble model over metrics and the latter is an ensemble model over Pareto solutions. Additionally, PMO ensemble uses the notion of ensembles only for the final decoding after tuning has completed.

5.1 Implementation Notes

All the proposed methods fit naturally within the usual SMT tuning framework. However, some changes are required in the decoder to support ensemble decoding and in the tuning scripts for optimizing with multiple metrics. For ensemble decoding, the decoder should be able to use multiple weight vectors and dynamically combine them according to some desired mixture operation. Note that, unlike Razmara et al. (2012), our approach uses just one model but has different weight vectors for each metric and the required decoder modifications are simpler than full ensemble decoding.

While any of the mixture operations proposed by Razmara et al. (2012) could be used, in this pa-

per we use *log-wsum* – the linear combination of the ensemble components and *log-wmax* – the combination that prefers the locally best component. These are simpler to implement and also performed competitively in their domain adaptation experiments. Unless explicitly noted otherwise, the results presented in Section 6 are based on linear mixture operation *log-wsum*, which empirically performed better than the *log-wmax* for ensemble tuning.

6 Experiments

We evaluate the different methods on Arabic-English translation in single as well as multiple references scenario. Corpus statistics are shown in Table 1. For all the experiments in this paper, we use Kriya, our in-house Hierarchical phrase-based (Chiang, 2007) (Hiero) system, and integrated the required changes for ensemble decoding. Kriya performs comparably to the state of the art in phrase-based and hierarchical phrase-based translation over a wide variety of language pairs and data sets (Sankaran et al., 2012).

We use PRO (Hopkins and May, 2011) for optimizing the feature weights and PMO-PRO (Duh et al., 2012) for optimizing meta weights, wherever applicable. In both cases, we use SVM-Rank (Joachims, 2006) as the optimizer.

We used the default parameter settings for different MT tuning metrics. For METEOR, we tried both METEOR-tune and METEOR-hter settings and found the latter to perform better in BLEU and TER scores, even though the former was marginally better in METEOR³ and RIBES scores. We observed the margin of loss in BLEU and TER to outweigh the gains in METEOR and RIBES and we chose METEOR-hter setting for both optimization and evaluation of all our experiments.

6.1 Evaluation on Tuning Set

Unlike conventional tuning methods, PMO (Duh et al., 2012) was originally evaluated on the tuning set to avoid potential mismatch with the test set. In order to ensure robustness of evaluation, they re-decode the devset using the optimal weights from the last tuning iteration and report the scores on 1-

³This behaviour was also noted by Denkowski and Lavie (2011) in their analysis of Urdu-English system for *tunable metrics* task in WMT11.

best candidates.

Corpus	Training size	Tuning/ test set
ISI corpus	1.1 M	1664/ 1313 (MTA)
		1982/ 987 (ISI)

Table 1: Corpus Statistics (# of sentences) for Arabic-English. MTA (4-refs) and ISI (1-ref).

We follow the same strategy and compare our PMO-ensemble approach with PMO-PRO (denoted P) and a linear combination⁴ (denoted L) baseline. Similar to Duh et al. (2012), we use five different BLEU:RIBES weight settings, viz. (0.0, 1.0), (0.3, 0.7), (0.5, 0.5), (0.7, 0.3) and (1.0, 0.0), marked L1 through L5 or P1 through P5. The Pareto frontier is then computed from 80 points (5 runs and 15 iterations per run) on the devset.

Figure 2(a) shows the Pareto frontier of L and P baselines using BLEU and RIBES as two metrics. The frontier of the P dominates that of L for most part showing that the PMO approach benefits from picking Pareto points during the optimization.

We use the PMO-ensemble approach to combine the optimized weights from the 5 tuning runs and re-decode the devset employing ensemble decoding. This yields the points *LEns* and *PEns* in the plot, which obtain better scores than most of the individual runs of L and P. This ensemble approach of combining the final weights also generalizes to the unseen test set as we show later.

Figure 2(b) plots the change in BLEU during tuning in the multiple references and the single reference scenarios. We show for each baseline method L and P, plots for two different weight settings that obtain high BLEU and RIBES scores. In both datasets, our ensemble tuning approach dominates the curves of the (L and P) baselines. In summary, these results confirm that the ensemble approach achieves results that are competitive with previous MMO methods on the devset Pareto curve. We now provide a more comprehensive evaluation on the test set.

6.2 Evaluation on Test Set

This section contains multi-metric optimization results on the unseen test sets, one test set has multiple references and the other has a single-reference.

⁴Linear combination is a generalized version of the combined (TER-BLEU)/2 metric and its variants.

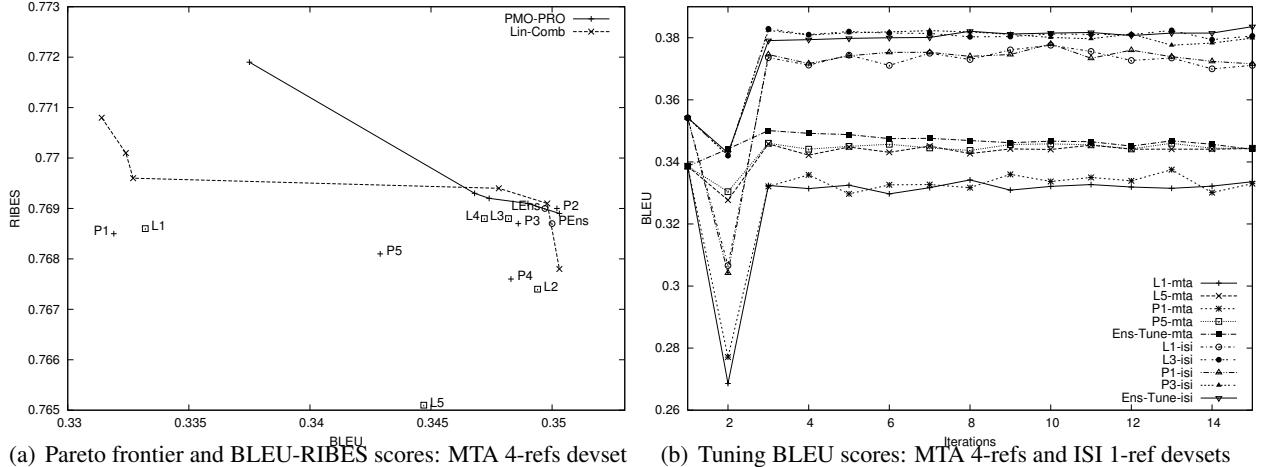

Figure 2: Devset (redecode): Comparison of Lin-comb (L) and PMO-PRO (P) with Ensemble decoding (Lens and PEns) and Ensemble tuning (Ens-Tune)

We plot BLEU scores against other metrics (RIBES, METEOR and TER) and this allows us to compare the performance of each metric relative to the defacto standard BLEU metric.

Baseline points are identified by single letters B for BLEU, T for TER, etc. and the baseline (single-metric optimized) score for each metric is indicated by a dashed line on the corresponding axis. MMO points use a series of single letters referring to the metrics used, e.g. BT for BLEU-TER. The union of metrics method is identified with the suffix 'J' and lateen method with suffix 'L' (thus BT-L refers to the lateen tuning with BLEU-TER). MMO points without any suffix use the ensemble tuning approach.

Figures 3 and 4(a) plot the scores for the MTA test set with 4-references. We see noticeable and some statistically significant improvements in BLEU and RIBES (see Table 2 for BLEU improvements). All our MMO approaches, except for the union method, show gains on both BLEU and RIBES axes. Figures 3(b) and 4(a) show that none of the proposed methods managed to improve the baseline scores for METEOR and TER. However, several of our ensemble tuning combinations work well for both METEOR (BR, BMRTB3, etc.) and TER (BMRT and BRT) in that they improved or were close to the baseline scores in either dimension. We again see in these figures that the MMO approaches can improve the BLEU-only tuning by 0.3 BLEU points, without much drop in other metrics. This is in tune with the finding that BLEU could be tuned easily (Callison-Burch et al., 2011) and also explains why it remains

Approach and Tuning Metric(s)	BLEU	
	MTA	ISI
Single Objective Baselines		
BLEU	36.06	37.20
METEOR	35.05	36.91
RIBES	33.35	36.60
TER	33.92	35.85
Ensemble Tuning: 2 Metrics

B-M-R-T	35.94	36.84
B-M-R-T-B3	36.16	37.12
B-M-R-T-B3-B2-B1	36.08	37.24

Table 2: BLEU Scores on MTA (4 refs) and ISI (1 ref) test sets using the standard *mteval* script. Boldface scores indicate scores that are comparable to or better than the baseline BLEU-only tuning. *Italicized* scores indicate statistically significant differences at p -value 0.05 computed with bootstrap significance test.

a popular choice for optimizing SMT systems.

Among the different MMO methods the ensemble tuning performs better than lateen or union approaches. In terms of the number of metrics being optimized jointly, we see substantial gains when using a small number (typically 2 or 3) of metrics. Results seem to suffer beyond this number; probably because there might not be a space that contain solution(s) optimal for *all* the metrics that are jointly optimized.

We hypothesize that each metric correlates well

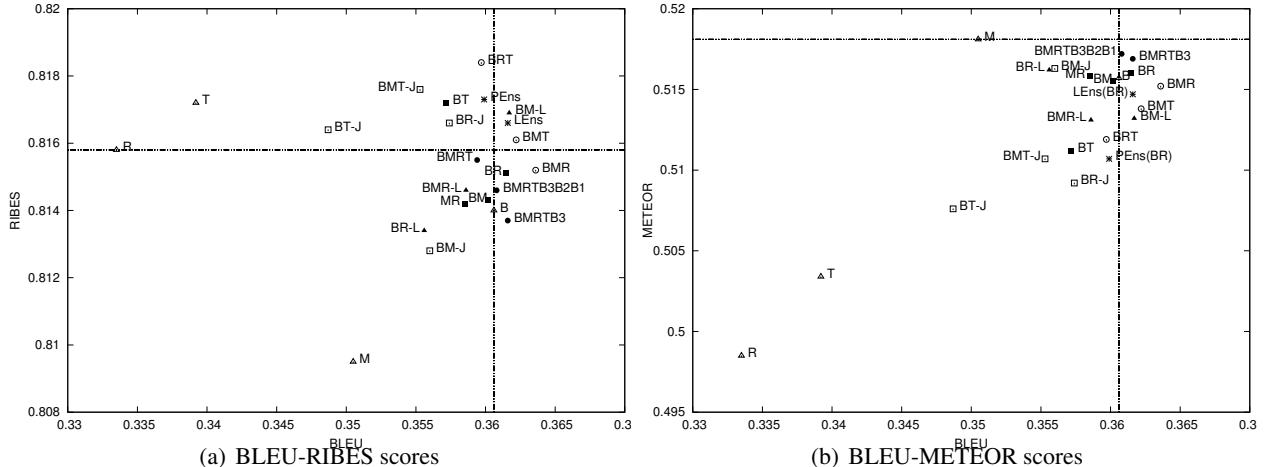

Figure 3: MTA 4-refs testset: Comparison of different MMO approaches. The dashed lines correspond to baseline scores tuned on the respective metrics in the axes. The union of metrics method is identified with the suffix J and lateen with suffix L.

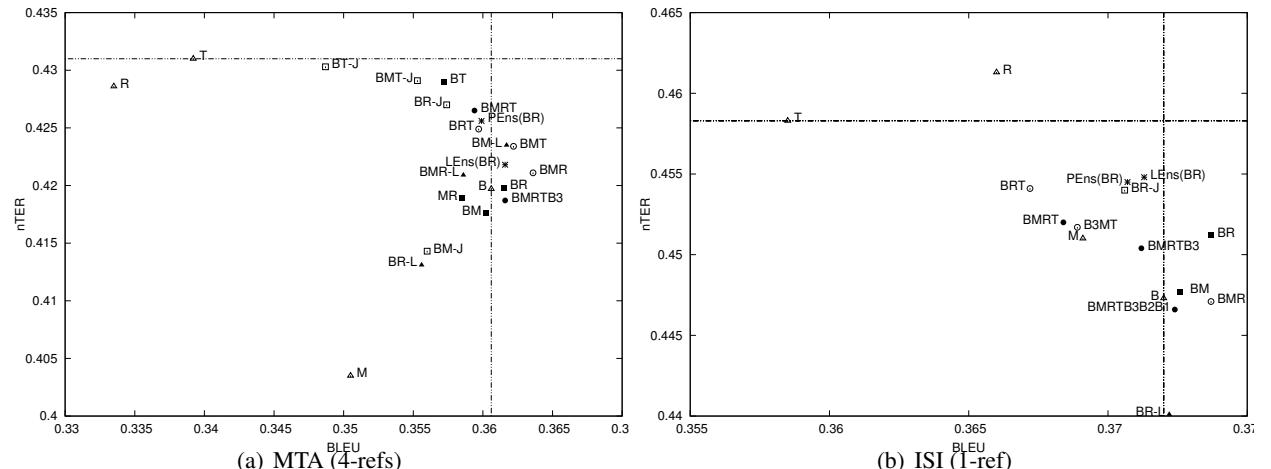

Figure 4: BLEU-TER scores: Comparison of different MMO approaches. We plot nTER (1-TER) scores for easy reading of the plots. The dashed lines correspond to baseline scores tuned on the respective metrics in the axes.

(in a looser sense) with few others, but not all. For example, union optimizations BR-J and BMT-J perform close to or better than RIBES and TER baselines, but get very poor score in METEOR. On the other hand BM-J is close to the METEOR baseline, while doing poorly on the RIBES and TER. This behaviour is also evident from the single-metric baselines, where R and T-only settings are clearly distinguished from the M-only system. It is not clear if such distinct classes of metrics could be bridged by some optimal solution and the *metric dichotomy* requires further study as this is key to practical multi-metric tuning in SMT.

The lateen and union approaches appear to be very sensitive to the number of metrics and they generally perform well for two metrics case and show degradation for more metrics. Unlike other

approaches, the union approach failed to improve over the baseline BLEU and this could be attributed to the conflict of interest among the metrics, while choosing example points for the optimization step. The positive example preferred by a particular metric could be a negative example for the other metric. This would only confuse the optimizer resulting in poor solutions. Our future line of work would be to study the effect of avoiding such of conflicting examples in the union approach.

For the single-reference (ISI) dataset, we only plot the BLEU-TER case in Figure 4(b) due to lack of space. The results are similar to the multiple references set indicating that MMO approaches are equally effective for single references⁵. Table 2

⁵One could argue that MMO methods require multiple references since each metric might be picking out a different ref-

Metric	Single-metric Tuning		Ensemble Tuning
	B-only	M-only	B-M-R
BLEU	37.89	37.18	39.01
HBLEU	51.93	53.59	53.14
METEOR	61.31	61.56	61.68
HMETEOR	72.35	72.39	72.74
TER	0.520	0.532	0.516
HTER	0.361	0.370	0.346

shows the BLEU scores for our ensemble tuning method (for various combinations) and we again see improvements over the baseline BLEU-only tuning.

6.3 Human Evaluation

So far we have shown that multi-metric optimization can improve over single-metric tuning on a single metric like BLEU and we have shown that our methods find a tuned model that performs well with respect to multiple metrics. Is the output that scores higher on multiple metrics actually a better translation? To verify this, we conducted a post-editing human evaluation experiment. We compared our ensemble tuning approach involving BLEU, METEOR and RIBES (B-M-R) with systems optimized for BLEU (B-only) and METEOR (M-only).

We selected 100 random sentences (that are at least 15 words long) from the Arabic-English MTA (4 references) test set and translated them using the three systems (two single metric systems and BMR ensemble tuning). We shuffled the resulting translations and split them into 3 sets such that each set has equal number of the translations from three systems. The translations were edited by three human annotators in a post-editing setup, where the goal was to edit the translations to make them as close to the references as possible, using the Post-Editing Tool: PET (Aziz et al., 2012). The annotators were not Arabic-literate and relied only on the reference translations during post-editing. The identifiers that link each translation to the system that generated it are removed to avoid annotator bias.

In the end we collated post-edited translations for each system and then computed the system-level

reference sentence. Our experiment shows that even with a single reference MMO methods can work.

human-targeted (HBLEU, HMETEOR, HTER) scores, by using respective post-edited translations as the reference. First comparing the HTER (Snover et al., 2006) scores shown in Table 3, we see that the single-metric system optimized for METEOR performs slightly worse than the one optimized for BLEU, despite using METEOR-hter version (Denkowski and Lavie, 2011). Ensemble tuning-based system optimized for three metrics (B-M-R) improves HTER by 4% and 6.3% over BLEU and METEOR optimized systems respectively.

The single-metric system tuned with M-only setting scores high on HBLEU, closely followed by the ensemble system. We believe this to be caused by chance rather than any systematic gains by the M-only tuning; the ensemble system scores high on HMETEOR compared to the M-only system. While HTER captures the edit distance to the targeted reference, HMETEOR and HBLEU metrics capture missing content words or synonyms by exploiting n -grams and paraphrase matching.

We also computed the regular variants (BLEU, METEOR and TER), which are scored against original references. The ensemble system outperformed the single-metric systems in all the three metrics. The improvements were also statistically significant at p -value of 0.05 for BLEU and TER.

7 Conclusion

We propose and present a comprehensive study of several multi-metric optimization (MMO) methods in SMT. First, by exploiting the idea of ensemble decoding (Razmara et al., 2012), we propose an effective way to combine multiple Pareto-optimal model weights from previous MMO methods (e.g. Duh et al. (2012)), obviating the need for manually trading off among metrics. We also proposed two new variants: lateen-style MMO and union of metrics.

We also extended ensemble decoding to a new tuning algorithm called *ensemble tuning*. This method demonstrates statistically significant gains for BLEU and RIBES with modest reduction in METEOR and TER. Further, in our human evaluation, ensemble tuning obtains the best HTER among competing baselines, confirming that optimizing on multiple metrics produces human-preferred translations compared to the conventional optimization approach involving a single metric.

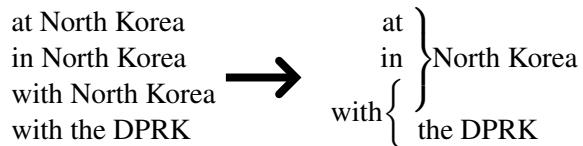

Figure 1: Hypotheses are grouped by common prefixes and suffixes.

Abstract

We propose a new algorithm to approximately extract top-scoring hypotheses from a hypergraph when the score includes an N -gram language model. In the popular cube pruning algorithm, every hypothesis is annotated with boundary words and permitted to recombine only if all boundary words are equal. However, many hypotheses share some, but not all, boundary words. We use these common boundary words to group hypotheses and do so recursively, resulting in a tree of hypotheses. This tree forms the basis for our new search algorithm that iteratively refines groups of boundary words on demand. Machine translation experiments show our algorithm makes translation 1.50 to 3.51 times as fast as with cube pruning in common cases.

1 Introduction

This work presents a new algorithm to search a packed data structure for high-scoring hypotheses when the score includes an N -gram language model. Many natural language processing systems have this sort of problem e.g. hypergraph search in hierarchical and syntactic machine translation (Mi et al., 2008; Klein and Manning, 2001), lattice rescoring in speech recognition, and confusion network decoding in optical character recognition (Tong and Evans, 1996). Large language models have been shown to improve quality, especially in machine translation (Brants et al., 2007; Koehn and Haddow, 2012). However, language models make search computationally expensive because they examine surface words without regard to the structure

of the packed search space. Prior work, including cube pruning (Chiang, 2007), has largely treated the language model as a black box. Our new search algorithm groups hypotheses by common prefixes and suffixes, exploiting the tendency of the language model to score these hypotheses similarly. An example is shown in Figure 1. The result is a substantial improvement over the time-accuracy trade-off presented by cube pruning.

The search spaces mentioned in the previous paragraph are special cases of a directed acyclic hypergraph. As used here, the difference from a normal graph is that an edge can go from one vertex to any number of vertices; this number is the *arity* of the edge. Lattices and confusion networks are hypergraphs in which every edge happens to have arity one. We experiment with parsing-based machine translation, where edges represent grammar rules that may have any number of non-terminals, including zero.

Hypotheses are paths in the hypergraph scored by a linear combination of features. Many features are *additive*: they can be expressed as weights on edges that sum to form hypothesis features. However, log probability from an N -gram language model is non-

additive because it examines surface strings across edge and vertex boundaries. Non-additivity makes search difficult because locally optimal hypotheses may not be globally optimal.

In order to properly compute the language model score, each hypothesis is annotated with its boundary words, collectively referred to as its *state* (Li and Khudanpur, 2008). Hypotheses with equal state may be recombined, so a straightforward dynamic programming approach (Bar-Hillel et al., 1964) simply treats state as an additional dimension in the dynamic programming table. However, this approach quickly becomes intractable for large language models where the number of states is too large.

Beam search (Chiang, 2005; Lowerre, 1976) approximates the straightforward algorithm by remembering a *beam* of up to k hypotheses¹ in each vertex. It visits each vertex in bottom-up order, each time calling a *beam filling algorithm* to select k hypotheses. The parameter k is a time-accuracy trade-off: larger k increases both CPU time and accuracy.

We contribute a new beam filling algorithm that improves the time-accuracy trade-off over the popular cube pruning algorithm (Chiang, 2007) discussed in §2.3. The algorithm is based on the observation that competing hypotheses come from the same input, so their language model states are often similar. Grouping hypotheses by these similar words enables our algorithm to reason over multiple hypotheses at once. The algorithm is fully described in §3.

2 Related Work

2.1 Alternatives to Bottom-Up Search

Beam search visits each vertex in the hypergraph in bottom-up (topological) order. The hypergraph can also be searched in left-to-right order (Watanabe et al., 2006; Huang and Mi, 2010). Alternatively, hypotheses can be generated on demand with cube growing (Huang and Chiang, 2007), though we note that it showed little improvement in Moses (Xu and Koehn, 2012). All of these options are compatible with our algorithm. However, we only experiment with bottom-up beam search.

¹We use K to denote the number of fully-formed hypotheses requested by the user and k to denote beam size.

2.2 Exhaustive Beam Filling

Originally, beam search was used with an exhaustive beam filling algorithm (Chiang, 2005). It generates every possible hypothesis (subject to the beams in previous vertices), selects the top k by score, and discards the remaining hypotheses. This is expensive: just one edge of arity a encodes $O(1 + a^k)$ hypotheses and each edge is evaluated exhaustively. In the worst case, our algorithm is exhaustive and generates the same number of hypotheses as beam search; in practice, we are concerned with the average case.

2.3 Baseline: Cube Pruning

Cube pruning (Chiang, 2007) is a fast approximate beam filling algorithm and our baseline. It chooses k hypotheses by popping them off the top of a priority queue. Initially, the queue is populated with hypotheses made from the best (highest-scoring) parts. These parts are an edge and a hypothesis from each vertex referenced by the edge. When a hypothesis is popped, several next-best alternatives are pushed. These alternatives substitute the next-best edge or a next-best hypothesis from one of the vertices.

Our work follows a similar pattern of popping one queue entry then pushing multiple entries. However, our queue entries are a group of hypotheses while cube pruning’s entries are a single hypothesis.

Hypotheses are usually fully scored before being placed in the priority queue. An alternative prioritizes hypotheses by their *additive score*. The additive score is the edge’s score plus the score of each component hypothesis, ignoring the non-additive aspect of the language model. When the additive score is used, the language model is only called k times, once for each hypothesis popped from the queue.

Cube pruning can produce duplicate queue entries. Gesmundo and Henderson (2010) modified the algorithm prevent duplicates instead of using a hash table. We include their work in the experiments.

Hopkins and Langmead (2009) characterized cube pruning as A* search (Hart et al., 1968) with an inadmissible heuristic. Their analysis showed deep and unbalanced search trees. Our work can be interpreted as a partial rebalancing of these search trees.

2.4 Exact Algorithms

A number of exact search algorithms have been developed. We are not aware of an exact algorithm that tractably scales to the size of hypergraphs and language models used in many modern machine translation systems (Callison-Burch et al., 2012).

The hypergraph and language model can be compiled into an integer linear program. The best hypothesis can then be recovered by taking the dual and solving by Lagrangian relaxation (Rush and Collins, 2011). However, that work only dealt with language models up to order three.

Iglesias et al. (2011) represent the search space as a recursive transition network and the language model as a weighted finite state transducer. Using standard finite state algorithms, they intersect the two automatons then exactly search for the highest-scoring paths. However, the intersected automaton is too large. The authors suggested removing low probability entries from the language model, but this form of pruning negatively impacts translation quality (Moore and Quirk, 2009; Chelba et al., 2010). Their work bears some similarity to our algorithm in that partially overlapping state will be collapsed and efficiently handled together. However, the key advantage to our approach is that groups have a score that can be used for pruning *before* the group is expanded, enabling pruning without first constructing the intersected automaton.

2.5 Coarse-to-Fine

Coarse-to-fine (Petrov et al., 2008) performs multiple pruning passes, each time with more detail. Search is a subroutine of coarse-to-fine and our work is inside search, so the two are compatible. There are several forms of coarse-to-fine search; the closest to our work increases the language model order each iteration. However, by operating inside search, our algorithm is able to handle hypotheses at different levels of refinement and use scores to choose where to further refine hypotheses. Coarse-to-fine decoding cannot do this because it determines the level of refinement before calling search.

3 Our New Beam Filling Algorithm

In our algorithm, the primary idea is to group hypotheses with similar language model state. The

following sections formalize what these groups are (partial state), that the groups have a recursive structure (state tree), how groups are split (bread crumbs), using groups with hypergraph edges (partial edge), prioritizing search (scoring) and best-first search (priority queue).

3.1 Partial State

An N -gram language model (with order N) computes the probability of a word given the $N - 1$ preceding words. The left state of a hypothesis is the first $N - 1$ words, which have insufficient context to be scored. Right state is the last $N - 1$ words; these might become context for another hypothesis. Collectively, they are known as *state*. State minimization (Li and Khudanpur, 2008) may reduce the size of state due to backoff in the language model.

For example, the hypothesis “the few nations that have diplomatic relations with North Korea” might have left state “the few” and right state “Korea” after state minimization determined that “North” could be elided. Collectively, the state is denoted (the few $\dashv \diamond \vdash$ Korea). The diamond \diamond is a stand-in for elided words. Terminators \dashv and \vdash indicate when left and right state are exhausted, respectively².

Our algorithm is based on *partial state*. Partial state is simply state with more inner words elided. For example, (the \diamond Korea) is a partial state for (the few $\dashv \diamond \vdash$ Korea). Terminators \dashv and \vdash can be elided just like words. Empty state is denoted using the customary symbol for empty string, ϵ . For example, ($\epsilon \diamond \epsilon$) is the empty partial state. The terminators serve to distinguish a completed state (which may be short due to state minimization) from an incomplete partial state.

3.2 State Tree

States (the few $\dashv \diamond \vdash$ Korea) and (the $\dashv \diamond \vdash$ Korea) have words in common, so the partial state (the \diamond Korea) can be used to reason over both of them. Generalizing this notion to the set of hypotheses in a beam, we build a *state tree*. The root of the tree is the empty partial state ($\epsilon \diamond \epsilon$) that reasons

²A corner case arises for hypotheses with less than $N - 1$ words. For these hypotheses, we still attempt state minimization and, if successful, the state is treated normally. If state minimization fails, a flag is set in the state. For purposes of the state tree, the flag acts like a different terminator symbol.

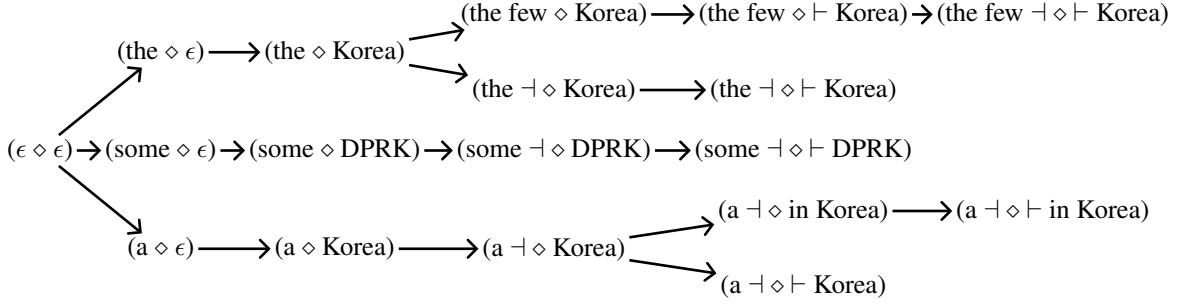

Figure 2: A state tree containing five states: $(\text{the few } \diamond \text{ Korea})$, $(\text{the } \neg \diamond \vdash \text{ Korea})$, $(\text{some } \neg \diamond \vdash \text{ DPRK})$, $(\text{a } \neg \diamond \vdash \text{ in Korea})$, and $(\text{a } \neg \diamond \vdash \text{ Korea})$. Nodes of the tree are partial states. The branching order is the first word, the last word, the second word, and so on. If the left or right state is exhausted, then branching continues with the remaining state. For purposes of branching, termination symbols \neg and \vdash act like normal words.

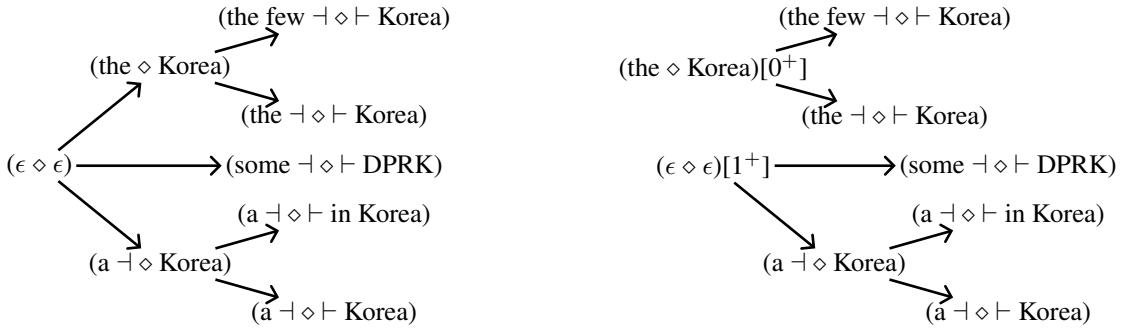

Figure 3: The optimized version of Figure 2. Nodes immediately reveal the longest shared prefix and suffix among hypotheses below them.

over all hypotheses. From the root, the tree branches by the first word of state, the last word, the second word, the second-to-last word, and so on. If left or right state is exhausted, then branching continues using the remaining state. The branching order prioritizes the outermost words because these can be used to update the language model probability. The decision to start with left state is arbitrary. An example tree is shown in Figure 2.

As an optimization, each node determines the longest shared prefix and suffix of the hypotheses below it. The node reports these words immediately, rendering some other nodes redundant. This makes our algorithm faster because it will then only encounter nodes when there is a branching decision to be made. The original tree is shown in Figure 2 and the optimized version is shown in Figure 3. As a side effect of branching by left state first, the algorithm did not notice that states $(\text{the } \diamond \text{ Korea})$ and

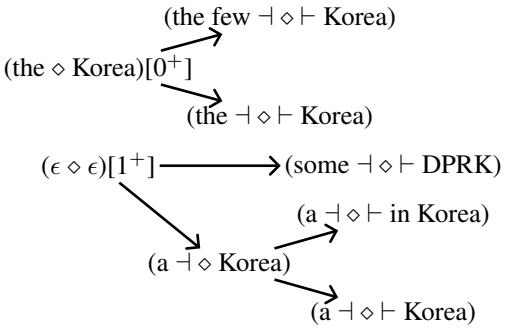

Figure 4: Visiting the root node partitions the tree into best child $(\text{the } \diamond \text{ Korea})[0^+]$ and bread crumb $(\epsilon \diamond \epsilon)[1^+]$. The data structure remains intact for use elsewhere.

$(\text{a } \neg \diamond \text{ Korea})$ both end with Korea. We designed the tree building algorithm for speed and plan to experiment with alternatives as future work.

The state tree is built lazily. A node initially holds a flat array of all the hypotheses below it. When its children are first needed, the hypotheses are grouped by the branching word and an array of child nodes is built. In turn, these newly created children each initially hold an array of hypotheses. CPU time is saved because nodes containing low-scoring nodes may never construct their children.

Each node has a score. For leaves, this score is copied from the underlying hypothesis (or best hypothesis if some other feature prevented recombination). The score of an internal node is the maximum score of its children. As an example, the root node's score is the same as the highest-scoring hypothesis in the tree. Children are sorted by score.

3.3 Bread Crumbs

The state tree is explored in a best-first manner. Specifically, when the algorithm visits a node, it considers that node's best child. The best child reveals more words, so the score may go up or down when the language model is consulted. Therefore, simply following best children may lead to a poor hypothesis. Some backtracking mechanism is required, for which we use bread crumbs. Visiting a node results in two items: the best child and a bread crumb. The bread crumb encodes the node that was visited and how many children have already been considered. Figure 4 shows an example.

More formally, each node has an array of children sorted by score, so it suffices for the bread crumb to keep an index in this array. An index of zero denotes that no child has been visited. Continuing the example from Figure 3, $(\epsilon \diamond \epsilon)[0^+]$ denotes the root partial state with children starting at index 0 (i.e. all of them). Visiting $(\epsilon \diamond \epsilon)[0^+]$ yields best child (the \diamond Korea) $[0^+]$ and bread crumb $(\epsilon \diamond \epsilon)[1^+]$. Later, the search algorithm may return to $(\epsilon \diamond \epsilon)[1^+]$, yielding best child (some $\dashv \diamond \vdash$ DPRK) $[0^+]$ and bread crumb $(\epsilon \diamond \epsilon)[2^+]$. If there is no remaining sibling, visiting yields only the best child.

The index serves to restrict the array of children to those with that index or above. Formally, let d map from a node or bread crumb to the set of leaves descended from it. The descendants of a node n are those of its children

$$d(n) = \bigsqcup_{i=0}^{|n|-1} d(n[i])$$

where \sqcup takes the union of disjoint sets and $n[i]$ is the i th child. In a bread crumb with index c , only descendants by the remaining children are considered

$$d(n[c^+]) = \bigsqcup_{i=c}^{|n|-1} d(n[i])$$

It follows that the set of descendants is *partitioned* into two disjoint sets

$$d(n[c^+]) = d(n[c]) \bigsqcup d(n[c + 1^+])$$

3.4 Partial Edge

The beam filling algorithm is tasked with selecting hypotheses given a number of hypergraph edges. Hypergraph edges are strings comprised of words and references to vertices (in parsing, terminals and non-terminals). A hypergraph edge is converted to a *partial edge* by replacing each vertex reference with the root node from that vertex. For example, the hypergraph edge “is v .” referencing vertex v becomes partial edge “is $(\epsilon \diamond \epsilon)[0^+]$.”

Partial edges allow our algorithm to reason over a large set of hypotheses at once. Visiting a partial edge divides that set into two as follows. A heuristic chooses one of the non-leaf nodes to visit. Currently, this heuristic picks the node with the fewest words revealed. As a tie breaker, it chooses the leftmost node. The chosen node is visited (partitioned), yielding the best child and bread crumb as described in the previous section. These are substituted into separate copies of the partial edge. Continuing our example with the vertex shown in Figure 3, “is $(\epsilon \diamond \epsilon)[0^+]$.” partitions into “is (the \diamond Korea) $[0^+]$.” and “is $(\epsilon \diamond \epsilon)[1^+]$.”

3.5 Scoring

Every partial edge has a score that determines its search priority. Initially, this score is the sum of the edge's score and the scores of each bread crumb (defined below). As words are revealed, the score is updated to account for new language model context.

Each edge score includes a log language model probability and possibly additive features. Whenever there is insufficient context to compute the language model probability of a word, an estimate r is used. For example, edge “is v .” incorporates estimate

$$\log r(\text{is})r(.)$$

into its score. The same applies to hypotheses: (the few $\dashv \diamond \vdash$ Korea) includes estimate

$$\log r(\text{the})r(\text{few} \mid \text{the})$$

because the words in left state are those with insufficient context.

In common practice (Chiang, 2007; Hoang et al., 2009; Dyer et al., 2010), the estimate is taken from the language model: $r = p$. However, querying the language model with incomplete context leads

Kneser-Ney smoothing (Kneser and Ney, 1995) to assume that backoff has occurred. An alternative is to use average-case rest costs explicitly stored in the language model (Heafield et al., 2012). Both options are used in the experiments³.

The score of a bread crumb is the maximum score of its descendants as defined in §3.3. For example, the bread crumb $(\epsilon \diamond \epsilon)[1^+]$ has a lower score than $(\epsilon \diamond \epsilon)[0^+]$ because the best child (the \diamond Korea) $[0^+]$ and its descendants no longer contribute to the maximum.

The score of partial edge “is $(\epsilon \diamond \epsilon)[0^+]$.” is the sum of scores from its two parts: edge “is v .” and bread crumb $(\epsilon \diamond \epsilon)[0^+]$. The edge’s score includes estimated log probability $\log r(\text{is})r(.)$ as explained earlier. The bread crumb’s score comes from its highest-scoring descendent (the few $\dashv \diamond \vdash$ Korea) and therefore includes estimate $\log r(\text{the})r(\text{few} | \text{the})$.

Estimates are updated as words are revealed. Continuing the example, “is $(\epsilon \diamond \epsilon)[0^+]$.” has best child “is (the \diamond Korea) $[0^+]$.” In this best child, the estimate $r(.)$ is updated to $r(. | \text{Korea})$. Similarly, $r(\text{the})$ is replaced with $r(\text{the} | \text{is})$. Updates examine only words that have been revealed: $r(\text{few} | \text{the})$ remains unrevised.

Updates are computed efficiently by using pointers (Heafield et al., 2011) with KenLM. To summarize, the language model computes

$$\frac{r(w_n | w_1^{n-1})}{r(w_n | w_i^{n-1})}$$

in a single call. In the popular reverse trie data structure, the language model visits w_i^n while retrieving w_1^n , so the cost is the same as a single query. Moreover, when the language model earlier provided estimate $r(w_n | w_i^{n-1})$, it also returned a data-structure pointer $t(w_i^n)$. Pointers are retained in hypotheses, edges, and partial edges for each word with an estimated probability. When context is revealed, our algorithm queries the language model with new context w_1^{i-1} and pointer $t(w_i^n)$. The language model uses this pointer to immediately retrieve denominator $r(w_n | w_i^{n-1})$ and as a starting point to retrieve numerator $r(w_n | w_1^{n-1})$. It can therefore avoid looking

³We also tested upper bounds (Huang et al., 2012; Carter et al., 2012) but the result is still approximate due to beam pruning and initial experiments showed degraded performance.

up $r(w_n), r(w_n | w_{n-1}), \dots, r(w_n | w_{i+1}^{n-1})$ as would normally be required with a reverse trie.

3.6 Priority Queue

Our beam filling algorithm is controlled by a priority queue containing partial edges. The queue is populated by converting all outgoing hypergraph edges into partial edges and pushing them onto the queue. After this initialization, the algorithm loops. Each iteration begins by popping the top-scoring partial edge off the queue. If all nodes are leaves, then the partial edge is converted to a hypothesis and placed in the beam. Otherwise, the partial edge is partitioned as described in §3.3. The two resulting partial edges are pushed onto the queue. Looping continues with the next iteration until the queue is empty or the beam is full. After the loop terminates, the beam is given to the root node of the state tree; other nodes will be built lazily as described in §3.2.

Overall, the algorithm visits hypergraph vertices in bottom-up order. Our beam filling algorithm runs in each vertex, making use of state trees in vertices below. The top of the tree contains full hypotheses. If a K -best list is desired, packing and extraction works the same way as with cube pruning.

4 Experiments

Performance is measured by translating the 3003-sentence German-English test set from the 2011 Workshop on Machine Translation (Callison-Burch et al., 2011). Two translation models were built, one hierarchical (Chiang, 2007) and one with target syntax. The target-syntax system is based on English parses from the Collins (1999) parser. Both were trained on Europarl (Koehn, 2005). The language model interpolates models built on Europarl, news commentary, and news data provided by the evaluation. Interpolation weights were tuned on the 2010 test set. Language models were built with SRILM (Stolcke, 2002), modified Kneser-Ney smoothing (Kneser and Ney, 1995; Chen and Goodman, 1998), default pruning, and order 5. Feature weights were tuned with MERT (Och, 2003), beam size 1000, 100-best output, and cube pruning. Systems were built with the Moses (Hoang et al., 2009) pipeline.

Measurements were collected by running the decoder on all 3003 sentences. For consistency, all

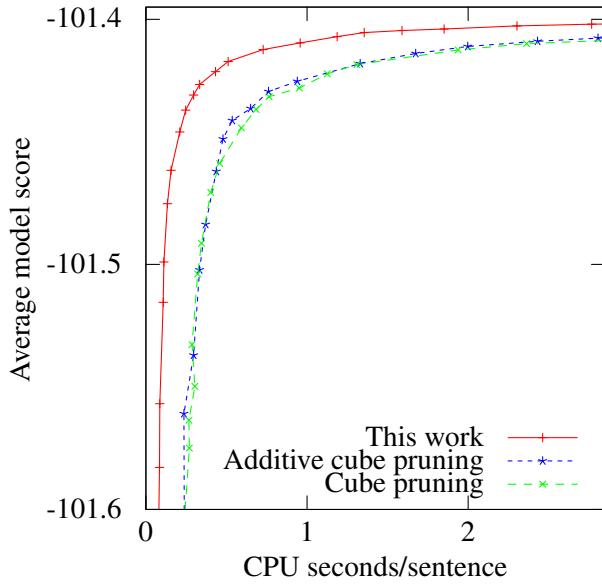

Figure 5: Hierarchical system in Moses with our algorithm, cube pruning with additive scores, and cube pruning with full scores (§2.3). The two baselines overlap.

relevant files were forced into the operating system disk cache before each run. CPU time is the total user and system time taken by the decoder minus loading time. Loading time was measured by running the decoder with empty input. In particular, CPU time includes the cost of parsing. Our test system has 32 cores and 64 GB of RAM; no run came close to running out of memory. While multi-threaded experiments showed improvements as well, we only report single-threaded results to reduce noise and to compare with cdec (Dyer et al., 2010). Decoders were compiled with the optimization settings suggested in their documentation.

Search accuracy is measured by average model score; higher is better. Only relative comparisons are meaningful because model scores have arbitrary scale and include constant factors. Beam sizes start at 5 and rise until a time limit determined by running the slowest algorithm with beam size 1000.

4.1 Comparison Inside Moses

Figure 5 shows Moses performance with this work and with cube pruning. These results used the hierarchical system with common-practice estimates (§3.5). The two cube pruning variants are explained in §2.3. Briefly, the queue can be prioritized using

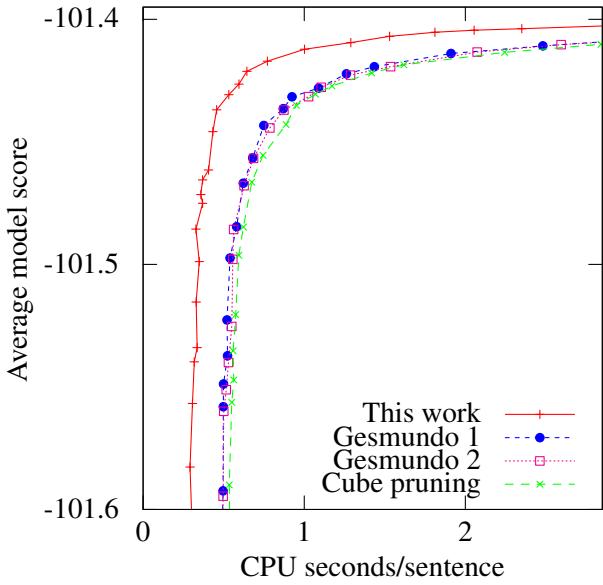

Figure 6: Hierarchical system in cdec with our algorithm, similarly-performing variants of cube pruning defined in Gesmundo and Henderson (2010), and the default.

additive or full scores. Performance with additive scores is roughly the same as using full scores with half the beam size.

Our algorithm is faster for every beam size tested. It is also more accurate than additive cube pruning with the same beam size. However, when compared with full scores cube pruning, it is less accurate for beam sizes below 300. This makes sense because our algorithm starts with additive estimates and iteratively refines them by calling the language model. Moreover, when beams are small, there are fewer chances to group hypotheses. With beams larger than 300, our algorithm can group more hypotheses, overtaking both forms of cube pruning.

Accuracy improvements can be interpreted as speed improvements by asking how much time each algorithm takes to achieve a set level of accuracy. By this metric, our algorithm is 2.04 to 3.37 times as fast as both baselines.

4.2 Comparison Inside cdec

We also implemented our algorithm in cdec (Dyer et al., 2010). Figure 6 compares with two enhanced versions of cube pruning (Gesmundo and Henderson, 2010) and the cdec baseline. The model scores

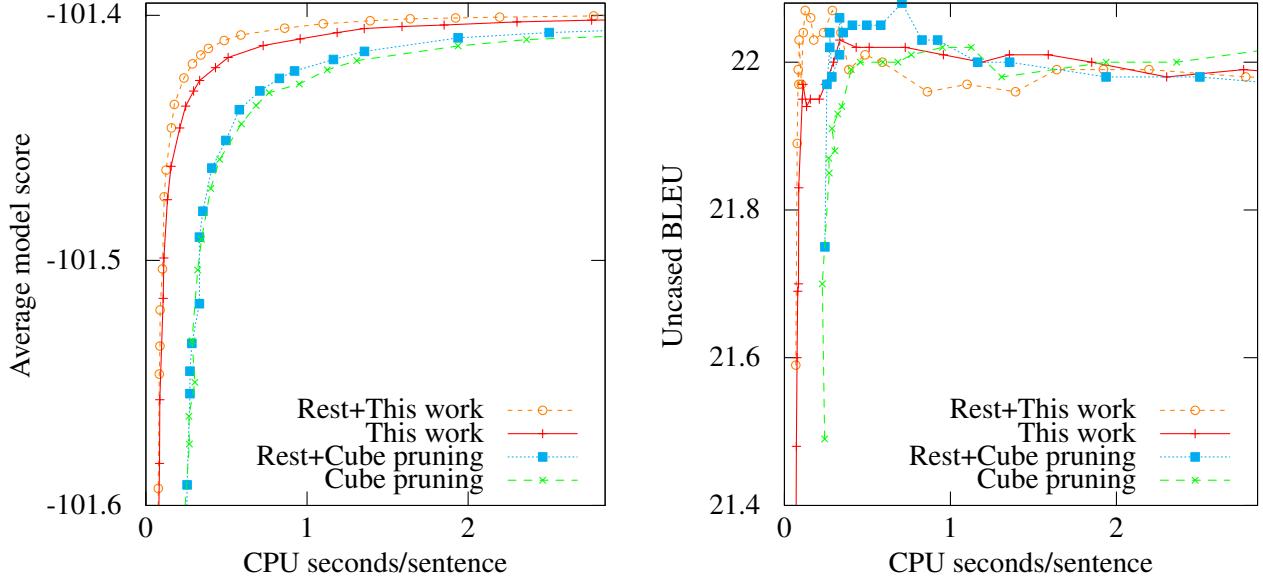

Figure 7: Effect of rest costs on our algorithm and on cube pruning in Moses. Noisy BLEU scores reflect model errors.

are comparable with Moses⁴.

Measuring at equal accuracy, our algorithm makes cdec 1.56 to 2.24 times as fast as the best baseline. At first, this seems to suggest that cdec is faster. In fact, the opposite is true: comparing Figures 5 and 6 reveals that cdec has a higher parsing cost than Moses⁵, thereby biasing the speed ratio towards 1. In subsequent experiments, we use Moses because it more accurately reflects search costs.

4.3 Average-Case Rest Costs

Previous experiments used the common-practice probability estimate described in §3.5. Figure 7 shows the impact of average-case rest costs on our algorithm and on cube pruning in Moses. We also looked at uncased BLEU (Papineni et al., 2002) scores, finding that our algorithm attains near-peak BLEU in less time. The relationship between model score and BLEU is noisy due to model errors.

⁴The glue rule builds hypotheses left-to-right. In Moses, glued hypotheses start with $\langle s \rangle$ and thus have empty left state. In cdec, sentence boundary tokens are normally added last, so intermediate hypotheses have spurious left state. Running cdec with the Moses glue rule led to improved time-accuracy performance. The improved version is used in all results reported. We accounted for constant-factor differences in feature definition i.e. whether $\langle s \rangle$ is part of the word count.

⁵In-memory phrase tables were used with both decoders. The on-disk phrase table makes Moses slower than cdec.

Average-case rest costs impact our algorithm more than they impact cube pruning. For small beam sizes, our algorithm becomes more accurate, mostly eliminating the disadvantage reported in §4.1. Compared to the common-practice estimate with beam size 1000, rest costs made our algorithm 1.62 times as fast and cube pruning 1.22 times as fast.

Table 1 compares our best result with the best baseline: our algorithm and cube pruning, both with rest costs inside Moses. In this scenario, our algorithm is 2.59 to 3.51 times as fast as cube pruning.

4.4 Target-Syntax

We took the best baseline and best result from previous experiments (Moses with rest costs) and ran the target-syntax system. Results are shown in Figure 8. Parsing and search are far more expensive. For beam size 5, our algorithm attains equivalent accuracy 1.16 times as fast. Above 5, our algorithm is 1.50 to 2.00 times as fast as cube pruning. Moreover, our algorithm took less time with beam size 6900 than cube pruning took with beam size 1000.

A small bump in model score occurs around 15 seconds. This is due to translating “durchzogenen” as “criss-crossed” instead of passing it through, which incurs a severe penalty (-100). The only rule capable of doing so translates “X durchzogenen” as “criss-crossed PP”; a direct translation rule was not

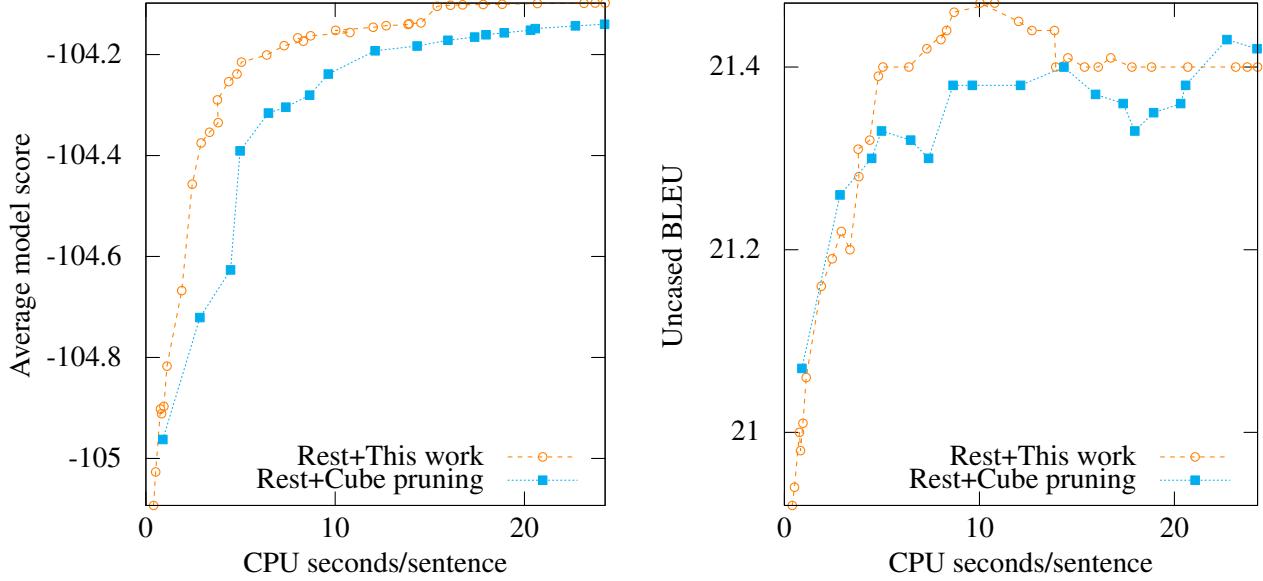

Figure 8: Performance of Moses with the target-syntax system.

extracted due to reordering. An appropriate prepositional phrase (PP) was pruned with smaller beam sizes because it is disfluent.

4.5 Memory

Peak virtual memory usage was measured before each process terminated. Compared with cube pruning at a beam size of 1000, our algorithm uses 160 MB more RAM in Moses and 298 MB less RAM in cdec. The differences are smaller with lower beam sizes and minor relative to 12-13 GB total size, most of which is the phrase table and language model.

k	Rest+This work		Rest+Cube pruning			
	CPU	Model BLEU	CPU	Model BLEU		
5	0.068	-1.698	21.59	0.243	-1.667	21.75
10	0.076	-1.593	21.89	0.255	-1.592	21.97
50	0.125	-1.463	22.07	0.353	-1.480	22.04

Table 1: Numerical results from the hierarchical system for select beam sizes k comparing our best result with the best baseline, both in Moses with rest costs enabled. To conserve space, model scores are shown with 100 added.

5 Conclusion

We have described a new search algorithm that achieves equivalent accuracy 1.16 to 3.51 times as fast as cube pruning, including two implementations and four variants. The algorithm is based on grouping similar language model feature states together and dynamically expanding these groups. In doing so, it exploits the language model’s ability to estimate with incomplete information. Our implementation is available under the LGPL as a stand-alone from <http://kheafield.com/code/> and distributed with Moses and cdec.

Abstract

The dominant yet ageing IBM and HMM word alignment models underpin most popular Statistical Machine Translation implementations in use today. Though beset by the limitations of implausible independence assumptions, intractable optimisation problems, and an excess of tunable parameters, these models provide a scalable and reliable starting point for inducing translation systems. In this paper we build upon this venerable base by recasting these models in the non-parametric Bayesian framework. By replacing the categorical distributions at their core with hierarchical Pitman-Yor processes, and through the use of collapsed Gibbs sampling, we provide a more flexible formulation and sidestep the original heuristic optimisation techniques. The resulting models are highly extendible, naturally permitting the introduction of phrasal dependencies. We present extensive experimental results showing improvements in both AER and BLEU when benchmarked against Giza++, including significant improvements over IBM model 4.

1 Introduction

The IBM and HMM word alignment models (Brown et al., 1993; Vogel et al., 1996) have underpinned the majority of statistical machine translation systems for almost twenty years. The key attraction of these models is their principled probabilistic formulation, and the existence of (mostly) tractable algorithms for their training.

The dominant Giza++ implementation of the IBM models (Och and Ney, 2003) employs a variety of exact and approximate EM algorithms to optimise categorical alignment distributions. While effective, this parametric approach results in a significant number of parameters to be tuned and intractable summations over the space of alignments for models 3 and 4. Giza++ hides the hyperparameters with defaults and approximates the intractable expectations using restricted alignment neighbourhoods. However this approach was shown to often return alignments with probabilities well below the true maxima (Ravi and Knight, 2010).

To overcome perceived limitations with the word based and non-syntactic nature of the IBM models many alternative approaches to word alignment have been proposed (e.g. (DeNero et al., 2008; Cohn and Blunsom, 2009; Levenberg et al., 2012)). While interesting results have been reported, these alternatives have failed to dislodge the IBM approach.

In this paper we proposed to retain the original generative stories of the IBM models, while replacing the inflexible categorical distributions with hierarchical Pitman-Yor (PY) processes – a mathematical tool which has been successfully applied to a range of language tasks (Teh, 2006b; Goldwater et al., 2006; Blunsom and Cohn, 2011). In the context of language modelling, the hierarchical PY process was shown to roughly correspond to interpolated Kneser-Ney (Kneser and Ney, 1995; Teh, 2006a). The key contribution of the hierarchical PY formulation is that it provides a principle probabilistic framework that easily extends to latent variable models, such as those used

for alignment, for which a Kneser-Ney formulation is unclear. While Bayesian priors have previously been applied to IBM model 1 (Riley and Gildea, 2012), in this work we go considerably further by implementing non-parametric priors for the full Giza++ training pipeline.

Inference for the proposed models and their hyper-parameters is done with Gibbs sampling. This eliminates the intractable summations over alignments and the need for tuning hyper-parameters. Further, we exploit the highly extendible nature of the hierarchical PY process to implement improvements to the original models such as the introduction of phrasal dependencies.

We present extensive experimental results showing improvements in both BLEU scores and AER when compared to Giza++. The demonstrated improvements over IBM model 4 suggest that the heuristics used in the implementation of the EM algorithm for this model were suboptimal.

We begin with a formal presentation of the hierarchical PY process used in our Bayesian approach to replace the original categorical distributions. Section 3 introduces our Bayesian formulation of the word alignment models, while its inference scheme is presented in the following section. Finally, the experimental results evaluating our models against the originals are given in section 5, demonstrating the superiority of the non-parametric approach.

2 The hierarchical PY process

Before giving the formal definition for the hierarchical Pitman-Yor (PY) process, we first give some intuition into how this distribution works and why it is commonly used to model problems in natural language.

The hierarchical PY process is an atomic distribution that can share its atoms between different levels in a hierarchy. When used for language modelling it captures the probability of observing a word after any given sequence of n words. It does so by interpolating the observed frequency of the whole sequence followed by the word of interest, with the observed frequency of a shorter sequence followed by the word of interest. This interpolation is done in such a way that tokens in a more specific distribution are interpolated with types in a less specific one.

If there is sufficient evidence for the whole word sequence, i.e. it is not sparse in the corpus, higher weight will be given to the frequency of the word of interest after the more specific sequence than the shorter one. If the sequence was not observed frequently and there is not enough information to model whether the word of interest follows after it frequently or not, the process will back-off to the shorter sequence and assign higher weight to its frequency instead. This is done in a recursive fashion, decreasing the sequence length by one every time until the probability is interpolated with the uniform distribution, much like interpolated Kneser-Ney, the state of the art for language modelling.

Unlike Kneser-Ney, the hierarchical PY approach naturally extends to model complicated conditional distributions involving latent variables. Moreover, almost all instances of priors with categorical distributions can be replaced by the PY process, where in its most basic representation (with no conditional) it provides a flexible model of power law frequencies.

The PY process generalises a number of simpler distributions. The Dirichlet distribution is a distribution over discrete probability mass functions of a certain given length which is often used to model prior beliefs on parameter sparsity in machine learning problems. The Dirichlet process generalises the Dirichlet distribution to a distribution over infinite sequences of non-negative reals that sum to one and is often used for nonparametric Bayesian inference. The PY process is used in the context of natural language processing as it further generalises the Dirichlet process by adding an additional degree of freedom that enables it to produce power-law discrete probability mass functions that resemble those seen experimentally in corpora (Goldwater et al., 2006).

Formally, draws from the PY process $G_1 \sim PY(d, \theta, G_0)$ with a discount parameter $0 \leq d < 1$, a strength parameter $\theta > -d$, and a base distribution G_0 , are constructed using a Chinese restaurant process analogy as follows:

$$X_{n+1}|X_1, \dots, X_n \sim \sum_{k=1}^K \frac{m_k - d}{\theta + n} \delta_{y_k} + \frac{\theta + dK}{\theta + n} G_0$$

Where m_k denotes the number of X_i s (customers) assigned to y_k (a table) and K is the total number of y_k s drawn from G_0 .

Hierarchical PY processes (Teh, 2006b), PY processes where the base distribution is itself a PY process, were developed as an extension which is often used in the context of natural language processing due to their relationship to back-off smoothing. Denoting a context of atoms \mathbf{u} as $(w_{i-l}, \dots, w_{i-1})$, the hierarchical PY process is defined using the above definition of the PY process by:

$$\begin{aligned} w_i &\sim G_{\mathbf{u}} \\ G_{\mathbf{u}} &\sim PY(d_{|\mathbf{u}|}, \theta_{|\mathbf{u}|}, G_{\pi(\mathbf{u})}) \\ &\dots \\ G_{(w_{i-1})} &\sim PY(d_1, \theta_1, G_{\emptyset}) \\ G_{\emptyset} &\sim PY(d_0, \theta_0, G_0) \end{aligned}$$

where $\pi(\mathbf{u}) = (w_{i-l+1}, \dots, w_{i-1})$ is the suffix of \mathbf{u} , $|\mathbf{u}|$ denotes the length of context \mathbf{u} , and G_0 is a base distribution.

3 A Bayesian approach to word alignment

In this work we replace the categorical distributions at the heart of statistical alignment models with PY processes. We start by describing the revised models for IBM model 1 and the HMM alignment model, before continuing to the more advanced IBM models 3 and 4. Throughout this section, we assume that the base distributions in our models (denoted G_0, H_0 , etc.) are uniform over all atoms, and omit the strength and concentration parameters of the PY process for clarity. We use subscripts to denote the hierarchy, and lower-case superscripts to denote a fixed condition (for example, G_0^m is the (uniform) base distribution that is determined uniquely for each possible foreign sentence length m).

3.1 Model 1 and the HMM alignment model

The most basic word alignment model, IBM model 1, can be described using the following generative process (Brown et al., 1993): Given an English sentence $E = e_1, \dots, e_l$, first choose a length m for the foreign sentence F . Next, choose a vector of random word positions from the English sentence $A = a_1, \dots, a_m$ to be the alignment, and then for each foreign word f_i choose a translation from the English word e_{a_i} aligned to it by A . The existence of a NULL word at the beginning of the English sentence is assumed, a word to which spurious words in

the foreign sentence can align. From this generative process the following probability model is derived:

$$P(F, A|E) = p(m|l) \times \prod_{i=1}^m p(a_i|m) p(f_i|e_{a_i})$$

Where $p(a_i) = \frac{1}{l+1}$ is uniform over all alignments and $p(f_i|e_{a_i}) \sim Categorical$.

In our approach we model these distributions using hierarchical PY processes instead of the categorical distributions. Thus we place the following assumptions on IBM model 1:

$$\begin{aligned} a_i|m &\sim G_0^m \\ f_i|e_{a_i} &\sim H_{e_{a_i}} \\ H_{e_{a_i}} &\sim PY(H_{\emptyset}) \\ H_{\emptyset} &\sim PY(H_0) \end{aligned}$$

In this probability modelling we assume that the alignment positions are determined using the uniform distribution, and that word translations are generated depending on the source word – the probability of translating to a specific foreign word depends on the observed frequency of pairs of the foreign word and the given source word. We back-off to the frequencies of the foreign words when the source word wasn't observed frequently.

The HMM alignment model uses the Hidden Markov Model to find word alignments. It treats the translations of the words of the English sentence as observables and the alignment positions as the latent variables to be discovered. Its generative process can be described in an abstract way as follows: we determine the length of the foreign sentence and then iterate over the words of the source sentence emitting translations for each word to fill-in the words in the foreign sentence from left to right.

The following probability model is derived for the HMM alignment model (Vogel et al., 1996):

$$\begin{aligned} P(F, A|E) = & \\ p(m|l) \times \prod_{i=1}^m & p(a_i|a_{i-1}, m) \times p(f_i|e_{a_i}) \end{aligned}$$

For the HMM alignment model we replace the categorical translation distribution $p(f_i|e_{a_i})$ with the same one we used for model 1, and

replace the categorical distribution for the transition $p(a_i|a_{i-1}, m)$ with a hierarchical PY process with a longer sequence of alignment positions in the conditional:

$$\begin{aligned} a_i|a_{i-1}, m &\sim G_{a_{i-1}}^m \\ G_{a_{i-1}}^m &\sim PY(G_\emptyset^m) \\ G_\emptyset^m &\sim PY(G_0^m) \end{aligned}$$

We use a unique distribution for each foreign sentence length, and condition the position on the previous alignment position, backing-off to the HMM's stationary distribution over alignment positions.

3.2 Models 3 and 4

IBM models 3 and 4 introduce the concept of a word's fertility, the number of foreign words that are generated from a specific English word. These models can be described using the following generative process. Given an English sentence E , first determine the length of the foreign sentence: for each word in the English sentence e_i choose a fertility, denoted ϕ_i . Every time a word is generated, an additional spurious word from the NULL word in the English sentence can be generated with a fixed probability. After the foreign sentence length is determined translate each English word into its foreign equivalent (including the NULL word) in the same way as for model 1. Finally, non-spurious words are rearranged into the final word positions and the spurious words inserted into the empty positions. In model 3 this is done with a zero order HMM, and in model 4 with two first order HMMs. One controls the distortion of the head of each English word (the first foreign word generated from it) relative to the centre (denoted here \odot) of the set of foreign words generated from the previous English word, and the other controls the distortion within the set itself by conditioning the word position on the previous word position.

For the probability model, we follow the notation of Och and Ney (2003) and define the alignment as a function from the source sentence positions i to $B_i \subset \{1, \dots, m\}$ where the B_i 's form a partition of the set $\{1, \dots, m\}$. The fertility of the English word i is $\phi_i = |B_i|$, and we use $B_{i,k}$ to refer to the k th element of B_i in ascending order.

Using the above notation, the following probability model is derived (Och and Ney, 2003):

$$\begin{aligned} P(F, A|E) = & p(B_0|B_1, \dots, B_l) \times \prod_{i=1}^l p(B_i|B_{i-1}, e_i) \\ & \times \prod_{i=0}^l \prod_{j \in B_i} p(f_j|e_i) \end{aligned}$$

For model 3 the dependence on previous alignment sets is ignored and the probability $p(B_i|B_{i-1}, e_i)$ is modelled as

$$p(B_i|B_{i-1}, e_i) = p(\phi_i|e_i) \phi_i! \prod_{j \in B_i} p(j|i, m),$$

whereas in model 4 it is modelled using two HMMs:

$$\begin{aligned} p(B_i|B_{i-1}, e_i) = & p(\phi_i|e_i) \times p_{=1}(B_{i,1} - \odot(B_{i-1})|\cdot) \\ & \times \prod_{k=2}^{\phi_i} p_{>1}(B_{i,k} - B_{i,k-1}|\cdot) \end{aligned}$$

For both these models the spurious word generation is controlled by a binomial distribution:

$$p(B_0|B_1, \dots, B_l) = \binom{m - \phi_0}{\phi_0} (1 - p_0)^{m - 2\phi_0} p_1^{\phi_0} \frac{1}{\phi_0!}$$

for some parameters p_0 and p_1 .

Replacing the categorical priors with hierarchical PY process ones, we set the translation and fertility probabilities $p(\phi_i|e_i) \prod_{j \in B_i} p(f_j|e_i)$ using a common prior that generates translation sequences:

$$\begin{aligned} (f^1, \dots, f^{\phi_i})|e_i &\sim H_{e_i} \\ H_{e_i} &\sim PY(H_{e_i}^{FT}) \\ H_{e_i}^{FT}((f^1, \dots, f^{\phi_i})) &= H_{e_i}^F(\phi_i) \prod_j H_{(f^{j-1}, e_i)}^T(f^j) \\ H_{e_i}^F &\sim PY(H_{\emptyset}^F) & H_{(f^{j-1}, e_i)}^T &\sim PY(H_{e_i}^T) \\ H_{\emptyset}^F &\sim PY(H_0^F) & H_{e_i}^T &\sim PY(H_{\emptyset}^T) \\ H_{\emptyset}^T &\sim PY(H_0^T) & H_{\emptyset}^T &\sim PY(H_0^T) \end{aligned}$$

Here we used superscripts for the indexing of words which do not have to occur sequentially in the sentence. We generate sequences instead of individual words and fertilities, and fall-back onto these only in sparse cases. For example, when aligning the English sentence "I don't speak French" to its

French translation “Je ne parle pas français”, the word “not” will generate the phrase (“ne”, “pas”), which will later on be distorted into its place around the verb.

The distortion probability for model 3, $p(j|i, m)$, is modelled simply as depending on the position of the source word i and its class:

$$\begin{aligned} j|(C(e_i), i), m &\sim G_{(C(e_i), i)}^m \\ G_{(C(e_i), i)}^m &\sim PY(G_i^m) \\ G_i^m &\sim PY(G_\emptyset^m) \\ G_\emptyset^m &\sim PY(G_0^m) \end{aligned}$$

where we back-off to the source word position and then to the frequencies of the alignment positions.

As opposed to this simple mechanism, in the distortion probability for IBM model 4 there exist two distinct probability distributions. The first probability distribution $p_{=1}$ controls the head distortion:

$$\begin{aligned} B_{i,1} - \odot(B_{i-1}) | (C(e_i), C(f_{B_{i,1}})), m \\ &\sim G_{(C(e_i), C(f_{B_{i,1}}))}^m \\ G_{(C(e_i), C(f_{B_{i,1}}))}^m &\sim PY(G_{C(f_{B_{i,1}})}^m) \\ G_{C(f_{B_{i,1}})}^m &\sim PY(G_\emptyset^m) \\ G_\emptyset^m &\sim PY(G_0^m) \end{aligned}$$

In this probability modelling we model the jump size itself, as depending on the word class for the source word and the word class for the proposed foreign word, backing-off to the proposed foreign word class and then to the relative jump frequencies.

The second probability distribution $p_{>1}$ controls the distortion within the set of words:

$$\begin{aligned} B_{i,j} - B_{i,j-1} | C(f_{B_{i,j}}), m &\sim H_{C(f_{B_{i,j}})}^m \\ H_{C(f_{B_{i,j}})}^m &\sim PY(H_\emptyset^m) \\ H_\emptyset^m &\sim PY(H_0^m) \end{aligned}$$

Here we again model the jump size as depending on the word class for the proposed foreign word, backing-off to the relative jump frequencies.

Lastly, we add to this probability model a treatment for fertility and translation of NULL words. The fertility generation follows the idea of the original model, where the number of spurious words is

determined by a binomial distribution created from a set of Bernoulli experiments, each one performed after the translation of a non-spurious word. We use an indicator function I to signal whether a spurious word was generated after a non-spurious word ($I = 1$) or not ($I = 0$).

$$\begin{aligned} I = 0, 1 | l &\sim H_l^{NF} \\ H_l^{NF} &\sim PY(H_\emptyset^{NF}) \\ H_\emptyset^{NF} &\sim PY(H_0^{NF}) \end{aligned}$$

Then, the translation of spurious words is done in a straightforward manner:

$$\begin{aligned} f_i &\sim H_\emptyset^{NT} \\ H_\emptyset^{NT} &\sim PY(H_0^{NT}) \end{aligned}$$

4 Inference

The Gibbs sampling inference scheme together with the Chinese Restaurant Franchise process (Teh and Jordan, 2009) are used to induce alignments for a parallel corpus. A set of restaurants \mathcal{S} is constructed and initialised either randomly or through a pipeline of alignment results from simpler models, and then at each iteration each alignment position is removed from the restaurants and re-sampled, conditioned on the rest of the alignment positions.

Denoting $\mathbf{e}, \mathbf{f}, \mathbf{a}$ the sets of all source sentences, their translations, and their corresponding alignments in our corpus, and denoting E, F, A a specific source sentence, its translation, and their corresponding alignment, where e_i is the i 'th word of the source sentence and f_j, a_j are the j 'th word in the foreign sentence and its alignment into the source sentence, we sample a new value for a_j using the univariate conditional distribution:

$$\begin{aligned} P(a_j = i | E, F, A_{-j}, \mathbf{e}_{-E}, \mathbf{f}_{-F}, \mathbf{a}_{-A}, \mathcal{S}_{-a_j}) \\ \propto P(F, (A_{-j}, a_j = i) | E, \mathbf{e}_{-E}, \mathbf{f}_{-F}, \mathbf{a}_{-A}, \mathcal{S}_{-a_j}) \end{aligned}$$

Where a minus sign in the subscript denotes the structure without the mentioned element, and \mathcal{S}_{-a_j} denotes the configuration of the restaurants after removing the alignment a_j .

This univariate conditional distribution is proportional to the probability assigned by the different models to an alignment sequence, where the restaurants replace the counts of the alignment positions

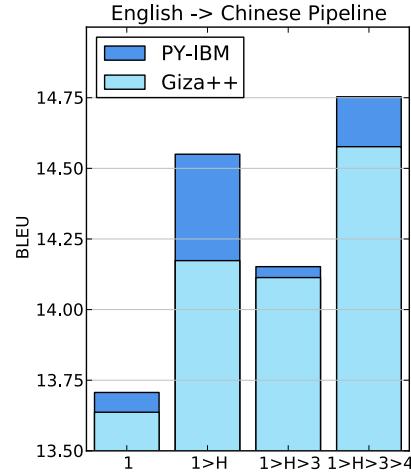

Figure 2: BLEU scores of pipelined Giza++ and pipelined PY-IBM translating from English into Chinese

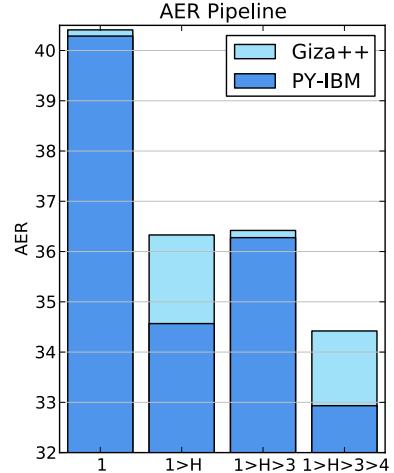

Figure 3: AER of pipelined Giza++ and pipelined PY-IBM aligning Chinese and English

in the prior. Maximum marginal decoding (Johnson and Goldwater, 2009) can then be used to get the MAP estimate of the probability distributions over the alignment positions for each sentence from the samples extracted from the Gibbs sampler.

In addition to sampling the alignments, we also place a uniform Beta prior on the discount parameters and a vague Gamma prior on the strength parameters, and sample them using slice sampling (Neal, 2003). The end result is that the alignment models have no free parameters to tune.

5 Experimental results

In order to assess our PY process alignment models (referred to as PY-IBM henceforth) several experiments were carried out to benchmark them against the original models (as implemented in Giza++). We evaluated the BLEU scores (Papineni et al., 2002) of translations from Chinese into English and from English into Chinese, as well as the alignment error rates (AER) of the induced symmetrised alignments compared to a human aligned dataset. Moses (Koehn et al., 2007) was used for the training of the SMT system and the symmetrisation (using the grow-diag-final procedure), with MERT (Och, 2003) used for tuning of the weights, and SRILM (Stolcke, 2002) to build the language model (5-grams based). The corpus used for training and evaluation was the Chinese

FBIS corpus. MT02 was used for tuning, and MT03 was used for evaluation. In each case we used one reference sentence in Chinese and 4 reference sentences in English.

Most translation systems rely on the Giza++ package in which the implementation of the original models is done by combining them in a pipeline. Model 1 and the HMM alignment model are run sequentially each for 5 iterations; then models 3 and 4 are run sequentially for 3 iterations each. This follows the observation of Och and Ney (2003) that bootstrapping from previous results assists the fertility algorithms find the best alignment neighbourhood in order to estimate the expectations.

We assessed the proposed models against the original models in a pipeline experiment where both systems were trained on a corpus starting at model 1, and used the results of the previous run to initialise the next one – noting the BLEU scores and AER at each step. The Gibbs samplers for the pipelined PY-IBM models were run for 50 iterations for each model and started accumulating samples after a burn-in period of 10 iterations, each experiment was repeated three times and the results averaged. As can be seen in figures 1 to 3, the pipelined PY-IBM models achieved higher BLEU scores across all steps, with the highest improvement of 1.6 percentage points in the pipelined HMM alignment models when translating

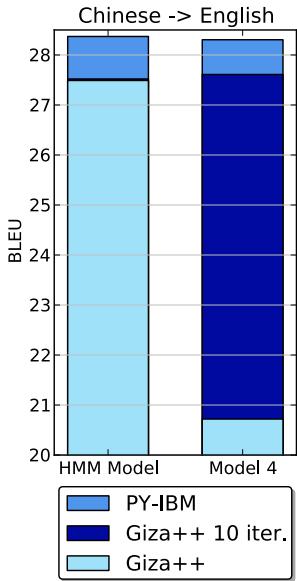

Figure 4: BLEU scores of Giza++’s and PY-IBM’s HMM model and model 4 translating from Chinese into English

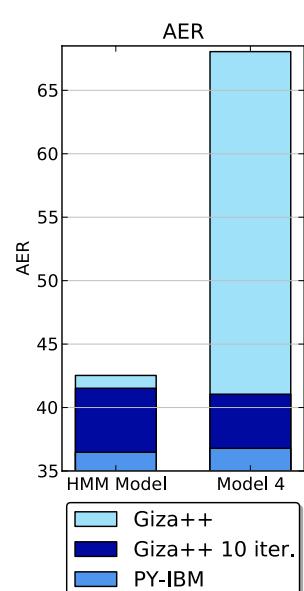

Figure 6: AER of Giza++’s and PY-IBM’s HMM model and model 4 aligning Chinese and English

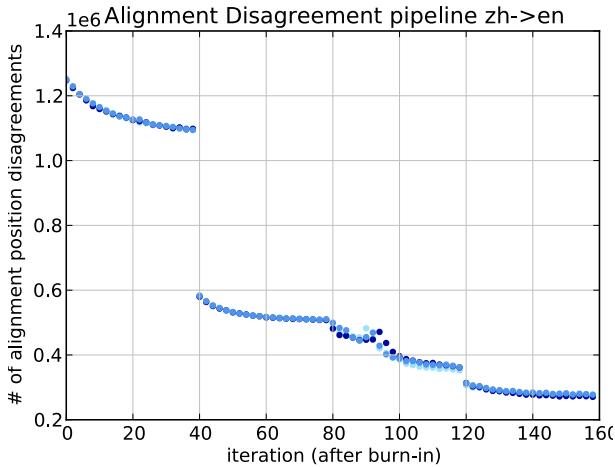

Figure 7: Alignment disagreement of the Chinese to English pipelined PY-IBM models for the 3 repetitions

from Chinese into English, and an improvement of 1.2 percentage points in the overall results after finishing the pipeline.

We also saw an improvement in AER for all models, where the pipelined PY-IBM model 4 achieved an error rate of 32.9, as opposed to the result obtained by the Giza++ pipelined model 4 of 34.4. We note an interesting observation that both Giza++ and PY-IBM model 3 underperformed compared to the previously run HMM alignment

model, as seen in the English to Chinese pipeline results and the AER pipeline results.

The alignment disagreement (the number of changed alignment positions between subsequent iterations) of the Chinese to English pipelined PY-IBM models (1 to 4) can be seen in fig. 7. This graph shows that each model in the pipeline reaches an alignment disagreement equilibrium after about 20 iterations, and that earlier models have greater initial deviation from their equilibrium than later models – which have an overall lower disagreement.

In order to assess the dependence of the fertility based models on the initialisation step another set of experiments was carried out. The models were trained with a randomly initialised set of alignments and assessed after a set number of iterations for the Giza++ models (5 and 10 for the Giza++ HMM alignment model, and 3 and 10 for the Giza++ IBM model 4), or after 100 iterations with a burn-in period of 10 iterations for the PY-IBM ones (we report the average of three runs for both models).

The results, reported in figures 4 to 6, show again that the PY-IBM model outperformed the Giza++ implementations, and to a large extent in the case of IBM model 4. This provides further evidence that the supposition underlying the neighbourhood

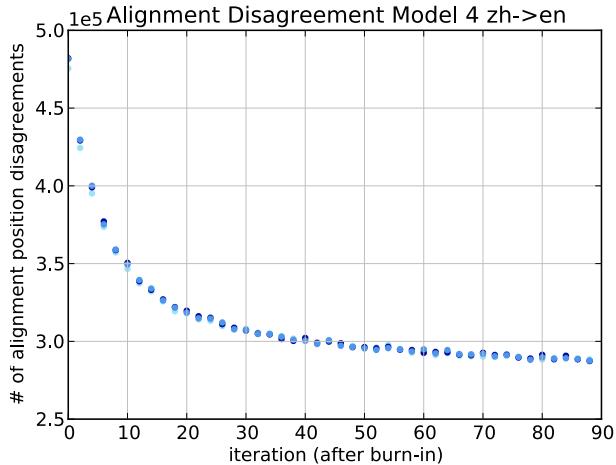

Figure 8: Alignment disagreement of the Chinese to English PY-IBM model 4 for the 3 repetitions

approximation for training models 3 and 4 – that there exists a small set of alignments on which most of the probability mass concentrates – is poor. An interesting observation to note is that the BLEU score of the non-pipelined PY-IBM model 4 is the same as the PY-IBM HMM model translating in both directions, as opposed to an improvement in the pipelined case. This suggests that the sampler might not have fully converged after 100 iterations for model 4 (the number of alignment disagreements for this experiment can be seen in figure 8). Further confirmation for this comes from the higher standard deviation of 0.54 observed for the PY-IBM model 4, as opposed to a standard deviation for the PY-IBM HMM model of 0.21 (which is still more significant than that of the pipelined PY-IBM model 4, whose standard deviation was 0.13).

Both the PY-IBM and the Giza++ trained models run in a linear time in the number of sentences, where due to the nature of MCMC sampling techniques, more iterations are required for its convergence. In our experiments, the running time of the unoptimised Gibbs sampler was 50 times slower than the optimised EM.

6 Discussion

The models described in this paper allow one to use non-parametric approaches to flexibly model word alignment distributions, overcoming a number of limitations of the EM algorithm for the fertility based alignment models. The models achieved a significant improvement in BLEU scores and AER

on the tested corpus, and are easy to extend without the need for additional modelling tools.

The alignment models proposed mostly follow the original generative stories while introducing additional phrasal conditioning into models 3 and 4. However there are many other areas in which we could make use of hierarchical tools to introduce new dependencies easily without running into sparsity problems.

One example is the extension of the transition history used in the HMM alignment model: IBM model 1 uses a uniform distribution over transitions, model 2 conditions on relative sentence positions, and the HMM model uses a first order dependency. One extension would be to use longer histories of n previous positions, handling sparsity with back-off.

Previously proposed approaches to extend the HMM alignment model include Och and Ney (2003)’s use of word classes and smoothing, and the combination of part-of-speech information of the words surrounding the source word (Brunning et al., 2009). Using our hierarchical model one could easily introduce such dependencies on the context words of the word to be translated and their part-of-speech information. This could assist in both translation and reordering disambiguation, and would incorporate back-off by using smaller and smaller contexts when such information is sparse.

Further improvements to models 3 and 4 could be carried out by introducing longer dependencies in the fertility and distortion distributions. Instead of conditioning on the previous word, one could use further information such as PoS tags, previously translated words, or previous fertilities. Additional research would involve the use of more effective variational inference algorithms for hierarchical PY process based models.

The PY-IBM models described in this paper were implemented within the Giza++ code base, and are available as an open source package for further development and research.¹

Abstract

We present a novel approach to automatic metaphor identification, that discovers both metaphorical associations and metaphorical expressions in unrestricted text. Our system first performs hierarchical graph factorization clustering (HGFC) of nouns and then searches the resulting graph for metaphorical connections between concepts. It then makes use of the salient features of the metaphorically connected clusters to identify the actual metaphorical expressions. In contrast to previous work, our method is fully unsupervised. Despite this fact, it operates with an encouraging precision (0.69) and recall (0.61). Our approach is also the first one in NLP to exploit the cognitive findings on the differences in organisation of abstract and concrete concepts in the human brain.

1 Introduction

Metaphor has traditionally been viewed as a form of linguistic creativity, that gives our expression more vividness, distinction and artistism. While this is true on the surface, the mechanisms of metaphor have a much deeper origin in our reasoning. Today metaphor is widely understood as a cognitive phenomenon operating at the level of mental processes, whereby one concept or domain is systematically viewed in terms of the properties of another (Lakoff and Johnson, 1980). Consider the examples (1) “He *shot down* all of my arguments” and (2) “He *attacked* every weak point in my argument”. They demonstrate a metaphorical mapping of the concept of *argument* to that of *war*. The *argument*, which is the target concept, is viewed in terms of a *battle* (or

a *war*), the source concept. The existence of such a link allows us to systematically describe *arguments* using the *war* terminology, thus leading to a number of metaphorical expressions. Lakoff and Johnson call such generalisations a source–target domain mapping, or *conceptual metaphor*.

The ubiquity of metaphor in language has been established in a number of corpus studies (Cameron, 2003; Martin, 2006; Steen et al., 2010; Shutova and Teufel, 2010) and the role it plays in human reasoning has been confirmed in psychological experiments (Thibodeau and Boroditsky, 2011). This makes metaphor an important research area for computational and cognitive linguistics, and its automatic processing indispensable for any semantics-oriented NLP application. The problem of metaphor modeling is gaining interest within NLP, with a growing number of approaches exploiting statistical techniques (Mason, 2004; Gedigian et al., 2006; Shutova, 2010; Shutova et al., 2010; Turney et al., 2011; Shutova et al., 2012). Compared to more traditional approaches based on hand-coded knowledge (Fass, 1991; Martin, 1990; Narayanan, 1997; Narayanan, 1999; Feldman and Narayanan, 2004; Barnden and Lee, 2002; Agerri et al., 2007), these more recent methods tend to have a wider coverage, as well as be more efficient, accurate and robust. However, even the statistical metaphor processing approaches so far often focused on a limited domain or a subset of phenomena (Gedigian et al., 2006; Krishnakumaran and Zhu, 2007), and only addressed one of the metaphor processing sub-tasks: identification of metaphorical mappings (Mason, 2004) or identification of metaphorical expressions (Shutova et al., 2010; Turney et al., 2011). In this paper, we present the first computational method

that identifies the generalisations that govern the production of metaphorical expressions, i.e. conceptual metaphors, and then uses these generalisations to identify metaphorical expressions in unrestricted text. As opposed to previous works on statistical metaphor processing that were supervised or semi-supervised, and thus required training data, our method is fully unsupervised. It relies on building a hierarchical graph of concepts connected by their association strength (using hierarchical clustering) and then searching for metaphorical links in this graph.

Shutova et al. (2010) introduced the hypothesis of “clustering by association” and claimed that in the course of distributional noun clustering, abstract concepts tend to cluster together if they are associated with the same source domain, while concrete concepts cluster by meaning similarity. We share this intuition, but take this idea a significant step further. Our approach is theoretically grounded in the cognitive science findings suggesting that abstract and concrete concepts are organised differently in the human brain (Crutch and Warrington, 2005; Binder et al., 2005; Wiemer-Hastings and Xu, 2005; Huang et al., 2010; Crutch and Warrington, 2010; Adorni and Proverbio, 2012). According to Crutch and Warrington (2005), these differences emerge from their general patterns of relation with other concepts. However, most NLP systems to date treat abstract and concrete concepts as identical. In contrast, we incorporate this distinction into our model by creating a network (or a graph) of concepts, and automatically learning the different patterns of association of abstract and concrete concepts with other concepts. We expect that, while concrete concepts would tend to naturally organise into a tree-like structure (with more specific terms descending from the more general terms), abstract concepts would exhibit a more complex pattern of associations. Consider the example in Figure 1. The figure schematically shows a small portion of the graph describing the concepts of *mechanism* (concrete), *political system* and *relationship* (abstract) at two levels of generality. One can see from this graph that if concrete concepts, such as *bike* or *engine* tend to be connected to only one concept at the higher level in the hierarchy (*mechanism*), abstract concepts may have multiple higher-level associates: the literal ones and the metaphorical ones. For ex-

ample, the abstract concept of *democracy* is literally associated with a more general concept of *political system*, as well as metaphorically associated with the concept of *mechanism*. Such multiple associations are due to the fact that *political systems* are metaphorically viewed as *mechanisms*, they can *function*, *break*, they can be *oiled* etc. We often discuss them using *mechanism* terminology, and thus a corpus-based distributional learning approach would learn that they share features with *political systems* (from their literal uses), as well as with *mechanisms* (from their metaphorical uses, as shown next to the respective graph edges in the figure). Our system discovers such association patterns within the graph and uses them to identify metaphorical connections between the concepts.

To the best of our knowledge, our method is the first one to use a hierarchical clustering model for the metaphor processing task. The original graph of concepts is built using hierarchical graph factorization clustering (HGFC) (Yu et al., 2006) of nouns, yielding a network of clusters with different levels of generality. The weights on the edges of the graph indicate association between the clusters (concepts). HGFC has not been previously employed for noun clustering in NLP, but showed successful results in the verb clustering task (Sun and Korhonen, 2011).

In summary, our system (1) builds a graph of concepts using HGFC, (2) traverses it to find metaphorical associations between clusters using weights on the edges of the graph, (3) generates lists of salient features for the metaphorically connected clusters and (4) searches the British National Corpus (BNC) (Burnard, 2007) for metaphorical expressions describing the target domain concepts using the verbs from the set of salient features. We evaluated the performance of the system with the aid of human judges in precision- and recall-oriented settings. In addition, we compared its performance to that of two baselines, an unsupervised baseline using agglomerative clustering (AGG) and a supervised baseline built upon WordNet (Fellbaum, 1998) (WN).

2 Method

2.1 Dataset and Feature Extraction

Our noun dataset used for clustering contains 2000 most frequent nouns in the BNC (Burnard, 2007).

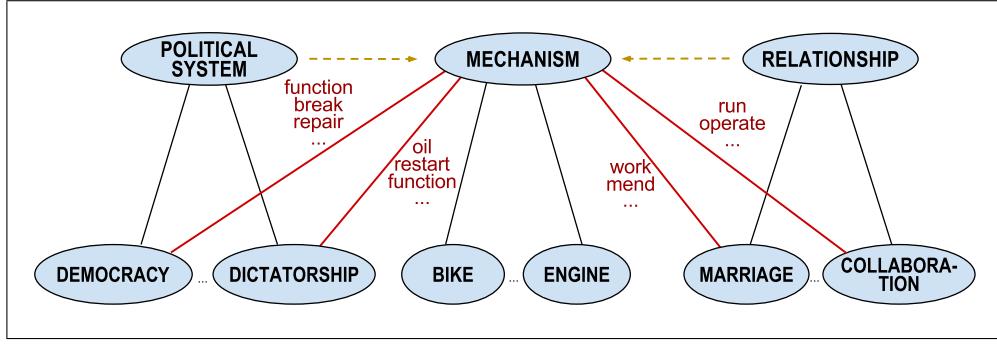

Figure 1: Organisation of the hierarchical graph of concepts

Following previous semantic noun classification experiments (Pantel and Lin, 2002; Bergsma et al., 2008), we use the grammatical relations (GRs) as features for clustering. We extracted the features from the Gigaword corpus (Graff et al., 2003), which was first parsed using the RASP parser (Briscoe et al., 2006). The verb lemmas in VERB–SUBJECT, VERB–DIRECT_OBJECT and VERB–INDIRECT_OBJECT relations with the nouns in the dataset were then extracted from the GR output of the parser. The feature values were the relative frequencies of the features.

2.2 Hierarchical Graph Factorization Clustering

The most widely used method for hierarchical word clustering is AGG (Schulte im Walde and Brew, 2001; Stevenson and Joanis, 2003; Ferrer, 2004; Devereux and Costello, 2005). The method treats each word as a singleton cluster and then successively merges two closest clusters until all the clusters have been merged into one. The cluster similarity is measured using linkage criteria (e.g. Ward (1963) measures the decrease in variance for the clusters being merged). As opposed to this, HGFC derives probabilistic bipartite graphs from the similarity matrix (Yu et al., 2006). Since we require a graph of concepts, our task is rather different from standard hierarchical word clustering that produces a tree of concepts. In a tree, each word can only have a unique parent cluster at each level. Our concept graph does not have this constraint: at any level a word can be associated with an arbitrary number of parent clusters. Therefore, not only HGFC outperformed agglomerative clustering methods in hi-

erarchical clustering tasks (Yu et al., 2006; Sun and Korhonen, 2011), but its hierarchical graph output is also a more suitable representation of the concept graph. In addition, HGFC can detect the number of levels and the number of clusters on each level of the hierarchical graph automatically. This is essential for our task as these settings are difficult to pre-define for a general-purpose concept graph.

Given a set of nouns, $V = \{v_n\}_{n=1}^N$, the similarity matrix W for HGFC is constructed using Jensen-Shannon Divergence. W can be encoded by an undirected graph G (Figure 2(a)), where the nouns are mapped to vertices and W_{ij} is the edge weight between vertices i and j . The graph G and the cluster structure can be represented by a bipartite graph $K(V, U)$. V are the vertices on G . $U = \{u_p\}_{p=1}^m$ represent the hidden m clusters. For example, looking at Figure 2(b), V on G can be grouped into three clusters u_1 , u_2 and u_3 . The matrix B denotes the $n \times m$ adjacency matrix, with b_{ip} being the connection weight between the vertex v_i and the cluster u_p . Thus, B represents the connections between clusters at an upper and lower level of clustering. A flat clustering algorithm can be induced by assigning a lower level node to the parent node that has the largest connection weight. The number of clusters at any level can be determined by only counting the number of non-empty nodes (namely the nodes that have at least one lower level node associated).

The bipartite graph K also induces a similarity (W') between v_i and v_j : $w'_{ij} = \sum_{p=1}^m \frac{b_{ip}b_{jp}}{\lambda_p} = (B\Lambda^{-1}B^T)_{ij}$ where $\Lambda = \text{diag}(\lambda_1, \dots, \lambda_m)$. Therefore, B can be found by minimizing the divergence distance (ζ) between the similarity matrices W and W' :

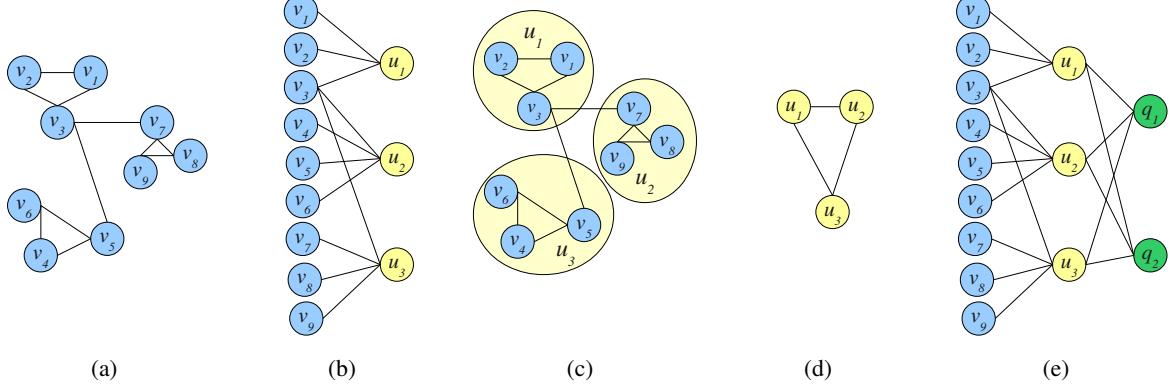

Figure 2: (a) An undirected graph G representing the similarity matrix; (b) The bipartite graph showing three clusters on G ; (c) The induced clusters U ; (d) The new graph G_1 over clusters U ; (e) The new bipartite graph over G_1

$$\min_{H, \Lambda} \zeta(W, H\Lambda H^T), \text{s.t. } \sum_{i=1}^n h_{ip} = 1 \quad (1)$$

$$H = B\Lambda^{-1}; \zeta(X, Y) = \sum_{ij} (x_{ij} \log \frac{x_{ij}}{y_{ij}} - x_{ij} + y_{ij})$$

Yu et al. (2006) showed that this cost function is non-increasing under the update rule:

$$\tilde{h}_{ip} \propto h_{ip} \sum_j \frac{w_{ij}}{(H\Lambda H^T)_{ij}} \lambda_p h_{jp} \text{ s.t. } \sum_i \tilde{h}_{ip} = 1 \quad (2)$$

$$\tilde{\lambda}_p \propto \lambda_p \sum_j \frac{w_{ij}}{(H\Lambda H^T)_{ij}} h_{ip} h_{jp} \text{ s.t. } \sum_p \tilde{\lambda}_p = \sum_{ij} w_{ij} \quad (3)$$

The cost function can thus be optimized by updating h and λ alternately.

The similarity between clusters $p(u_p, u_q)$ can be induced from B , as follows:

$$p(u_p, u_q) = p(u_p)p(u_p|u_q) = (B^T D^{-1} B)_{pq} \quad (4)$$

$$D = \text{diag}(d_1, \dots, d_n) \text{ where } d_i = \sum_{p=0}^m b_{ip}$$

We can then construct a new graph G_1 (Figure 2(d)) with the clusters U as vertices, and the cluster similarity p as the connection weight. The clustering algorithm can now be applied again (Figure 2(e)). This process can go on iteratively, leading to a hierarchical graph.

The number of levels (L) and the number of clusters (m_l) are detected automatically, using the method of Sun and Korhonen (2011). Clustering starts with an initial setting of number of clusters (m_0) for the first level. In our experiment, we set the

value of m_0 to 800. For the subsequent levels, m_l is set to the number of non-empty clusters (bipartite graph nodes) on the parent level. The matrices B and Λ are initialized randomly. We found that the actual initialization values have little impact on the final result. The rows in B are normalized after the initialization so the values in each row add up to one. For a word v_i , the probability of assigning it to cluster $x_p^{(l)} \in X_l$ at level l is given by:

$$\begin{aligned} p(x_p^{(l)} | v_i) &= \sum_{X_{l-1}} \dots \sum_{x^{(1)} \in X_1} p(x_p^{(l)} | x^{(l-1)}) \dots p(x^{(1)} | v_i) \\ &= (D_1^{(-1)} B_1 D_2^{-1} B_2 \dots D_l^{-1} B_l)_{ip} \end{aligned} \quad (5)$$

Due to the random walk property of the graph, m_l is non-increasing for higher levels (Sun and Korhonen, 2011). The algorithm can thus terminate when all nouns are assigned to one cluster. We run 1000 iterations of updates of h and λ (equation 2 and 3) for each two adjacent levels.

The resulting graph is composed of a set of bipartite graphs defined by B_l, B_{l-1}, \dots, B_1 . A bipartite graph has a similar structure as in Figure 1. For a given noun, we can rank the clusters at any level according to the soft assignment probability (eq. 5). The clusters that have no member noun were hidden from the ranking since they do not explicitly represent any concept. However, these clusters are still part of the organisation of conceptual space within the model and they contribute to the probability for the clusters on upper levels (eq. 5). We call the *view* of the hierarchical graph where these empty clusters

are hidden an *explicit graph*. The whole algorithm can be summarized as follows:

Require: N nouns V , initial number of clusters m_1

Compute the similarity matrix W_0 from V

Build the graph G_0 from W_0 , $l \leftarrow 1$

while $m_l > 1$ **do**

- Factorize G_{l-1} to obtain bipartite graph K_l with the adjacency matrix B_l (eq. 1, 2 and 3)
- Build a graph G_l with similarity matrix $W_l = B_l^T D_l^{-1} B_l$ according to equation 4
- $l \leftarrow l + 1$; $m_l \leftarrow$ No. non-empty clusters (eq. 5)

end while

return $B_l, B_{l-1} \dots B_1$

2.3 Identification of Metaphorical Associations

Once we obtained the explicit graph of concepts, we can now identify metaphorical associations based on the weights connecting the clusters at different levels (eq. 5). Taking a single noun (e.g. *fire*) as input, the system computes the probability of its cluster membership for each cluster at each level, using these weights. We expect the cluster membership probabilities to indicate the level of association of the input noun with the clusters. The system can then rank the clusters at each level based on these probabilities. We chose level 3 as the optimal level of generality for our experiments, based on our qualitative analysis of the graph. The system selects 6 top-ranked clusters from this level (we expect an average source concept to have no more than 5 typical target associates) and excludes the literal cluster containing the input concept (e.g. “*fire flame blaze*”). The remaining clusters represent the target concepts associated with the input source concept. Example output for the input concepts of *fire* and *disease* is shown in Figure 3. One can see from the Figure that each of the noun-to-cluster mappings represents a new conceptual metaphor, e.g. EMOTION is FIRE, VIOLENCE is FIRE, CRIME is a DISEASE etc. These mappings are exemplified in language by a number of metaphorical expressions (e.g. “His anger will *burn him*”, “violence *flared again*”, “it’s time they found a *cure for corruption*”).

2.4 Identification of Salient Features and Metaphorical Expressions

After extracting the source–target domain mappings, we now move on to the identification of the cor-

SOURCE: fire

TARGET 1: sense hatred emotion passion enthusiasm sentiment hope interest feeling resentment optimism hostility excitement anger

TARGET 2: coup violence fight resistance clash rebellion battle drive fighting riot revolt war confrontation volcano row revolution struggle

Figure 4: Salient features for *fire* and the *violence* cluster

responding metaphorical expressions. The system does this by harvesting the salient features that lead to the input noun being strongly associated with the extracted clusters. The salient features are selected by ranking the features according to the joint probability of the feature (f) occurring both with the input noun (w) and the cluster (c). Under a simplified independence assumption, $p(w, c|f) = p(w|f) \times p(c|f)$. $p(w|f)$ and $p(c|f)$ are calculated as the ratio of the frequency of the feature f to the total frequency of the input noun and the cluster respectively. The features ranked higher are expected to represent the source domain vocabulary that can be used to metaphorically describe the target concepts. We selected the top 50 features from the ranked list. Example features (verbs and their grammatical relations) extracted for the source domain noun *fire* and the *violence* cluster are shown in Figure 4.

We then refined the lists of features by means of selectional preference (SP) filtering. We use SPs to

FEELING IS FIRE

hope *lit* (Subj), anger *blazed* (Subj), optimism *raged* (Subj), enthusiasm *engulfed* them (Subj), hatred *flared* (Subj), passion *flared* (Subj), interest *lit* (Subj), *fuel* resentment (Dobj), anger *crackled* (Subj), feelings *roared* (Subj), hostility *blazed* (Subj), *light* with hope (Iobj)

CRIME IS A DISEASE

cure crime (Dobj), abuse *transmitted* (Subj), *eradicate* terrorism (Dobj), *suffer from* corruption (Iobj), *diagnose* abuse (Dobj), *combat* fraud (Dobj), *cope with* crime (Iobj), *cure* abuse (Dobj), *eradicate* corruption

Figure 5: Identified metaphorical expressions for the mappings FEELING IS FIRE and CRIME IS A DISEASE

quantify how well the extracted features describe the source domain (e.g. *fire*). We extracted nominal argument distributions of the verbs in our feature lists for VERB–SUBJECT, VERB–DIRECT_OBJECT and VERB–INDIRECT_OBJECT relations. We used the algorithm of Sun and Korhonen (2009) to create SP classes and the measure of Resnik (1993) to quantify how well a particular argument class fits the verb. Resnik measures selectional preference strength $S_R(v)$ of a predicate as a Kullback-Leibler distance between two distributions: the prior probability of the noun class $P(c)$ and the posterior probability of the noun class given the verb $P(c|v)$. $S_R(v) = D(P(c|v)||P(c)) = \sum_c P(c|v) \log \frac{P(c|v)}{P(c)}$. In order to quantify how well a particular argument class fits the verb, Resnik defines selectional association as $A_R(v, c) = \frac{1}{S_R(v)} P(c|v) \log \frac{P(c|v)}{P(c)}$. We rank the nominal arguments of the verbs in our feature lists using their selectional association with the verb, and then only retain the features whose top 5 arguments contain the source concept. For example, the verb *start*, that is a common feature for both *fire* and the *violence* cluster (e.g. “start a war”, “start a fire”), would be filtered out in this way, whereas the verbs *flare* or *blaze* would be retained as descriptive source domain vocabulary.

We then search the RASP-parsed BNC for grammatical relations, in which the nouns from the target domain cluster appear with the verbs from the source domain vocabulary (e.g. “war *blazed*” (subj), “to *fuel* violence” (dobj) for the mapping VIOLENCE is FIRE). The system thus annotates metaphorical expressions in text, as well as the corresponding conceptual metaphors, as shown in Figure 5.

3 Evaluation and Discussion

3.1 Baselines

AGG: the agglomerative clustering baseline is constructed using SciPy implementation (Oliphant, 2007) of Ward’s linkage method (Ward, 1963). The output tree is cut according to the number of levels and the number of clusters of the explicit graph detected by HGFC. The resulting tree is converted into a graph by adding connections from each cluster to all the clusters one level above. The connection weight (the cluster distance) is measured using Jensen-Shannon Divergence between the cluster centroids. This graph is used in place of the HGFC graph in the metaphor identification experiments.

WN: in the WN baseline, the WordNet hierarchy is used as the underlying graph of concepts, to which the metaphor extraction method is applied. Given a source concept, the system extracts all its sense-1 hypernyms two levels above and subsequently all of their sister terms. The hypernyms themselves are considered to represent the literal sense of the source noun and are, therefore, removed. The sister terms are kept as potential target domains.

3.2 Evaluation of Metaphorical Associations

To create our dataset, we extracted 10 common source concepts that map to multiple targets from the Master Metaphor List (Lakoff et al., 1991) and linguistic analyses of metaphor (Lakoff and Johnson, 1980; Shutova and Teufel, 2010). These included FIRE, CHILD, SPEED, WAR, DISEASE, BREAKDOWN, CONSTRUCTION, VEHICLE, SYSTEM, BUSINESS. Each of the three systems identified 50 source–target domain mappings for the given source domains, resulting in a set of 150 conceptual metaphors (each representing a number of submappings since all the target concepts are clusters or synsets). These were then evaluated against human judgements in two different experimental settings.

Setting 1: The judges were presented with a set of conceptual metaphors identified by the three systems, randomized. They were asked to annotate the mappings they considered valid. In all our experiments, the judges were encouraged to rely on their own intuition of metaphor, but they also reviewed the metaphor annotation guidelines of Shutova and Teufel (2010). Two independent judges, both na-

tive speakers of English, participated in this experiment. Their agreement on the task was $\kappa = 0.60$ ($n = 2, N = 150, k = 2$) (Siegel and Castellan, 1988). The main differences in the annotators' judgements stem from the fact that some metaphorical associations are less obvious and common than others, and thus need more context (or imaginative effort) to establish. Such examples, where the judges disagreed included metaphorical mappings such as INTENSITY is SPEED, GOAL is a CHILD, COLLECTION is a SYSTEM, ILLNESS is a BREAKDOWN.

The system performance was then evaluated against these judgements in terms of precision (P), i.e. the proportion of the valid metaphorical mappings among those identified. We calculated system precision (in all experiments) as an average over both annotations. HGFC operates with a precision of $P = 0.69$, whereas the baselines attain $P = 0.36$ (AGG) and $P = 0.29$ (WN). The precision of annotator judgements against each other (the human ceiling) is $P = 0.80$, suggesting that this is a challenging task.

Setting 2: To measure recall, R , of the systems we asked two annotators (both native speakers with a background in metaphor, different from Setting 1) to write down up to 5 target concepts they strongly associated with each of the 10 source concepts. Their annotations were then aggregated into a single metaphor association gold standard, consisting of 63 mappings in total. The recall of the systems was measured against this gold standard, resulting in HGFC $R = 0.61$, AGG $R = 0.11$ and WN $R = 0.03$.

As expected, HGFC outperforms both AGG and WN baselines in both settings. AGG has been previously shown to be less accurate than HGFC in the verb clustering task (Sun and Korhonen, 2011). Our analysis of the noun clusters indicated that HGFC tends to produce more pure and complete clusters than AGG. Another important reason AGG fails is that it by definition organises all concepts into tree and optimises its solution locally, taking into account a small number of clusters at a time. However, being able to discover connections between more distant domains and optimising globally over all concepts is crucial for metaphor identification. This makes AGG less suitable for the task, as demonstrated by our results. However, AGG identified a number of interesting mappings missed by HGFC,

e.g. CAREER IS A CHILD, LANGUAGE IS A SYSTEM, CORRUPTION IS A VEHICLE, EMPIRE IS A CONSTRUCTION, as well as a number of mappings in common with HGFC, e.g. DEBATE IS A WAR, DESTRUCTION IS A DISEASE. The WN system also identified a few interesting metaphorical mappings (e.g. COGNITION IS FIRE, EDUCATION IS CONSTRUCTION), but its output is largely dominated by the concepts similar to the source noun and contains some unrelated concepts. The comparison of HGFC to WN shows that HGFC identifies meaningful properties and relations of abstract concepts that can not be captured in a tree-like classification (even an accurate, manually created one). The latter is more appropriate for concrete concepts, and a more flexible representation is needed to model abstract concepts. The fact that both baselines identified some valid metaphorical associations, relying on less suitable conceptual graphs, suggests that our way of traversing the graph is a viable approach in principle.

HGFC identifies valid metaphorical associations for a range of source concepts. One of them (CRIME IS A VIRUS) happened to have been already validated in psychological experiments (Thibodeau and Boroditsky, 2011). The most frequent type of error of HGFC is the presence of target clusters similar or closely related to the source noun (e.g. the *parent* cluster for *child*). The clusters from the same domain can, however, be filtered out if their nouns frequently occur in the same documents with the source noun (in a large corpus), i.e. by topical similarity. The latter is less likely for the metaphorically connected nouns. We intend to implement this improvement in the future version of the system.

3.3 Evaluation of Metaphorical Expressions

For each of the identified conceptual metaphors, the three systems extracted a number of metaphorical expressions from the corpus (average of 430 for HGFC, 148 for AGG, and 855 for WN). The expressions were also evaluated against human judgements. The judges were presented with a set of randomly sampled sentences containing metaphorical expressions as annotated by the system and by the baselines (200 each), randomized. They were asked to mark the tagged expressions that were metaphorical in their judgement as correct. Their agreement on the task was $\kappa = 0.56$ ($n = 2, N = 600, k = 2$),

HLJ 26 [...] "effective action" was needed to **eradicate terrorism, drug-trafficking and corruption**.
 EG0 275 In the 1930s the words "means test" was a curse, **fuelling the resistance** against it both among the unemployed and some of its administrators.
 CRX 1054 [...] if the rehabilitative approach were demonstrably successful in **curing crime**.
 HL3 1206 [...] he would strive to **accelerate progress** towards the economic integration of the Caribbean.
 HXJ 121 [...] it is likely that some **industries will flourish** in certain countries as the **market widens**.

Figure 6: Metaphors tagged by the system (in bold)

whereby the main source of disagreement was the presence of lexicalized metaphors, e.g. verbs such as *impose*, *decline* etc. The system performance against these annotations is $P = 0.65$ (HGFC), $P = 0.47$ (AGG) and $P = 0.12$ (WN). The human ceiling for this task was measured at $P = 0.79$. Figure 6 shows example sentences annotated by HGFC. The performance of our unsupervised approach is close to the previous supervised systems of Mason (2004) (accuracy of 0.73) and Shutova et al. (2010) (precision of 0.79), however, the results are not directly comparable due to different experimental settings.

The system errors in this task stem from multiple word senses of the salient features or the source and target sharing some physical properties (e.g. one can "*die from crime*" and "*die from a disease*"). Some identified expressions invoke a chain of mappings (e.g. ABUSE IS A DISEASE, DISEASE IS AN ENEMY for "*combat abuse*"), however, such chains are not yet incorporated into the system. The performance of AGG is higher than in the mappings identification task, since it outputs only few expressions for the incorrect mappings. In contrast, WN tagged a large number of literal expressions due to the incorrect prior identification of the underlying associations.

Since there is no large metaphor-annotated corpus available, it was impossible for us to reliably evaluate the recall of metaphorical expressions. However, we estimated it as a recall of salient features. We manually compiled sets of typical features for the 10 source domains, and measured their recall among the top 50 HGFC features at $R = 0.70$. However, in practice the coverage in this task would directly depend on that of the metaphorical associations.

4 Related Work

One of the first attempts to identify and interpret metaphorical expressions in text is the met* system of Fass (1991), that utilizes hand-coded knowledge and detects non-literalness via selectional preference violation. In case of a violation, the respective phrase is first tested for being metonymic using hand-coded patterns (e.g. CONTAINER-FOR-CONTENT). If this fails, the system searches the knowledge base for a relevant analogy in order to discriminate metaphorical relations from anomalous ones. The system of Krishnakumaran and Zhu (2007) uses WordNet (the hyponymy relation) and word bigram counts to predict verbal, nominal and adjectival metaphors at the sentence level. The authors discriminate between conventional metaphors (included in WordNet) and novel metaphors. Birke and Sarkar (2006) present a sentence clustering approach that employs a set of seed sentences annotated for literalness and computes similarity between the new input sentence and all of the seed sentences. The system then tags the sentence as literal or metaphorical according to the annotation in the most similar seeds, attaining an f-score of 53.8%.

The first system to discover source–target domain mappings automatically is CorMet (Mason, 2004). It does this by searching for systematic variations in domain-specific verb selectional preferences. For example, *pour* is a characteristic verb in both LAB and FINANCE domains. In the LAB domain it has a strong preference for *liquids* and in the FINANCE domain for *money*. From this the system infers the domain mapping FINANCE – LAB and the concept mapping *money* – *liquid*. Gedigan et al. (2006) trained a maximum entropy classifier to discriminate between literal and metaphorical use. They annotated the sentences from PropBank (Kingsbury and Palmer, 2002) containing the verbs of MOTION and CURE for metaphoricity. They used PropBank annotation (arguments and their semantic types) as features for classification and report an accuracy of 95.12% (however, against a majority baseline of 92.90%). The metaphor identification system of Shutova et al. (2010) starts from a small seed set of metaphorical expressions, learns the analogies involved in their production and extends the set of analogies by means of verb and noun clustering. As

a result, the system can recognize new metaphorical expressions in unrestricted text (e.g. from the seed “*stir excitement*” it infers that “*swallow anger*” is also a metaphor), achieving a precision of 79%.

Turney et al. (2011) classify verbs and adjectives as literal or metaphorical based on their level of concreteness or abstractness in relation to a noun they appear with. They learn concreteness rankings for words automatically (starting from a set of examples) and then search for expressions where a concrete adjective or verb is used with an abstract noun (e.g. “*dark humour*” is tagged as a metaphor and “*dark hair*” is not). They report an accuracy of 73%.

5 Conclusions and Future Directions

Previous research on metaphor addressed a number of different aspects of the phenomenon, and has shown that these aspects can be successfully modeled using statistical techniques. However, the methods often focused on a limited domain and needed manually-labeled training data. This made them difficult to apply in a real-world setting with the goal of improving semantic interpretation in NLP at large. Our method takes a step towards this direction. It is fully unsupervised, and thus more robust, and can perform accurate metaphor identification in unrestricted text. It identifies metaphor with a precision of 69% and a recall of 61%, which is a very encouraging result for an unsupervised method. We believe that this work has important implications for computational and cognitive modeling of metaphor, but is also applicable to a range of other semantic tasks within NLP. Integrating different representations of abstract and concrete concepts into NLP systems may improve their performance, as well as make the models more cognitively plausible.

One of our key future research objectives is to investigate the use and adaptation of the created conceptual graph to perform metaphor interpretation. In addition, we plan to extend this work to cover nominal and adjectival metaphors, by harvesting salient nominal and adjectival features.

remus@kds1.informatik.tu-darmstadt.de, biem@cs.tu-darmstadt.de

Abstract

We present three approaches to lexical chaining based on the LDA topic model and evaluate them intrinsically on a manually annotated set of German documents. After motivating the choice of statistical methods for lexical chaining with their adaptability to different languages and subject domains, we describe our new two-level chain annotation scheme, which rooted in the concept of cohesive harmony. Also, we propose a new measure for direct evaluation of lexical chains. Our three LDA-based approaches outperform two knowledge-based state-of-the art methods to lexical chaining by a large margin, which can be attributed to lacking coverage of the knowledge resource. Subsequent analysis shows that the three methods yield a different chaining behavior, which could be utilized in tasks that use lexical chaining as a component within NLP applications.

1 Introduction

A text that is understandable by its nature exhibits an underlying structure which makes the text coherent; that is, the structure is responsible for making the text “hang” together (Halliday and Hasan, 1976). The theoretic foundation of this structure is defined as *coherence* and *cohesion*. While the former is concerned with the meaning of a text, the latter can be seen as a collection of devices for creating it. Cohesion and coherence build the basis for most of the current natural language processing problems that deal with text understanding. *Lexical cohesion* ties together words or phrases that

are semantically related. Once all the cohesive ties are identified the involved items can be grouped together to form so-called *lexical chains*, which form a theoretically well-founded building block in various natural language processing applications, such as word sense disambiguation (Okumura and Honda, 1994), summarization (Barzilay and Elhadad, 1997), malapropism detection and correction (Hirst and St-Onge, 1998), document hyperlinking (Green, 1996), text segmentation (Stokes et al., 2004), topic tracking (Carthy, 2004), and others. The performance of the individual task heavily depends on the quality of the identified lexical chains.

1.1 Motivation for Corpus-driven Approach

Previous approaches mainly focus on the use of knowledge resources like lexical semantic databases (Hirst and St-Onge, 1998) or thesauri (Morris and Hirst, 1991) as background information in order to resolve possible semantic relations. A major drawback of this strategy is the dependency on the coverage of the resource, which has a direct impact on the lexical chains. Their quality can be expected to be poor for resource-scarce languages or specialized application domains.

Statistical methods to modeling language semantics have proven to deliver good results in many natural language processing applications. In particular, probabilistic topic models have been successfully used for tasks such as summarization (Gong and Liu, 2001; Hennig, 2009), text segmentation (Misra et al., 2009), lexical substitution (Dinu and Lapata, 2010) or word sense disambiguation (Cai et al., 2007; Boyd-Graber et al., 2007).

In this work, we address the question, whether statistical methods for the extraction of lexical chains can yield better results than existing knowledge-based methods, especially for underresourced languages or domains, following principles of Structure Discovery (Biemann, 2012). To address this, we have developed a methodology for evaluating the quality of lexical chains intrinsically, have carried out an annotation study, and report results on a corpus of manually annotated German news documents.

After defining a measure for the comparison of (manually or automatically created) lexical chains in Section 2, Section 3 describes our annotation methodology and discusses issues regarding the inherent subjectivity of lexical chain annotation. In Section 4, three statistical approaches for lexical chaining are developed on the basis of the LDA topic model. Experiments that demonstrate the advantage of these approaches over a knowledge-baseline are conducted and evaluated in Section 5, and Section 6 concludes and provides an outlook future directions.

1.2 Previous Work on Lexical Chains

Morris and Hirst (1991) initially proposed an algorithm for lexical chaining based on Roget’s thesaurus (Roget, 1852), and manually assessed the quality of their algorithm. Hirst and St-Onge (1998) first presented a computational approach to lexical chaining based on WordNet showing that the lexical database is a reasonable replacement to Roget’s. The basic idea behind these algorithms is that semantically close words should be connected to form chains. Subsequent approaches mainly concentrated on disambiguation of words to WordNet concepts (WSD), since ambiguous words can lead to the over-generation of connections. Barzilay and Elhadad (1997) improved the implicit word sense disambiguation (WSD) by keeping a list of different interpretations of the text and finally choosing the most plausible senses for chaining. Silber and McCoy (2002) introduced an efficient variant of the algorithm with linear complexity in the number of candidate terms. Galley and McKeown (2003) further improved accuracy by first performing WSD, and then using the remaining links between the disambiguated concepts only. They also introduced a so-called *disambiguation graph*, a representation that

has also been utilized by the method of Medelyan (2007), where she applied a graph clustering algorithm to the disambiguation graph to cut weak links, performing implicit WSD. A combination of statistical and knowledge-based methods is presented by Marathe and Hirst (2010), who combine distributional co-occurrence information with semantic information from a lexicographic resource for extracting lexical chains and evaluate them by text segmentation. We are not aware of previous lexical chaining algorithms that do not rely on a lexicographic resource at all.

A major issue in developing a new lexical chaining algorithm is the comparison to previous systems. Most of previous approaches are validated by the evaluation in a certain task like summarization, word sense disambiguation, keyphrase extraction or information retrieval (Stairmand, 1996). Hence, these extrinsic evaluations are heavily influenced by the particular task at hand. We propose to re-consider lexical chaining as a task on its own, and propose objective criteria for directly comparing lexical chains to this end.

2 Comparing Lexical Chains

The comparison of lexical chains is a non-trivial task. We adopt the idea of interpreting lexical chains as clusters and a particular set of lexical chains as a clustering, and develop a suitable cluster comparison measure. As stated by Meilă (2005) and Amigó et al. (2009), a best clustering comparison measure for the general case does not exist. It should be stressed that the appropriate clustering measure highly depends on the task at hand.

After exploring a number of measures¹, we decided on a combination of the adjusted Rand index (*ARI*, Hubert and Arabie (1985)) and the *basic merge distance* (*BMD*, Menestrina et al. (2010)) for our new measure. Menestrina et al. (2010) introduced a linear time algorithm for computing the *generalized merge distance* (*GMD*), which counts

¹Explored measures which are unsatisfactory for the given task are: Closest Cluster F_1 (Benjelloun et al., 2009), K (Ajmera et al., 2002), Pairwise F_1 (Manning et al., 2008), Variation of Information (Meilă, 2005), B^3 (Bagga and Baldwin, 1998), V-Measure (Rosenberg and Hirschberg, 2007), Normalized Mutual Information (Strehl, 2002). The last two measures are equal. A proof of this can be found in the appendix.

split and *merge* cluster editing operations. Using a constant factor of 1 for both splits and merges gives the *basic merge distance* (*BMD*): Considering \top as the most general clustering of a dataset D , where all elements are grouped into the same cluster, and further considering \perp as the most specific clustering of D , where each element builds its own cluster, the *lattice* between \top and \perp spans all possible clusterings and the *BMD* can be interpreted as the *shortest path* from a clustering C to a clustering C' in the lattice with some restrictions (see Menestrina et al. (2010) for details). We normalize the *BMD* score by the maximum *BMD*² to the normalized basic merge distance (*NBMD*). *ARI* is based on pair comparisons, and is computed as³:

$$\begin{aligned} \text{index} &= TP \\ \text{expected index} &= \frac{(TP + FP) \times (TP + FN)}{TP + TN + FP + FN} \\ \text{max index} &= TP + \frac{1}{2}(FP + FN) \\ ARI(C, C') &= \frac{\text{index} - \text{expected index}}{\text{max index} - \text{expected index}} \end{aligned}$$

The reasons for choosing these two particular measures are the following: *ARI* is a well known measure which is adjusted (corrected) for decisions made by chance. But since it is based on pairwise element comparison it completely disregards singleton clusters (chains) and some types of errors are not adequately penalized. The *NBMD* on the other hand penalizes various errors almost equally.

We combine the two single measures into a new *lccm* (*lexical chain comparison measure*), defined as the arithmetic mean between *ARI* and $1 - \text{NBMD}$. An *lccm* of 1 indicates perfect congruence and an *lccm* = 0 indicates that not a single pair of items in C is found in a cluster together in C' .

$$\begin{aligned} lccm(C, C') &= \\ &\frac{1}{2} [1 - \text{NBMD}(C, C') + ARI(C, C')] \end{aligned}$$

² $BMD(\top, \perp)$ for $|D| \leq 2$, $BMD(\top, \perp) + 1$ otherwise

³ TP : pairs in D and D' , FP : pairs in D' but not in D , FN : pairs in D but not in D' , TN : pairs not in D and not in D' , where D is the underlying dataset of C , D' is the underlying dataset of C' , and pairs means all unique combinations of elements that are in the same cluster.

3 Annotating Lexical Chains

A challenge with the annotation of lexical chains is the subjective interpretation of the text by individual annotators (Morris and Hirst, 2004), which also substantiates the fact that currently no gold standard exist, and all previous automatic approaches are evaluated by performing a certain NLP task. Hollingsworth and Teufel (2005) as well as Cramer et al. (2008) conclude from their lexical chain annotation projects that high inter-annotator agreement is very hard to achieve. We argue that directly evaluating on lexical chains should enable us to optimize towards higher-quality chain annotations, which is a task of its own right and which has the potential to improve all subsequent applications. For this, we devise an annotation scheme that gets us reasonable inter-annotator agreement, inspired by the concept of *cohesive harmony* (Hasan, 1984), and report on an annotation project for German newswire texts.

Documents from the SALSA 2.0 (Burchardt et al., 2006) corpus were chosen to form the basis for the annotation of lexical chain information. SALSA is based on the semi-automatically annotated TIGER Treebank 2.1 (Brants et al., 2002). The TIGER treebank provides manual annotations, such as lemmas, part-of-speech tags, and syntactic structure, the SALSA part of the corpus is also partially annotated with FrameNet-style (Baker et al., 1998) frame annotation. The documents are general domain news articles from a German newspaper comprising about 1,550 documents and around 50,000 sentences in total, with a median document length of 275 tokens.

3.1 Annotation Scheme

In order to minimize the subjectiveness of choices by different annotators, annotation guidelines were developed comprising a total of ten pages. We decided to consider only nouns, noun compounds and non-compositional adjective noun phrases like “dirty money” as candidate terms for lexical chaining, which is consistent with the procedures of Hollingsworth and Teufel (2005) and Cramer et al. (2008). For annotation, we used the MMAX2⁴ (Müller and Strube, 2006) tool.

We introduce the term *dense chain*, which refers to a type of lexical chain in which every element is

⁴<http://mmax2.sourceforge.net>

related to every other element in that chain. Terms are considered to be related if they share the same topic, i.e. common sense and knowledge of the language is needed to decide which terms belong together in the same topic and whether a chosen topic is neither too broad nor too narrow. A single dense chain can thus be assigned a definite topical description of its items. Whereas Hollingsworth and Teufel (2005) dealt with the inherent fuzziness of membership of terms to lexical chains by allowing terms to occur in different lexical chains, we follow the concept of *cohesive harmony* introduced by Hasan (1984) here, where complete chains can be linked to others. For this purpose, we introduce so-called *level two links*, which are cohesive ties between lexical items in distinct dense chains. Having such a link between two chains, both chains can be assigned a topical description which is broader than the description of the individual chains. This results in a two-level representation of chains. We report on dense lexical chains and merged lexical chains (dense chains are merged into a common chain if a level two link exists between them) separately.

In total, 100 documents were annotated by two expert annotators. Documents were chosen around the length median and consist of 248 – 304 tokens. The two rightmost columns of Table 3 show the characteristics of the annotated data set. It can be concluded that there is a moderate to high agreement regarding the annotator selections of candidate terms, which is ensured by preselection of candidate terms by part-of-speech patterns. A value of 81 % in the average agreement on lexical items (cf. Figure 1) shows that even though the choice of lexical items is limited to nouns and adjective noun phrases only, the decision on candidate termhood is somewhat different between the annotators, but compares favorably with previous findings of 63 % average pairwise agreement (Morris and Hirst, 2004).

Figure 2 shows the annotator agreement on the individual documents using the *lccm* (cf. Sec. 2), sorted in the same way as in Figure 1. In order to use the level two link information the figure also shows a second agreement score, which was computed on merged chains.

The agreement scores of the assignment of lexical items to lexical chains depend partially on the agreement scores of the identified lexical items them-

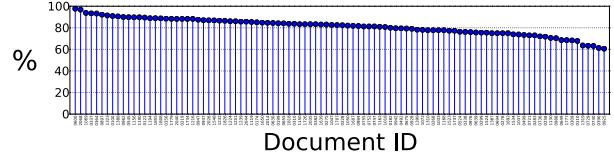

Figure 1: Agreement of lexical items annotated by annotator A and annotator B as a percentage of lexical items annotated by annotator A or annotator B. The average agreement is 81 %.

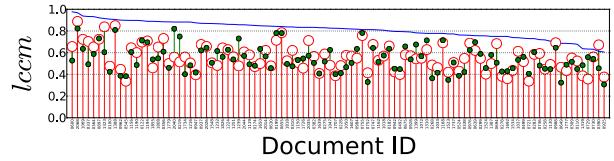

Figure 2: Individual annotator agreement scores on 100 documents sorted by their agreement on candidate terms. The red circles show the agreement of both annotators on the dense lexical chains disregarding the cohesive links, and the green dots show the agreement of both annotators on the merged lexical chains (via the cohesive links) both using the proposed *lexical chain comparison measure*.

selves, which is a desired property. Across all documents, a perfect agreement was never achieved, which confirms the difficulty of annotating such a subjective task: The average *lccm* per document on the manual annotations is 0.56 (dense chains), respectively 0.54 (merged chains). However, the considerable overlap between the annotators still enables us to evaluate automatic chaining methods, and the *lccm* agreement score serves as an upper bound. Note that by performing no reconciliation of the annotations we explicitly allow the possibility of different interpretations which is in our opinion appropriate here due to the subjectiveness of the task itself. By doing so, we evaluate our algorithms against individual annotator interpretations.

4 Statistical Methods for Lexical Chaining

This work employs a well-studied statistical method for creating something that Barzilay (1997) called an *automatic thesaurus* which will then be adapted for lexical chaining. For our automatic approaches, candidate lexical items in a text are preselected by the same heuristic that is also applied in Section 3 for the annotation process.

Topic models (TMs) are a suite of unsuper-

vised algorithms designed for unveiling some hidden structure in large data collections. The key idea is that documents can be represented as composites of so-called *topics* where a topic itself represents as a composite of words. Hofmann (1999) defined a topic to be a probability distribution over words and a document to be a probability distribution over a fixed set of topics. We use the *latent Dirichlet allocation* (LDA, Blei et al. (2003)) topic model for estimating the semantic closeness of candidate terms, and explore different ways of utilizing LDA’s topic information in automatic lexical chainers. Specifically, we use the GibbsLDA++⁵ framework for topic model estimation and inference, and examine the following LDA parameters: number of topics T , Dirichlet hyperparameters for document-topic distribution α and topic-term distribution β .

We now describe three LDA-based approaches to lexical chaining.

4.1 LDA Mode Method (LDA-MM)

The LDA-MM approach places all word tokens that share the same topic ID into the same chain. The point is now how to decide to which topic a word belongs to. Since single samples of topics per word exhibit a large variance (Riedl and Biemann, 2012), we follow these authors by sampling several times and using the mode (most frequently assigned) topic ID per word as the topic assignment. This strategy reduced the variance in the *lccm* to a tenth⁶.

More formally, let $\text{samples}^{(d,w)}$ be the vector of assignments that have been collected for a certain word w in a certain document d with each $\text{samples}_i^{(d,w)}$ referring to the i -th sampled topic ID for (d, w) . In other words, $\text{samples}^{(d,w)}$ can be seen as the Markov chain for a particular word in a particular document. Further let $z^{(d,w)}$ be the topic ID that was most assigned to the word w with respect to the samples in $\text{samples}^{(d,w)}$. Precisely, $z^{(d,w)}$ is defined to be the sampled mode in $\text{samples}^{(d,w)}$ — in case of multiple modes a random mode is chosen,

⁵<http://gibbslda.sourceforge.net>

⁶Preliminary experiments yielded a variance of 2.6×10^{-6} in *lccm* using the mode method and 3.07×10^{-5} using a single sample for lexical chain assignment.

which never happened in our experiments.

$$\begin{aligned} z^{(d,w)} &= \text{mode}(\text{samples}^{(d,w)}) \\ &\approx \arg \max_j (P(z = j | w, d)) \end{aligned}$$

The LDA-MM assigns for every word w which is a candidate lexical item of a certain document d which is assigned the same topic $z^{(d,w)}$ to the same chain; hence implicitly disambiguating the terms.

The possibility to create level two links is given by taking the second most occurring topic for a given word if it exceeds a certain threshold.

4.2 LDA Graph Method (LDA-GM)

The LDA-GM algorithm creates a similarity graph based on the comparison of topic distributions for given words and then applies a clustering algorithm in order to find semantically related words.

Let $\psi^{(d,w)}$ be the per-word topic distribution $P(z|w, d)$. Analogously to the LDA-MM, $\psi^{(d,w)}$ can be obtained by counting the occurrences of a certain topic ID z in the sample collection $\text{samples}^{(d,w)}$ for a particular word w and document d .

The semantic relatedness between any two words w_i and w_j can then be measured by their similarity score of the topic distributions $\psi^{(d,w_i)}$ and $\psi^{(d,w_j)}$, which is stored in a term similarity matrix. This matrix can also be interpreted as an adjacency matrix of a graph, with candidate items being nodes and edges being weighted with the similarity value sim_{ij} for any two nodes $i, j : i \neq j \wedge i, j \in \{1, 2, \dots, N_d\}$. We test two similarity measures: Euclidian (dis-)similarity and cosine similarity.

Let $G = (V, E)$ be the graph representation of a document with term vertices $V = \{v_1, \dots, v_{N_d}\}$ and weighted edges $E = \{(v_1, v_2, \text{sim}_{12}), \dots, (v_{N_d}, v_{N_d-1}, \text{sim}_{N_d N_d-1})\}$, where sim_{ij} is either the cosine or Euclidean similarity of term vectors. For simplicity, we reduce this representation to an unweighted graph by only retaining edges (of unit weight) that have a similarity above a parameter threshold ϵ_{sim} . To identify chains as clusters in this graph, we follow Medelyan (2007) and apply the *Chinese Whispers* graph clustering algorithm (CW, Biemann (2006)), which finds the number of clusters automatically. The CW algorithm implementation comes with

three parameters to regulate the node weight based on its degree, which influences cluster size and granularity. We test options "top", "dist log" and "dist lin".

The final chaining procedure is straightforward: The LDA-GM algorithm assigns every candidate lexical item w_i of a certain document d which is assigned the same class label c_i to the same chain. Level two links are drawn using the second dominant class of a vertex's neighborhood, which is provided by the CW implementation.

4.3 LDA Top-N Method (LDA-TM)

The LDA-TM method is different to the others in that it uses the information of the per-topic word distribution $\phi^{(z)} = P(w|z)$ and the per-document topic distribution $\theta^{(d)} = P(z|d)$. Given a parameter n referring to the top n topics to choose from $\theta^{(d)}$ and a parameter m referring to the top m words to choose from $\phi^{(z)}$ the main procedure can be described as follows: for all $z \in \text{top } n \text{ topics in } \theta^{(d)}$: chain the top m words in $\phi^{(z)}$.

Note that although the number of chains and chain members for each chain is bound and could lead to the same number and sizes of chains, in practice the number of generated chains as well as the number of chain members still varies considerably across documents: often some of the top m words for a (globally computed) topic do not even occur in a particular document. This implies that the parameters n and m must not be set globally but dependent on the particular document. To overcome this to some extent, additional thresholding parameters ϵ_θ and ϵ_ϕ are used for further bounding the respective n or m parameter. The procedure works like this: for all $z \in \text{top } n \text{ topics in } \theta^{(d)} \wedge \theta_z^{(d)} < \epsilon_\theta$: chain the top m words w in $\phi^{(z)} \wedge \phi_w^{(z)} < \epsilon_\phi$.

Level two links are created by computing the cosine similarity between every pair of the top n topic distributions, and thresholding with a link parameter.

4.4 Repetition Heuristic

All methods described above can be applied to new unseen documents that are not in the training set. To alleviate a possible vocabulary mismatch between training set and test set, which happens when terms in the test set have not been contained in our training

documents, we add a heuristic that chains repetitions of (previously unknown) words as a post-processing step to all methods.

5 Empirical Analysis

In order to provide a realistic estimate of the quality of our methods to unseen material, we randomly split our annotated documents in two parts of 50 documents each. One part is used as a *development set* for optimizing the parameters of the methods (i.e. model selection), the other part forms our *test set* for evaluation.

The *training corpus*, on the other hand, consists of all 1,211 SALSA/Tiger documents that are not part of the development and test corpus and neither very long nor very short. These documents are taken from the German newspaper "Frankfurter Rundschau" around 1992. Additionally the training corpus is enriched with 12,264 news texts from the same newspaper around 1997 with similar characteristics⁷, making up a total of 13,457 training documents for the estimation of topic models.

Input to the LDA model training are verbs, nouns and adjectives, as well as candidate terms as described in Section 3.1, all in their lemmatized form. We further filter words that occur in more than $1/3$ of the training documents, as well as known stop-words, and words that occur in less than two documents which results in a vocabulary size of about 100K words.

5.1 Experimental Setup

For comparison, we implemented three baselines, which we describe below. One baseline is trivial, two baselines are state-of-the art knowledge-based systems adapted to German.

Random: Candidate lexical items are randomly tied together to form sets of lexical chains. Level two links are created analogously. We regulate the process to yield the same average number of chains and links as in the development and test data.

S&M GermaNet: Algorithm by Silber and McCoy (2002) with GermaNet as its knowledge resource.

⁷as provided by Projekt Deutscher Wortschatz, <http://wortschatz.uni-leipzig.de/>

G&M GermaNet: Algorithm by Galley and McKown (2003), also using GermaNet.

GermaNet (Hamp and Feldweg, 1997) is a large WordNet-like resource for German, containing almost 100,000 lexical units and over 87,000 conceptual relations between synsets. While its size is only about half of WordNet, it is one of the largest non-English lexical semantic resources.

5.2 Model Selection

We optimize two sets of parameters: parameters for the LDA topic model (number of topics K , Dirichlet hyperparameters α and β) are optimized for the LDA-MM method only, and the same LDA model is used in the other two LDA-based methods. Parameters particular to the respective method are optimized individually. For LDA, we tested sensible combinations in the ranges $K = 50..1000$, $\alpha = 0.05/K..50/K$ and $\beta = 0.001..0.1$. The highest performance of the LDA-MM method was found for $K = 500$, $\alpha = 50/K$, $\beta = 0.001$, and the resulting topic model is used across all methods. The final parameter values for the other methods, found by exhaustive search, are summarized in Table 1.

Method	Parameter
LDA-GM	<i>similarityfunction</i> = cosine similarity <i>labelweightscheme</i> = dist log $\epsilon_{sim} = 0.95$
LDA-TM	$n = 10$, $m = 20$, $\epsilon_\theta = 0.2$, $\epsilon_\phi = 0.2$

Table 1: Final parameter values.

5.3 Evaluation

For evaluation purposes, terms that consist of multiple words are mapped to its rightmost term which is assumed to be the head, e.g. “dirty money” is mapped to “money”. Additionally, singleton chains, i.e. chains that contain only a single lexical item are omitted unless the respective lexical item is not linked by a level two link.

Dense Chains Comparative results of the approaches in terms of $lccm$ for both annotators are summarized in Table 2 (upper half). We observe that all our new methods beat the random baseline and the two knowledge-based baselines by a large margin. The knowledge-based baselines, both using

	Anno A	Anno B	Average
LDA-MM	0.320	0.306	0.313
LDA-TM	0.307	0.299	0.303
LDA-GM	0.328	0.314	0.321
G&M	0.255	0.215	0.235
S&M	0.248	0.209	0.229
Random	0.126	0.145	0.135
<hr/>			
LDA-MM	0.316	0.300	0.308
LDA-TM	0.303	0.280	0.291
LDA-GM	0.279	0.267	0.273
G&M	0.184	0.166	0.176
S&M	0.179	0.159	0.169
Random	0.196	0.205	0.201

Table 2: Results of the evaluation based on dense chains (upper half) and merged chains (lower half). The annotator agreement on the test set’s chains = 0.585; on merged chains = 0.553

GermaNet, produce very similar $lccm$ scores, which highlights the important role of the knowledge resource. Data analysis revealed that while chains produced by knowledge-based baselines are sensible, the main problem is a lack of coverage in terms of vocabulary and relations in GermaNet. Comparing the statistical methods, the LDA-GM method excels over the others.

Level Two Links Table 2 (lower half) summarizes the evaluation results of the merged chains via level two links. Because of merging, a text now contains fewer chains with more lexical items each. Note that knowledge-based baselines do not construct level two links, which is why they are heavily penalized in this setup.

Again, the statistical methods beat the baselines by a substantial amount. In this evaluation, the random baseline performs above the knowledge-based methods, which is rooted in the fact that $lccm$ penalizes small, correct chains, whereas the random baseline with linking often produces very large chains containing most of the terms – something that we also observe for many manually annotated documents. The large overlap in the biggest chain then leads to the comparatively high random baseline score. In this evaluation, the LDA-MM is the clear winner, with LDA-GM being clearly inferior this time.

	LDA-MM	LDA-GM	LDA-TM	S&M	G&M	Anno A	Anno B
avg. num. of lexical items per doc.	38.20	29.32	30.82	14.40	15.29	38.66	38.96

Figure 3: Diverse output of the various lexical chaining systems after applying them on a short German example text from the used TIGER/SALSA corpus. For a better understanding the text is calqued. Candidate items are highlighted and the c_i are the resulting dense lexical chains and the l_i are the level two links produced by the various methods.

Data Analysis Table 3 shows quantitative numbers of the extracted lexical chains in the test set.

The LDA-MM approach chains and links a lot more items than the other statistical methods: it creates a lot more links between items that would otherwise be removed because they form unlinked singleton chains. As opposed to this, the graph method (LDA-GM), as well as the top-n method (LDA-TM) perform an implicit filtering on the candidate lexical items by creating less level two links, yet larger dense chains. The knowledge based algorithms by Silber and McCoy (2002) and Galley and McKeown (2003) extract fewer and smaller chains than the statistical approaches, which reflects GermaNet’s sparsity issues. While higher lexical coverage in the underlying resource would increase the coverage of our knowledge-based systems, this is only one part of the story. The other part is rooted in the fact that lexical cohesion relations, which are used in lexical chains, encompass many more semantic relations than listed in today’s lexical semantic net-

works. This especially holds for cases where several expressions refer to the same event or theme for which no well-defined relation exists, such as e.g. "captain" and "harbor".

Comparing the three LDA-based approaches, no overall best method could be determined. the LDA-MM seems especially suited for a high coverage and coarse (level two) chains, the LDA-GM appears most suited for dense chains, and LDA-TM produces the longest chains on average.

Figure 3 shows the resulting dense lexical chains and level two links after applying our chainers to a short example text from our corpus. In the example the LDA-TM produces the most adequate lexical chains, at least in our intuition. The LDA-GM and the LDA-MM produce slightly wrong chains, yet the LDA-MM additionally creates some meaningful level two links which the LDA-GM does not. Both knowledge-based approaches perform poorly compared to the knowledge-free approaches, where the S&M algorithm creates no chains at all and the

G&M algorithm produces only a single chain containing only two words. This is mostly due to GermaNet's lacking lexical and relational coverage and the scope of the algorithms for finding relations between the words.

6 Conclusion

In this paper, we presented experiments for automatic lexical chain annotation and evaluated them directly on a manually annotated dataset for German. A new two-level annotation scheme for lexical chains was proposed and motivated by the concept of cohesive harmony. We further proposed a new measure for comparing lexical chain annotations that is especially suited for the characteristics of lexical chain annotations. Three variants of statistical lexical chaining methods based on the LDA topic model were proposed and evaluated against two knowledge-based baseline systems. Our statistical methods exhibit a substantially higher performance than the knowledge-based systems on our dataset. This can partially be attributed to missing relations, partially to the lack of lexical coverage of GermaNet, which was used in these systems. Since GermaNet is a large lexical-semantic net, however, this strengthens our main point: Especially for under-resourced languages or subject domains, statistical and data-driven methods should be preferred over their knowledge-based counterparts, since they do not require the development of lexical-semantic nets and adopt easily to subject domains by training their unsupervised models on an in-domain collection.

In future work, we would like to explore better ways of selecting candidate items. While our POS-pattern-based selection mechanism works for practical purposes, it currently only extracts noun phrases and over-generates on compositional adjective modifiers. We would like to define a better filter to reduce over-generation. Further, especially for compounding languages such as German, we would like to decompose one-word compounds as to be able to link their heads in lexical chains.

While we found it important to directly evaluate our lexical chaining algorithms on manually annotated data, a natural next step in this line of research is to use our lexical chaining methods as

pre-processing steps for applications such as summarization, text segmentation or word sense disambiguation. This would enable to find out advantages and disadvantages of our three variants with respect to an application.

The manually annotated data, the open source annotation tool, the annotation guidelines and the implementations of all described methods and baselines are available for download⁸.

Proof: Equality of NMI and V

Using the standard notation from information retrieval $H(X)$ = Entropy, $I(X, Y)$ = Information, $H(X|Y)$ = Conditional Entropy, $NMI(X, Y)$ = Normalized Mutual Information, $V(X, Y)$ = V-Measure:

$$V(C, K) = 2 \times \frac{h \times c}{h + c} \quad (1)$$

$$h = 1 - \frac{H(C|K)}{H(C)} \quad , \quad c = 1 - \frac{H(K|C)}{H(K)} \quad (2)$$

and

$$NMI(C, K) = \frac{I(C, K)}{\frac{H(C)+H(K)}{2}} = 2 \times \frac{I(C, K)}{H(C) + H(K)} \quad (3)$$

reformulate h and c using the fact that $I(C, K) = H(C) - H(C|K) = H(K) - H(K|C)$:

$$h = 1 - \frac{H(C|K)}{H(C)} \quad c = 1 - \frac{H(K|C)}{H(K)} \quad (4)$$

$$= \frac{H(C)}{H(C)} - \frac{H(C|K)}{H(C)} \quad (4) \quad = \frac{H(K)}{H(K)} - \frac{H(K|C)}{H(K)} \quad (5)$$

$$= \frac{I(C, K)}{H(C)} \quad = \frac{I(C, K)}{H(K)}$$

simplifying $h \times c$ using (4) and (5):

$$h \times c = \frac{I(C, K)}{H(C)} \times \frac{I(C, K)}{H(K)} \quad (6)$$

$$= \frac{I(C, K)^2}{H(C)H(K)}$$

simplifying $h + c$ using (4) and (5):

$$h + c = \frac{I(C, K)}{H(C)} + \frac{I(C, K)}{H(K)} \quad (7)$$

$$= \frac{I(C, K)H(K) + I(C, K)H(C)}{H(C)H(K)}$$

$$= \frac{I(C, K)[(H(K) + H(C)]}{H(C)H(K)}$$

simplifying $\frac{h \times c}{h + c}$ using (6) and (7):

$$\frac{h \times c}{h + c} = \frac{I(C, K)^2}{H(C)H(K)} \times \frac{H(C)H(K)}{I(C, K)[H(K) + H(C)]} \quad (8)$$

$$= \frac{I(C, K)}{H(K) + H(C)}$$

⁸<http://www.ukp.tu-darmstadt.de/~data/lexical-chains-for-german/>

substituting (8) into (1) shows that NMI and V are equal:

$$V(C, K) = 2 \times \frac{h \times c}{h + c} = 2 \times \frac{I(C, K)}{H(K) + H(C)} = NMI(C, K) \quad (9)$$

Abstract

In this work, we study the problem of measuring relational similarity between two word pairs (e.g., *silverware:fork* and *clothing:shirt*). Due to the large number of possible relations, we argue that it is important to combine multiple models based on heterogeneous information sources. Our overall system consists of two novel general-purpose relational similarity models and three specific word relation models. When evaluated in the setting of a recently proposed SemEval-2012 task, our approach outperforms the previous best system substantially, achieving a 54.1% relative increase in Spearman’s rank correlation.

1 Introduction

The problem of measuring relational similarity is to determine the degree of correspondence between two word pairs. For instance, the analogous word pairs *silverware:fork* and *clothing:shirt* both exemplify well a *Class-Inclusion:Singular_Collective* relation and thus have high relational similarity. Unlike the problem of *attributional similarity*, which measures whether two words share similar attributes and is addressed in extensive research work (Budanitsky and Hirst, 2006; Reisinger and Mooney, 2010; Radinsky et al., 2011; Agirre et al., 2009; Yih and Qazvinian, 2012), measuring relational similarity is a relatively new research direction pioneered by Turney (2006), but with many potential applications. For instance, problems of identifying specific relations between words, such as synonyms,

antonyms or associations, can be reduced to measuring relational similarity compared to prototypical word pairs with the desired relation (Turney, 2008). In scenarios like information extraction or question answering, where identifying the existence of certain relations is often the core problem, measuring relational similarity provides a more flexible solution rather than creating relational classifiers for predefined or task-specific categories of relations (Turney, 2006; Jurgens et al., 2012).

In order to promote this research direction, Jurgens et al. (2012) proposed a new shared task of measuring relational similarity in SemEval-2012 recently. In this task, each submitted system is required to judge the degree of a target word pair having a particular relation, measured by its relational similarity compared to a few prototypical example word pairs. The system performance is evaluated by its correlation with the human judgments using two evaluation metrics, Spearman’s rank correlation and MaxDiff accuracy (more details of the task and evaluation metrics will be given in Sec. 3). Although participating systems incorporated substantial amounts of information from lexical resources (e.g., WordNet) and contextual patterns from large corpora, only one system (Rink and Harabagiu, 2012) is able to outperform a simple baseline that uses PMI (pointwise mutual information) scoring, which demonstrates the difficulty of this task.

In this paper, we explore the problem of measuring relational similarity in the same task setting. We argue that due to the large number of possible relations, building an ensemble of relational simi-

*Work conducted while interning at Microsoft Research.

larity models based on heterogeneous information sources is the key to advance the state-of-the-art on this problem. By combining two general-purpose relational similarity models with three specific word-relation models covering relations like IsA and synonymy/antonymy, we improve the previous state-of-the-art substantially – having a relative gain of 54.1% in Spearman’s rank correlation and 14.7% in the MaxDiff accuracy!

Our main contributions are threefold. First, we propose a novel directional similarity method based on the vector representation of words learned from a recurrent neural network language model. The relation of two words is captured by their vector offset in the latent semantic space. Similarity of relations can then be naturally measured by a distance function in the vector space. This method alone already performs better than all existing systems. Second, unlike the previous finding, where SVMs learn a much poorer model than naive Bayes (Rink and Harabagiu, 2012), we show that using a highly-regularized log-linear model on simple contextual pattern features collected from a document collection of 20GB, a discriminative approach can learn a strong model as well. Third, we demonstrate that by augmenting existing word-relation models, which cover only a small number of relations, the overall system can be further improved.

The rest of this paper is organized as follows. We first survey the related work in Sec. 2 and formally define the problem in Sec. 3. We describe the individual models in detail in Sec. 4. The combination approach is depicted in Sec. 5, along with experimental comparisons to individual models and existing systems. Finally, Sec. 6 concludes the paper.

2 Related Work

Building a classifier to determine whether a relationship holds between a pair of words is a natural approach to the task of measuring relational similarity. While early work was mostly based on hand-crafted rules (Finin, 1980; Vanderwende, 1994), Rosario and Hearst (2001) introduced a machine learning approach to classify word pairs. They targeted classifying noun modifier pairs from the medical domain into 13 classes of semantic relations. Features for each noun modifier pair were constructed

using large medical lexical resources and a multi-class classifier was trained using a feed-forward neural network with one hidden layer. This work was later extended by Nastase and Szpakowicz (2003) to classify general domain noun-modifier pairs into 30 semantic relations. In addition to extracting features using WordNet and Roget’s Thesaurus, they also experimented with several different learners including decision trees, memory-based learning and inductive logic programming methods like RIPPER and FOIL. Using the same dataset as in (Nastase and Szpakowicz, 2003), Turney and Littman (2005) created a 128-dimentional feature vector for each word pair based on statistics of their co-occurrence patterns in Web documents and applied the k -NN method ($k = 1$ in their work).

Measuring relational similarity, which determines whether two word pairs share the same relation, can be viewed as an extension of classifying relations between two words. Treating a relational similarity measure as a distance metric, a testing pair of words can be judged by whether they have a relation that is *similar* to some prototypical word pairs having a particular relation. A multi-relation classifier can thus be built easily in this framework as demonstrated in (Turney, 2008), where the problems of identifying synonyms, antonyms and associated words are all reduced to finding good analogous word pairs. Measuring relational similarity has been advocated and pioneered by Turney (2006), who proposed a latent vector space model for answering SAT analogy questions (e.g., *mason:stone* vs. *carpenter:wood*). In contrast, we take a slightly different view when building a relational similarity measure. Existing classifiers for specific word relations (e.g., synonyms or Is-A) are combined with general relational similarity measures. Empirically, mixing heterogeneous models tends to make the final relational similarity measure more robust.

Although datasets for semantic relation classification or SAT analogous questions can be used to evaluate a relational similarity model, their labels are either binary or categorical, which makes the datasets suboptimal for determining the quality of a model when evaluated on instances of the same relation class. As a result, Jurgens et al. (2012) proposed a new task of “Measuring Degrees of Relational Similarity” at SemEval-2012, which includes 79 relation

categories exemplified by three or four prototypical word pairs and a schematic description. For example, for the *Class-Inclusion:Taxonomic* relation, the schematic description is “*Y is a kind/type/instance of X*”. Using Amazon Mechanical Turk¹, they collected word pairs for each relation, as well as their degrees of being a good representative of a particular relation when compared with defining examples. Participants of this shared task proposed various kinds of approaches that leverage both lexical resources and general corpora. For instance, the Duluth systems (Pedersen, 2012) created word vectors based on WordNet and estimated the degree of a relation using cosine similarity. The BUAP system (Tovar et al., 2012) represented each word pair as a whole by a vector of 4 different types of features: context, WordNet, POS tags and the average number of words separating the two words in text. The degree of relation was then determined by the cosine distance of the target pair from the prototypical examples of each relation. Although their models incorporated a significant amount of information of words or word pairs, unfortunately, the performance were not much better than a random baseline, which indicates the difficulty of this task. In comparison, a supervised learning approach seems more promising. The UTD system (Rink and Harabagiu, 2012), which mined lexical patterns between co-occurring words in the corpus and then used them as features to train a Naive Bayes classifier, achieved the best results. However, potentially due to the large feature space, this strategy did not work as well when switching the learning algorithm to SVMs.

3 Problem Definition & Task Description

Following the setting of SemEval-2012 Task 2 (Jurgens et al., 2012), the problem of measuring the degree of relational similarity is to rate word pairs by the degree to which they are prototypical members of a given relation class. For instance, comparing to the prototypical word pairs, $\{\text{cutlery:spoon}, \text{clothing:shirt}, \text{vermin:rat}\}$ of the *Class-Inclusion:Singular_Collective* relation, we would like to know among the input word pairs $\{\text{dish:bowl}, \text{book:novel}, \text{furniture:desk}\}$, which one

best demonstrates the relation.

Because our approaches are evaluated using the data provided in this SemEval-2012 task, we describe briefly below how the data was collected, as well as the metrics used to evaluate system performance. The dataset consists of 79 relation classes that are chosen according to (Bejar et al., 1991) and broadly fall into 10 main categories, including *Class-Inclusion*, *Part-Whole*, *Similar* and more. With the help of Amazon Mechanical Turk, Jurgens et al. (2012) used a two-phase approach to collect word pairs and their degrees. In the first phase, a lexical schema, such as “*a Y is one item in a collection/group of X*” for the aforementioned relation *Class-Inclusion:Singular_Collective*, and a few prototypical pairs for each class were given to the workers, who were asked to provide approximately a list of 40 word pairs representing the same relation class. Naturally, some of these pairs were better examples than the others. Therefore, in the second phase, the goal was to measure the degree of their similarity to the corresponding relation. This was done using the MaxDiff technique (Louviere and Woodworth, 1991). For each relation, about one hundred questions were first created. Each question consists of four different word pairs randomly sampled from the list. The worker was then asked to choose the most and least representative word pairs for the specific relation in each question.

The set of 79 word relations were randomly split into *training* and *testing* sets. The former contains 10 relations and the latter has 69. Word pairs in all 79 relations were given to the task participants in advance, but only the human judgments of the *training* set were available for system development. In this work, we treat the training set as the validation set – all the model exploration and refinement is done using this set of data, as well as the hyper-parameter tuning when learning the final model combination.

The quality of a relational similarity measure is estimated by its correlation to human judgments. This is evaluated using two metrics in the task: the MaxDiff accuracy and Spearman’s rank correlation coefficient (ρ). A system is first asked to pick the most and least representative word pairs of each question in the MaxDiff setting. The average accuracy of the predictions compared to the human answers is then reported. In contrast, Spearman’s ρ

¹<http://www.mturk.com>

measures the correlation between the total orderings of all word pairs of a relation, where the total ordering is derived from the MaxDiff answers (see (Jurgen et al., 2012) for the exact procedure).

4 Models for Relational Similarity

We investigate three types of models for relational similarity. Operating in a word vector space, the *directional similarity* model compares the vector differences of target and prototypical word pairs to estimate their relational similarity. The *lexical pattern* method collects contextual information of pairs of words when they co-occur in large corpora, and learns a highly regularized log-linear model. Finally, the *word relation* models incorporate existing, specific word relation measures for general relational similarity.

4.1 Directional Similarity Model

Our first model for relational similarity extends previous work on semantic word vector representations to a directional similarity model for pairs of words. There are many different methods for creating real-valued semantic word vectors, such as the distributed representation derived from a word co-occurrence matrix and a low-rank approximation (Landauer et al., 1998), word clustering (Brown et al., 1992) and neural-network language modeling (Bengio et al., 2003; Mikolov et al., 2010). Each element in the vectors conceptually represents some latent topicality information of the word. The goal of these methods is that words with similar meanings will tend to be close to each other in the vector space.

Although the vector representation of *single* words has been successfully applied to problems like semantic word similarity and text classification (Turian et al., 2010), the issue of how to represent and compare pairs of words in a vector space remains unclear (Turney, 2012). In a companion paper (Mikolov et al., 2013), we present a vector offset method which performs consistently well in identifying both syntactic and semantic regularities. This method measures the degree of the analogy “*a* is to *b* as *c* is to *d*” using the cosine score of $(\vec{v}_b - \vec{v}_a + \vec{v}_c, \vec{v}_d)$, where *a*, *b*, *c*, *d* are the four given words and $\vec{v}_a, \vec{v}_b, \vec{v}_c, \vec{v}_d$ are the corresponding vec-

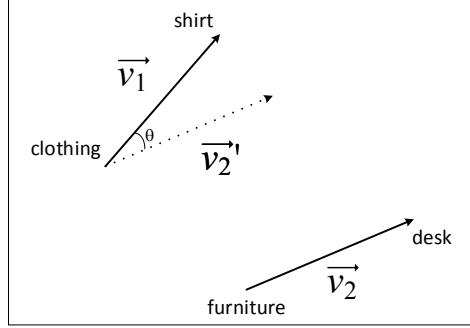

Figure 1: Directional vectors v_1 and v_2 capture the relations of *clothing:shirt* and *furniture:desk* respectively in this semantic vector space. The relational similarity of these two word pairs is estimated by the cosine of θ .

tors. In this paper, we propose a variant called the *directional similarity* model, which performs better for semantic relations. Let $\omega_i = (w_{i1}, w_{i2})$ and $\omega_j = (w_{j1}, w_{j2})$ be the two word pairs being compared. Suppose $(\vec{v}_{i1}, \vec{v}_{i2})$ and $(\vec{v}_{j1}, \vec{v}_{j2})$ are the corresponding vectors of these words. The *directional vectors* of ω_i and ω_j are defined as $\vec{v}_i \equiv \vec{v}_{i2} - \vec{v}_{i1}$ and $\vec{v}_j \equiv \vec{v}_{j2} - \vec{v}_{j1}$, respectively. Relational similarity of these two word pairs can be measured by some distance function of v_i and v_j , such as the cosine function:

$$\frac{\vec{v}_i \cdot \vec{v}_j}{\|\vec{v}_i\| \|\vec{v}_j\|}$$

The rationale behind this variant is as follows. Because the difference of two word vectors reveals the change from one word to the other in terms of multiple topicality dimensions in the vector space, two word pairs having similar offsets (i.e., being relatively parallel) can be interpreted as they have similar relations. Fig. 1 further illustrates this method.

Compared to the original method, this variant places less emphasis on the similarity between words w_{j1} and w_{j2} . That similarity is necessary for syntactic relations where the words are often related by morphology, but not for semantic relations. On semantic relations studied in this paper, the *directional similarity* model performs about 18% relatively better in Spearman’s ρ than the original one.

The quality of the directional similarity method depends heavily on the underlying word vector space model. We compared two choices with dif-

Word Embedding	Spearman's ρ	MaxDiff Acc. (%)
LSA-80	0.055	34.6
LSA-320	0.066	34.4
LSA-640	0.102	35.7
RNNLM-80	0.168	37.5
RNNLM-320	0.214	39.1
RNNLM-640	0.221	39.2
RNNLM-1600	0.234	41.2

Table 1: Results of measuring relational similarity using the directional similarity method, evaluated on the training set. The 1600-dimensional RNNLM vector space achieves the highest Spearman's ρ and MaxDiff accuracy.

ferent dimensionality settings: the word embedding learned from the recurrent neural network language model (RNNLM)² and the LSA vectors, both were trained using the same Broadcast News corpus of 320M words as described in (Mikolov et al., 2011). All the word vectors were first normalized to unit vectors before applying the directional similarity method. Given a target word pair, we computed its relational similarity compared with the prototypical word pairs of the same relation. The average of these measurements was taken as the final model score. Table 1 summarizes the results when evaluated on the training set. As shown in the table, the RNNLM vectors consistently outperform their LSA counterparts with the same dimensionality. In addition, more dimensions seem to preserve more information and lead to better performance. Therefore, we take the 1600-dimensional RNNLM vectors to construct our final directional similarity model.

4.2 Lexical Pattern Model

Our second model for measuring relational similarity is built based on lexical patterns. It is well-known that contexts in which two words co-occur often provide useful cues for identifying the word relation. For example, having observed frequent text fragments like “*X such as Y*”, it is likely that there is a *Class-Inclusion:Taxonomic* relation between *X* and *Y*; namely, *Y* is a type of *X*. Indeed, by mining lexical patterns from a large corpus, the UTD system (Rink and Harabagiu, 2012) managed to outperform other participants in the SemEval-2012 task of measuring relational similarity.

²<http://www.fit.vutbr.cz/~imikolov/rnnlm>

In order to find more co-occurrences of each pair of words, we used a large document set that consists of the Gigaword corpus (Parker et al., 2009), Wikipedia and LA Times articles³, summing up to more than 20 Gigabytes of texts. For each word pair (w_1, w_2) that co-occur in a sentence, we collected the words in between as its *context* (or so-called “raw pattern”). For instance, “such as” would be the context extracted from “*X such as Y*” for the word pair (*X*, *Y*). To reduce noise, contexts with more than 9 words were dropped and 914,295 patterns were collected in total.

Treating each raw pattern as a feature where the value is the logarithm of the occurrence count, we then built a probabilistic classifier to determine the association of the context and relation. For each relation, we treated all its word pairs as positive examples and all the word pairs in other relations as negative examples⁴. 79 classifiers were trained in total, where each one was trained using 3,218 examples. The degree of relational similarity of each word pair can then be judged by the output of the corresponding classifier⁵. Although this seems like a standard supervised learning setting, the large number of features poses a challenge here. Using almost 1M features and 3,218 examples, the model could easily overfit if not regularized properly, which may explain why learning SVMs on pattern features performed poorly (Rink and Harabagiu, 2012). Instead of employing explicit feature selection methods, we used an efficient L_1 regularized log-linear model learner (Andrew and Gao, 2007) and chose the hyper-parameters based on model performance on the training data. The final models we chose were trained with $L_1 = 3$, where 28,065 features in average were selected automatically by the algo-

³We used a Nov-2010 dump of English Wikipedia, which contains approximately 917M words after pre-processing. The LA Times corpus consists of articles from 1985 to 2002 and has about 1.1B words.

⁴Given that not all word pairs belonging to the same relation category are equally good, removing those with low judgment scores may help improve the quality of the labeled data. We leave this study to future work.

⁵Training a separate classifier for each MaxDiff question using all words pairs except the four target pairs appears to be a better setting, as it would avoid including the target pairs in the training process. We did not use this setting because it is more complicated and performed roughly the same empirically.

rithm. The performance on the training data is 0.322 in Spearman’s ρ and 41.8% in MaxDiff accuracy.

4.3 Word Relation Models

The directional similarity and lexical pattern models can be viewed as *general* purpose methods for relational similarity as they do not differentiate the specific relation categories. In contrast, for *specific* word relations, there exist several high-quality methods. Although they are designed for detecting specific relations between words, incorporating them could still improve the overall results. Next, we explore the use of some of these word relation models, including information encoded in the knowledge base and a lexical semantic model for synonymy and antonymy.

4.3.1 Knowledge Bases

Predetermined types of relations can often be found in existing lexical and knowledge databases, such as WordNet’s Is-A taxonomy and the extensive relations stored in the NELL (Carlson et al., 2010) knowledge base. Although in theory, these resources can be directly used to solve the problem of relational similarity, such direct approaches often suffer from two practical issues. First, the word coverage of these databases is usually very limited and it is common that the relation of a given word pair is absent. Second, the degree of relation is often not included, which makes the task of measuring the degree of relational similarity difficult.

One counter example, however, is Probbase (Wu et al., 2012), which is a knowledge base that establishes connections between more than 2.5 million concepts discovered automatically from the Web. For the *Is-A* and *Attribute* relations it encodes, Probbase also returns the probability that two input words share the relation, based on the co-occurrence frequency. We used some relations in the training set to evaluate the quality of Probbase. For instance, its Is-A model performs exceptionally well on the relation *Class-Inclusion:Taxonomic*, reaching a high Spearman’s $\rho = 0.642$ and MaxDiff accuracy 55.8%. Similarly, its Attribute model performs better than our lexical pattern model on *Attribute:Agent_Attribute-State* with Spearman’s $\rho = 0.290$ and MaxDiff accuracy 32.7%.

4.3.2 Lexical Semantics Measures

Most lexical semantics measures focus on the semantic similarity or relatedness of two words. Since our task focuses on distinguishing the difference between word pairs in the *same* relation category. The crude relatedness model does not seem to help in our preliminary experimental study. Instead, we leverage the recently proposed polarity-inducing latent semantic analysis (PILSA) model (Yih et al., 2012), which specifically estimates the degree of synonymy and antonymy. This method first forms a signed co-occurrence matrix using synonyms and antonyms in a thesaurus and then generalizes it using a low-rank approximation derived by SVD. Given two words, the cosine score of their PILSA vectors tend to be negative if they are antonymous and positive if synonymous. When tested on the *Similar:Synonymity* relation, it has a Spearman’s $\rho = 0.242$ and MaxDiff accuracy 42.1%, both are better than those of our directional similarity and lexical pattern models.

5 Model Combination

In order to fully leverage the diverse models proposed in Sec. 4, we experiment with a model combination approach and conduct a model ablation study. Performance of the combined and individual models is evaluated using the *test* set and compared with existing systems.

We seek an optimal linear combination of all the individual models by treating their output as *features* and use a logistic regression learner to learn the weights⁶. The training setting is essentially the same as the one used to learn the lexical pattern model (Sec. 4.2). For each relation, we treat all the word pairs in this relation group as positive examples and all other word pairs as negative ones. Consequently, 79 sets of weights for model combination are learned in total. The average Spearman’s ρ of the 10 training relations is used for selecting the values of the L_1 and L_2 regularizers⁷. Evaluated on the remaining 69 relations (i.e., the test set), the average results of each main relation group and the overall

⁶Nonlinear methods, such as MART (Friedman, 2001), do not perform better in our experiments (not reported here).

⁷We tested 15 combinations, where $L_1 \in \{0, 0.01, 0.1\}$ and $L_2 \in \{0, 0.001, 0.01, 1, 10\}$. The parameter setting that gave the highest Spearman rank correlation coefficient score on the training set was selected.

Table 2: Average Spearman’s ρ (Top) and MaxDiff accuracy (%) (Bottom) of each major relation group and all 69 testing relations. The best result in each row is highlighted in boldface font. Statistical significance tests are conducted by comparing each of our systems with the previous best performing system, UTD_{NB}. \dagger and \ddagger indicate the difference in the average results is statistically significant with 95% or 99% confidence level, respectively.

results are presented in Table 2. For comparison, we also show the performance of a random baseline and the best performing system of each participant in the SemEval-2012 task.

We draw two conclusions from this table. First, both of our general relational similarity models, the directional similarity (DS) and lexical pattern (Pat) models are fairly strong. The former outperforms the previous best system UTD_{NB} in both Spearman’s ρ and MaxDiff accuracy, where the differences are statistically significant⁸; the latter has comparable performance, where the differences are not statistically significant. In contrast, while the IsA relation from Probbase is exceptionally good in identifying *Class-Inclusion* relations, with high Spearman’s $\rho = 0.619$ and MaxDiff accuracy

⁸We conducted a paired- t test on the results of each of the 69 relation. The difference is considered statistically significant if the p -value is less than 0.05.

59.6%, it does not have high correlations with human judgments in other relations. Like in the case of Probbase Attribute and PILSA, specific word-relation models individually are not good measures for general relational similarity. Second, as expected, combining multiple diverse models (Com) is a robust strategy, which provides the best overall performance. It achieves superior results in both evaluation metrics compared to UTD_{NB} and only a lower Spearman’s ρ value in one of the ten relation groups (namely, *Reference*). The differences are statistically significant with p -value less than 10^{-3} .

In order to understand the interaction among different component models, we conducted an ablation study by iteratively removing one model from the final combination. The weights are re-trained using the same procedure that finds the best regularization parameters with the help of training data. Table 3 summarizes the results and compares them with the

Table 3: Average Spearman’s ρ and MaxDiff accuracy results of different model combinations. *Com* indicates combining all models, where other columns show the results when the specified model is removed. The best result in each row is highlighted in boldface font. Statistical significance tests are conducted by comparing each ablation configuration with *Com*. \ddagger indicates the difference in the average results is statistically significant with 99% confidence level.

original combination model.

Overall, it is clear that the directional similarity method based on RNNLM vectors is the most critical component model. Removing it from the final combination decreases both the Spearman’s ρ and MaxDiff accuracy by a large margin; both differences (*Com* vs. -DS) are statistically significant. The Probase IsA model also has an important impact on the performance on the *Class-Inclusion* relation group. Eliminating the IsA model makes the overall MaxDiff accuracy statistically significantly lower (*Com* vs. -IsA). Again, the benefits of incorporating Probase Attribute and PILSA models are not clear. Removing them from the final combination lowers the MaxDiff accuracy, but neither the difference in Spearman’s ρ nor MaxDiff accuracy is statistically significant. Compared to the RNNLM directional similarity model, the lexical pattern model seems less critical. Removing it lowers the *Similar* and *Contrast* relation groups, but improves some other relation groups like *Class-Inclusion* and *Case Relations*. The final MaxDiff accuracy becomes slightly higher but the Spearman’s ρ drops a little (*Com* vs. -Pat); neither is statistically significant.

Notice that the main purpose of the ablation study is to verify the importance of an individual component model when a significant performance drop is observed after removing it. However, occasionally the overall performance may go up slightly. Typi-

cally this is due to the fact that some models do not provide useful signals to a particular relation, but instead introduce more noise. Such effects can often be alleviated when there are enough quality training data, which is unfortunately not the case here.

6 Conclusions

In this paper, we presented a system that combines heterogeneous models based on different information sources for measuring relational similarity. Our two individual general-purpose relational similarity models, *directional similarity* and *lexical pattern* methods, perform strongly when compared to existing systems. After incorporating specific word-relation models, the final system sets a new state-of-the-art on the SemEval-2012 task 2 test set, achieving Spearman’s $\rho = 0.353$ and MaxDiff accuracy 45.4% – resulting in 54.1% and 14.7% relative improvement in these two metrics, respectively.

Despite its simplicity, our directional similarity approach provides a robust model for relational similarity and is a critical component in the final system. When the lexical pattern model is included, our overall model combination method can be viewed as a two-stage learning system. As demonstrated in our work, with an appropriate regularization strategy, high-quality models can be learned in both stages. Finally, as we observe from the positive effect of adding the Probase IsA model, specific word-relation models can further help improve the system

although they tend to cover only a small number of relations. Incorporating more such models could be a steady path to enhance the final system.

In the future, we plan to pursue several research directions. First, as shown in our experimental results, the model combination approach does not always outperform individual models. Investigating how to select models to combine for each specific relation or relation group individually will be our next step for improving this work. Second, because the labeling process of relational similarity comparisons is inherently noisy, it is unrealistic to request a system to correlate human judgments perfectly. Conducting some user study to estimate the performance ceiling in each relation category may help us focus on the weaknesses of the final system to enhance it. Third, it is intriguing to see that the directional similarity model based on the RNNLM vectors performs strongly, even though the RNNLM training process is not related to the task of relational similarity. Investigating the effects of different vector space models and proposing some theoretical justifications are certainly interesting research topics. Finally, we would like to evaluate the utility our approach in other applications, such as the SAT analogy problems proposed by Turney (2006) and question answering.

Abstract

Hidden properties of social media users, such as their ethnicity, gender, and location, are often reflected in their observed attributes, such as their first and last names. Furthermore, users who communicate with each other often have similar hidden properties. We propose an algorithm that exploits these insights to cluster the observed attributes of hundreds of millions of Twitter users. Attributes such as user names are grouped together if users with those names communicate with other similar users. We separately cluster millions of unique first names, last names, and user-provided locations. The efficacy of these clusters is then evaluated on a diverse set of classification tasks that predict hidden users properties such as ethnicity, geographic location, gender, language, and race, using only profile names and locations when appropriate. Our readily-replicable approach and publicly-released clusters are shown to be remarkably effective and versatile, substantially outperforming state-of-the-art approaches and human accuracy on each of the tasks studied.

1 Introduction

There is growing interest in automatically classifying users in social media by various hidden properties, such as their gender, location, and language (e.g. Rao et al. (2010), Cheng et al. (2010), Bergsma et al. (2012)). Predicting these and other properties for users can enable better advertising and personalization, as well as a finer-grained analysis of user opinions (O’Connor et al., 2010), health (Paul

and Dredze, 2011), and sociolinguistic phenomena (Eisenstein et al., 2011). Classifiers for user properties often rely on information from a user’s social network (Jernigan and Mistree, 2009; Sadilek et al., 2012) or the textual content they generate (Pennacchiotti and Popescu, 2011; Burger et al., 2011).

Here, we propose and evaluate classifiers that better exploit the *attributes* that users explicitly provide in their user profiles, such as names (e.g., first names like *Mary*, last names like *Smith*) and locations (e.g., *Brasil*). Such attributes have previously been used as “profile features” in supervised user classifiers (Pennacchiotti and Popescu, 2011; Burger et al., 2011; Bergsma et al., 2012). There are several motivations for exploiting these data. Often the only information available for a user is a name or location (e.g. for a new user account). Profiles also provide an orthogonal or complementary source of information to a user’s social network and textual content; gains based on profiles alone should therefore add to gains based on other data. The decisions of profile-based classifiers could also be used to bootstrap training data for other classifiers that use complementary features.

Prior work has encoded profile attributes via lexical or character-based features (e.g. Pennacchiotti and Popescu (2011), Burger et al. (2011), Bergsma et al. (2012)). Unfortunately, due to the long-tailed distribution of user attributes, a profile-based classifier will encounter many examples at test time that were not observed during training. For example, suppose a user *wassim hassan* gives their location as *tanger*. If the attribute tokens *wassim*, *hassan*, and *tanger* do not occur in training (nor indicative sub-

strings), then a classifier can only guess at the user’s ethnicity and location. In social media, the prevalence of fake names and large variations in spelling, slang, and language make matters worse.

Our innovation is to enhance attribute-based classifiers with new data, derived from the communications of Twitter users with those attributes. Users with the name tokens *wassim* and *hassan* often talk to users with Arab names like *abdul* and *hussein*. Users listing their location as *tanger* often talk to users from *morocco*. Since users who communicate often share properties such as ethnicity and location (§8), the user *wassim hassan* might be an Arab who uses the French spelling of the city *Tangier*.

Our challenge is to encode these data in a form readily usable by a classifier. Our approach is to represent each unique profile attribute (e.g. *tanger* or *hassan*) as a vector that encodes the communication pattern of users with that attribute (e.g. how often they talk to users from *morocco*, etc.); we then cluster the vectors to discover latent groupings of similar attributes. Based on transitive (third party) connections, *tanger* and *tangier* can appear in the same cluster, even if no two users from these locations talk directly. To use the clusters in an attribute-based classifier, we add new features that indicate the cluster memberships of the attributes. Clustering thus lets us convert a high-dimensional space of all attribute pairs to a low-dimensional space of cluster memberships. This makes it easier to share our data, yields fewer parameters for learning, and creates attribute groups that are interpretable to humans.

We cluster names and locations in a very large corpus of 168 million Twitter users (§2) and use a distributed clustering algorithm to separately cluster millions of first names, last names, and user-provided locations (§3). We evaluate the use of our cluster data as a novel feature in supervised classifiers, and compare our result to standard classifiers using character and token-level features (§4). The cluster data enables significantly improved performance in predicting the gender, location, and language of social media users, exceeding both existing state-of-the-art machine and human performance (§6). Our cluster data can likewise improve performance in other domains, on both established and new NLP tasks as further evaluated in this paper (§6). We also propose a way to

<i>First names:</i>	maria, david, ana, daniel, michael, john, alex, jessica, carlos, jose, chris, sarah, laura, juan
<i>Last names:</i>	silva, santos, smith, garcia, oliveira, rodriguez, jones, williams, johnson, brown, gonzalez
<i>Locations:</i>	brasil, indonesia, philippines, london, jakarta, são paulo, rio de janeiro, venezuela, brazil

Table 1: Most frequent profile attributes for our collection of 168 million Twitter users, in descending order

enhance a geolocation system by using communication patterns, and show strong improvements over a hand-engineered baseline (§7). We share our clusters with the community to use with other tasks. The clusters, and other experimental data, are available for download from www.clsp.jhu.edu/~sbergsma/TwitterClusters/.

2 Attribute Associations on Twitter

Data and Processing Our raw Twitter data comprises the union of 2.2 billion tweets from 05/2009 to 10/2010 (O’Connor et al., 2010), 1.8 billion tweets collected from 07/2011 to 08/2012, and 80 million tweets collected from followers of 10 thousand location and language-specific Twitter feeds.

We implemented each stage of processing using MapReduce (Dean and Ghemawat, 2008). The total computation (from extracting profiles to clustering attributes) was 1300 days of wall-clock CPU time.

Attribute Extraction Tweets provide the name and self-reported location of the tweeter. We find 126M unique users with these attributes in our data. When tweets mention other users via an @user construction, Twitter also includes the profile name of the mentioned user; we obtain a further 42M users from these cases. We then normalize the extracted attributes by converting to lower-case, deleting symbols, numbers, and punctuation, and removing common honorifics and suffixes like *mr/mrs* and *jr/sr*. Common prefixes like *van* and *de la* are joined to the last-name token.¹ This processing yields 8.3M

¹www.clsp.jhu.edu/~sbergsma/TwitterClusters/ also provides our scripts for normalizing attributes. The scripts can be used to ensure consistency/compatibility between arbitrary datasets and our shared cluster data. Note we use no special processing for the companies, organizations, and spammers among our users, nor for names arising from different conventions (e.g. 1-word names, reversed first/last names).

Table 2: Top associates and PMIs for three first names.

unique locations, 7.4M unique last names, and 5.5M unique first names. These three sets provide the target attributes that we cluster in §3. Table 1 shows the most frequent names in each of these three sets.

User-User Links We extract each user mention as an undirected communication link between the user tweeting and the mentioned user (including self-mentions but not retweets). We consider each user-user link as a single event; we count it once no matter how often two specific users interact. We extract 436M user-user links in total.

Attribute-Attribute Pairs We use our profile data to map each user-user link to an attribute-attribute pair; we separately count each pair of first names, last names, and locations. For example, the first-name pair (*henrik, fredrik*) occurs 181 times. Rather than using the raw count, we calculate the association between attributes a_1 and a_2 via their pointwise mutual information (PMI), following prior work in distributional clustering (Lin and Wu, 2009):

$$\text{PMI}(a_1, a_2) = \log \frac{\text{P}(a_1, a_2)}{\text{P}(a_1)\text{P}(a_2)}$$

PMI essentially normalizes the co-occurrence by what we would expect if the attributes were independently distributed. We smooth the PMI by adding a count of 0.5 to all co-occurrence events.

The most highly-associated name attributes reflect similarities in ethnicity and gender (Table 2). The most highly-ranked associates for locations are often nicknames and alternate/misspellings of those locations. For example, the locations *charm city*, *bmore*, *balto*, *westbaltimore*, *b a l t i m o r e*, *baltimoreee*, and *balitmore* each have the U.S. city of *baltimore* as their highest-PMI associate. We show how this can be used to help geolocate users (§7).

3 Attribute Clustering

Representation We first represent each target attribute as a feature vector, where each feature corresponds to another attribute of the same type as the target and each value gives the PMI between this attribute and the target (as in Table 2).² To help cluster the long-tail of infrequent attributes, we also include orthographic features. For first and last names, we have binary features for the last 2 characters in the string. For locations, we have binary features for (a) any ideographic characters in the string and (b) each token (with diacritics removed) in the string. We normalize the feature vectors to unit length.

Distributed K-Means Clustering Our approach to clustering follows Lin and Wu (2009) who used k-means to cluster tens of millions of phrases. We also use cosine similarity to compute the closest centroid (i.e., we use the *spherical* k-means clustering algorithm (Dhillon and Modha, 2001)). We keep track of the average cosine similarity between each vector and its nearest centroid; this average is guaranteed to increase at each iteration.

Like Lin and Wu (2009), we parallelize the algorithm using MapReduce. Each mapper finds the nearest centroids for a portion of the vectors, while also computing the partial sums of the vectors assigned to each centroid. The mappers emit the centroid IDs as keys and the partial sums as values. The Reducer aggregates the partial sums from each partition and re-normalizes each sum vector to unit length to obtain the new centroids. We also use an inverted index at each iteration that, for each input feature, lists which centroids each feature belongs to. Using this index greatly speeds up the centroid similarity computations.

Clustering Details We cluster with nine separate configurations: over first names, last names, and locations, and each with 50, 200, and 1000 cluster centroids (denoted C^{50} , C^{200} , and C^{1000}). Since k-

²We decided to restrict the features for a target to be attributes of the same type (e.g., we did not use *last name* associations for a *first name* target) because each attribute type conveys distinct information. For example, first names convey gender and age more than last names. By separately clustering representations using first names, last names, and locations, each clustering can capture its own distinct latent-class associations.

<i>Cluster 463</i> (Serbian): pavlović, jovanovic, jo-vanović, stanković, srbiја, marković, petrović, radovic, nenad, milenkovic, nikolic, sekulic, todorovic, stojanovic, petrovic, aleksic, ilic, markovic

Table 3: Example C^{1000} last-name clusters

<i>Cluster 56</i> [sim=0.497]: gregg, bryn, bret, stewart, lyndsay, howie, elyse, jacqui, becki, rhett, meaghan, kirstie, russ, jaclyn, zak, katey, seamus, brennan, fraser, kristie, stu, jaimie, kerri, heath, carley, griffin
<i>Cluster 104</i> [sim=0.442]: stephon, devonte, deion, demarcus, janae, tyree, jarvis, donte, dewayne, javon, destinee, tray, janay, tyrell, jamar, iesha, chyna, jaylen, darion, lamont, marquise, domonique, alexus
<i>Cluster 132</i> [sim=0.292]: moustafa, omnya, mennatallah, إسلام, shorouk, ragab, رؤي, radwa, moemen, mohab, hazem, yehia, حرية, اسراء, mennah, مصرى, abdelrahman, حزب مصطفى، تامر، nermeen, hebatallah
...

Table 4: C^{200} soft clustering for first name *yasmeen*

means is not guaranteed to reach a global optimum, we use ten different random initializations for each configuration, and select the one with the highest average similarity after 20 iterations. We run this one for an additional 30 iterations and take the output as our final set of centroids for that configuration.

The resulting clusters provide data that could help classify hidden properties of social media users. For example, Table 3 shows that last names often cluster by ethnicity, even at the sub-national level (e.g. Zulu tribe surnames *nkosi*, *dlamini*, *mathebula*, etc.). Note the Serbian names include two entries that are not last names: *srbiја*, the Serbian word for *Serbia*, and *nenad*, a common Serbian first name.

Soft Clustering Rather than assigning each attribute to its single highest-similarity cluster, we can assign each vector to its N most similar clusters. These soft-cluster assignments often reflect different social groups where a name or location is used. For example, the name *yasmeen* is similar to both common American names (Cluster 56), African American names (Cluster 104), and Arabic names (Cluster 132) (Table 4). As another example, the C^{1000} assignments for the location *trujillo* comprise separate clusters containing towns and cities in Peru, Venezuela, Colombia, etc., reflecting the various places in the Latin world with this name. In general, the soft cluster assignment is a low-dimensional representation of each of our attributes. Although it can be interpretable to humans, it need not be in order to be useful to a classifier.

4 Classification with Cluster Features

Our motivating problem is to classify users for hidden properties such as their gender, location, race, ethnicity, and language. We adopt a discriminative solution. We encode the relevant data for each instance in a feature vector and train a (linear) support vector machine classifier (Cortes and Vapnik, 1995). SVMs represent the state-of-the-art on many NLP classification tasks, but other classifiers could also be used. For multi-class classification, we use a one-versus-all strategy, a competitive approach on most multi-class problems (Rifkin and Klautau, 2004).

The input to our system is one or more observed user attributes (e.g. name and location fields from a user profile). We now describe how features are created from these attributes in both state-of-the-art systems and via our new cluster data.

Token Features (*Tok*) are binary features that indicate the presence of a specific attribute (e.g., *first-name=bob*). Burger et al. (2011) and Bergsma et al. (2012) used *Tok* features to encode user profile features. For multi-token fields (e.g. location), our *Tok* features also indicate the specific position of each token (e.g., $loc_1=s\tilde{a}o$, $loc_2=paulo$, $loc_N=brasil$).

Character N-gram Features (*Ngm*) give the count of all character n-grams of length 1-to-4 in the input. *Ngm* features have been used in user classification (Burger et al., 2011) and represent the state-

of-the-art in detecting name ethnicity (Bhargava and Kondrak, 2010). We add special begin/end characters to the attributes to mark the prefix and suffix positions. We also use a smoothed log-count; we found this to be most effective in preliminary work.

Cluster Features (*Clus*) indicate the soft-cluster memberships of the attributes. We have features for the top-2, 5, and 20 most similar clusters in the C^{50} , C^{200} , and C^{1000} clusterings, respectively. Like Lin and Wu (2009), we “side-step the matter of choosing the optimal value k in k-means” by using features from clusterings at different granularities. Our feature dimensions correspond to cluster IDs; feature values give the similarity to the cluster centroid. Other strategies (e.g. hard clustering, binary features) were less effective in preliminary work.

5 Classification Experiments

5.1 Methodology

Our main objective is to assess the value of using cluster features (*Clus*). We add these features to classifiers using *Tok+Ngm* features, which represents the current state-of-the-art. We compare these feature settings on both Twitter tasks (§5.2) and tasks not related to social-media (§5.3). For each task, we randomly divide the gold standard data into 50% train, 25% development and 25% test, unless otherwise noted. As noted above, the gold-standard datasets for all of our experiments are available for download. We train our SVM classifiers using the LIBLINEAR package (Fan et al., 2008). We optimize the classifier’s regularization parameter on development data, and report our final results on the held-out test examples. We report *accuracy*: the proportion of test examples classified correctly. For comparison, we report the accuracy of a majority-class baseline on each task (*Base*).

Classifying hidden properties of social media users is challenging (Table 5). Pennacchiotti and Popescu (2011) even conclude that “profile fields do not contain enough good-quality information to be directly used for user classification.” To provide insight into the difficulty of the tasks, we had two humans annotate 120 examples from each of the test sets, and we average their results to give a “*Human*” performance number. The two humans are experts in

this domain and have very wide knowledge of global names and locations.

5.2 Twitter Applications

Country A number of recent papers have considered the task of predicting the geolocation of users, using both user content (Cheng et al., 2010; Eisenstein et al., 2010; Hecht et al., 2011; Wing and Baldridge, 2011; Roller et al., 2012) and social network (Backstrom et al., 2010; Sadilek et al., 2012).

Here, we first predict user location at the level of the user’s location *country*. To our knowledge, we are the first to exploit user locations *and* names for this prediction. For this task, we obtain gold data from the portion of Twitter users who have GPS enabled (geocoded tweets). We were able to obtain a very large number of gold instances for this task, so selected only 10K for testing, 10K for development, and retained the remaining 782K for training.

Language ID Identifying the language of users is an important prerequisite for building language-specific social media resources (Tromp and Pech-

enizkiy, 2011; Carter et al., 2013). Bergsma et al. (2012) recently released a corpus of tweets marked for one of nine languages grouped into three confusable character sets: Arabic, Farsi, and Urdu tweets written in Arabic characters; Hindi, Nepali, and Marathi written in Devanagari, and Russian, Bulgarian, and Ukrainian written in Cyrillic. The tweets were marked for language by native speakers via Amazon Mechanical Turk. We again discard the tweet content and extract each user’s first name, last name, and user location as our input data, while taking the annotated language as the class label.

Gender We predict whether a Twitter user is male or female using data from Burger et al. (2011). This data was created by linking Twitter users to structured profile pages on other websites where users must select their gender. Unlike prior systems using this data (Burger et al., 2011; Van Durme, 2012), we make the predictions using only user names.

5.3 Other Applications

Origin Knowing the origin of a name can improve its automatic pronunciation (Llitjos and Black, 2001) and transliteration (Bhargava and Kondrak, 2010). We evaluate our cluster data on name-origin prediction using a corpus of names marked as either Indian or non-Indian by Bhargava and Kondrak (2010). Since names in this corpus are not marked for entity type, we include separate cluster features from both our first and last name clusters.

Ethnicity We also evaluate on name-origin data from Konstantopoulos (2007). This data derives from lists of football players on European national teams; it marks each name (with diacritics removed) as arising from one of 13 European languages. Following prior work, we test in two settings: (1) using last names only, and (2) using first and last names.

Race We also evaluate our ability to identify ethnic groups at a sub-national level. To obtain data for this task, we mined the publicly-available arrest records on mugshots.com for the U.S. state of New Jersey (a small but diverse and densely-populated area). Over 99% of users were listed as either *black* or *white*, and we structure the task as a binary classification problem between these two classes. We predict the race of each person based purely on their

name; this contrasts with prior work in social media which looked at identifying African Americans on the basis of their Twitter *content* (Eisenstein et al., 2011; Pennacchiotti and Popescu, 2011).

6 Classification Results

Table 6 gives the results on each task. The system incorporating our novel *Clus* features consistently improves over the *Ngm+Tok* system; all differences between *All* and *Ngm+Tok* are significant (McNemar’s, $p < 0.01$). The relative reduction in error from adding *Clus* features ranges between 7% and 51%. The *All* system including *Clus* features also exceeds human performance on all studied tasks.

On **Country**, the U.S. is the majority class, occurring in 42.5% of cases.³ It is impressive that *All* so significantly exceeds *Tok+Ngm* (86.7% vs. 84.8%); with 782K training examples, we did not expect such room for improvement. Both names and locations play an important role: *All* achieves 66% using names alone and 70% with only location. On the subset of data where all three attributes are non-empty, the full system achieves 93% accuracy.

Both feature classes are likewise important for **Lang. ID**; *All* achieves 67% with only first+last names, 72% with just locations, but 83% with both.

Our smallest improvement is on **Gender**. This task is easier (with higher human/system accuracy) and has plenty of training data (more data *per class* than any other task); there is thus less room to improve. Looking at the feature weights, the strongest-weighted *female* cluster apparently captures a sub-community of Justin Bieber fans (showing loyalty with “first names” *jbieber*, *belieb*, *biebz*, *beliebing*, *jbiebs*, etc.). Just because a first name like *madison* has a high similarity to this cluster does not imply girls named *Madison* are Justin Bieber fans; it simply means that Madisons have similar names to the *friends* of Justin Bieber fans (who tend to be girls). Also, note that while the majority of the 34K users in our training data are assigned this cluster somewhere in their soft clustering, only 6 would be assigned this

³We tried other baselines: e.g., we predict countries if they are substrings of the location (otherwise predicting U.S.); and we predict countries if they often occur as a string following the given location in our profile data (e.g., we predict *Spain* for *Madrid* since *Madrid, Spain* is common). Variations on these approaches consistently performed between 48% and 56%.

Task	Input	Num. Train	Num. Class	Base	Human	Tok	Ngm	Clus	Tok+ Ngm	All	Δ
Country	first+last+loc	781920	53	42.5	71.7	83.0	84.5	80.2	84.8	86.7	12.5
Lang. ID	first+last+loc	2492	9	27.0	74.2	74.6	80.6	71.1	80.4	82.7	11.7
Gender	first+last	33805	2	52.4	88.3	85.3	88.6	79.5	89.5	90.2	6.7
Origin	entity name	500	2	52.4	80.4	-	75.6	81.2	75.6	88.0	50.8
Ethnicity	last	6026	13	20.8	47.9	-	54.6	48.5	54.6	62.4	17.2
Ethnicity	first+last	7457	13	21.2	53.3	67.6	77.5	73.6	78.4	81.3	13.4
Race	first+last	7977	2	54.7	71.4	80.4	81.6	84.6	82.4	84.6	12.5

Table 6: Task details and accuracy (%) for attribute-based classification tasks. Δ = relative error reduction (%) of *All* (*Tok+Ngm+Clus*) over *Ngm+Tok*. *All* always exceeds both *Tok+Ngm* and the human performance.

cluster in a *hard* clustering. This clearly illustrates the value of the soft clustering representation.

Note the *All* system performed between 83% and 90% on each Twitter task. This level of performance strongly refutes the prevailing notion that Twitter profile information is useless in general (Pennacchiotti and Popescu, 2011) and especially for geolocation (Cheng et al., 2010; Hecht et al., 2011).

We now move to applications beyond social media. Bhargava and Kondrak (2010) have the current state-of-the-art on **Origin** and **Ethnicity** based on an SVM using character-n-gram features; we reimplemented this as *Ngm*. We obtain a huge improvement over their work using *Clus*, especially on **Origin** where we reduce error by >50%.⁴ This improvement can partly be attributed to the small amount of training data; with fewer parameters to learn, *Clus* learns more from limited data than *Ngm*. We likewise see large improvements over the state-of-the-art on **Ethnicity**, on both last name and full name settings.

Finally, *Clus* features also significantly improve accuracy on the new **Race** task. Our cluster data can therefore help to classify names into sub-national groups, and could potentially be used to infer other interesting communities such as castes in India and religious divisions in many countries.

In general, the relative value of our cluster models varies with the amount of training data; we see huge gains on the smaller **Origin** data but smaller gains on the large **Gender** set. Figure 1 shows how performance of *Clus* and *Ngm* varies with training data on **Race**. Again, *Clus* is especially helpful with less

⁴Note *Tok* is not used here because the input is a single token and training and test splits have distinct instances.

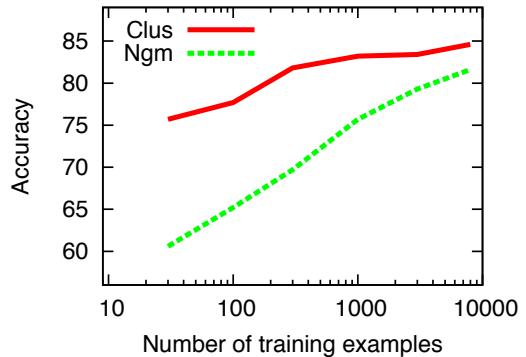

Figure 1: Learning curve on Race: *Clus* perform as well with 30 training examples as *Ngm* features do with 1000.

data; thousands of training examples are needed for *Ngm* to rival the performance of *Clus* using only a handful. Since labeled data is generally expensive to obtain or in short supply, our method for exploiting unlabeled Twitter data can both save money and improve top-end performance.

7 Geolocation by Association

There is a tradition in computational linguistics of grouping words both by the similarity of their context vectors (Hindle, 1990; Pereira et al., 1993; Lin, 1998) and directly by their statistical association in text (Church and Hanks, 1990; Brown et al., 1992). While the previous sections explored clusters built by vector similarity, we now explore a direct application of our attribute association data (§2).

We wish to use this data to improve an existing Twitter geolocation system based on user profile locations. The system operates as follows: 1) normal-

ize user-provided locations using a set of regular expressions (e.g. remove extra spacing, punctuation); 2) look up the normalized location in an *alias list*; 3) if found, map the alias to a unique string (target location), corresponding to a structured location object that includes geo-coordinates.

The alias list we are currently using is based on extensive work in hand-writing aliases for the most popular Twitter locations. For example, the current aliases for *Nashville, Tennessee* include *nashville*, *nashville tn*, *music city*, etc. Our objective is to improve on this human-designed list by automatically generating aliases using our association data.

Aliases by Association For each target, we propose new aliases from the target’s top-PMI associates (§2). To become an alias, the PMI between the alias and target must be above a threshold, the alias must occur more than a fixed number of times in our profile data, the alias must be within the top- N_1 associates of the target, and the target must be within the top- N_2 associates of the alias. We merge our automatic aliases with the manually-written aliases. The new aliases for *Nashville, Tennessee* include *east nashville*, *nashville tenn*, *music city usa*, *nashvegas*, *cashville tn*, etc.

Experiments To evaluate the geolocation system, we use tweets from users with GPS enabled (§5.2). For each tweet, we resolve the location using the system and compare to the gold coordinates. The system can skip a location if it does not match the alias list; more than half of the locations are skipped, which is consistent with prior work (Hecht et al., 2011). We evaluate the alias lists using two measures: (1) its coverage: the percentage of locations it resolves, and (2) its precision: of the ones resolved, the percentage that are correct. We define a *correct* resolution to be one where the resolved coordinates are within 50 miles of the gold coordinates.

We use 56K gold tweets to tune the parameters of our automatic alias-generator, trading off coverage and precision. We tune such that the system using these aliases obtains the highest possible coverage, while being at least as precise as the baseline system. We then evaluate both the baseline set of aliases and our new set on 56K held-out examples.

Results On held-out test data, the geolocation system using baseline aliases has a coverage of 38.7% and a precision of 59.5%. Meanwhile, the system using the new aliases has a coverage of 44.6% and a precision of 59.4%. With virtually the same precision, the new aliases are thus able to resolve 15% more users. This provides an immediate benefit to our existing Twitter research efforts.

Note that our alias lists can be viewed as *clusters* of locations. In ongoing work, we are exploring techniques based on discriminative learning to infer alias lists using not only *Clus* information but also *Ngm* and *Tok* features as in the previous sections.

8 Related Work

In both real-world and online social networks, “people socialize with people who are like them in terms of gender, sexual orientation, age, race, education, and religion” (Jernigan and Mistree, 2009). Social media research has exploited this for two main purposes: (1) to predict friendships based on user properties, and (2) to predict user properties based on friendships. Friendship prediction systems (e.g. Facebook’s *friend suggestion tool*) use features such as whether both people are computer science majors (Taskar et al., 2003) or whether both are at the same location (Crandall et al., 2010; Sadilek et al., 2012). The inverse problem has been explored in the prediction of a user’s location given the location of their peers (Backstrom et al., 2010; Cho et al., 2011; Sadilek et al., 2012). Jernigan and Mistree (2009) predict a user’s sexuality based on the sexuality of their Facebook friends, while Garera and Yarowsky (2009) predict a user’s gender partly based on the gender of their conversational partner. Jha and El-hadad (2010) predict the cancer stage of users of an online cancer discussion board; they derive complementary information for prediction from both the text a user generates and the cancer stage of the people that a user interacts with.

The idea of clustering data in order to provide features for supervised systems has been successfully explored in a range of NLP tasks, including named-entity-recognition (Miller et al., 2004; Lin and Wu, 2009; Ratinov and Roth, 2009), syntactic chunking (Turian et al., 2010), and dependency parsing (Koo et al., 2008; Täckström et al., 2012). In each case,

the clusters are derived from the distribution of the words or phrases in text, not from their communication pattern. It would be interesting to see whether prior distributional clusters can be combined with our communication-based clusters to achieve even better performance. Indeed, there is evidence that features derived from text can improve the prediction of name ethnicity (Pervouchine et al., 2010).

There has been an explosion of work in recent years in predicting user properties in social networks. Aside from the work mentioned above that analyzes a user’s social network, a large amount of work has focused on inferring user properties based on the content they generate (e.g. Burger and Henderson (2006), Schler et al. (2006), Rao et al. (2010), Mukherjee and Liu (2010), Pennacchiotti and Popescu (2011), Burger et al. (2011), Van Durme (2012)).

9 Conclusion and Future Work

We presented a highly effective and readily replicable algorithm for generating language resources from Twitter communication patterns. We clustered user attributes based on both the communication of users with those attributes as well as substring similarity. Systems using our clusters significantly outperform state-of-the-art algorithms on each of the tasks investigated, and exceed human performance on each task as well. The power and versatility of our clusters is exemplified by the fact we reduce error by a larger margin on each of the non-Twitter tasks than on any Twitter task itself.

Twitter provides a remarkably large sample and effectively a partial census of much of the world’s population, with associated metadata, descriptive content and sentiment information. Our ability to accurately assign numerous often unspecified properties such as race, gender, language and ethnicity to such a large user sample substantially increases the sociological insights and correlations one can derive from such data.

Abstract

Information extraction from microblog posts is an important task, as today microblogs capture an unprecedented amount of information and provide a view into the pulse of the world. As the core component of information extraction, we consider the task of Twitter entity linking in this paper.

In the current entity linking literature, mention detection and entity disambiguation are frequently cast as equally important but distinct problems. However, in our task, we find that mention detection is often the performance bottleneck. The reason is that messages on micro-blogs are short, noisy and informal texts with little context, and often contain phrases with ambiguous meanings.

To rigorously address the Twitter entity linking problem, we propose a structural SVM algorithm for entity linking that jointly optimizes mention detection and entity disambiguation as a single end-to-end task. By combining structural learning and a variety of first-order, second-order, and context-sensitive features, our system is able to outperform existing state-of-the art entity linking systems by 15% F_1 .

1 Introduction

Microblogging services, such as Twitter and Facebook, are today capturing the largest volume ever recorded of fine-grained discussions spanning a huge breadth of topics, from the mundane to the historic. The micro-blogging service Twitter reports that it alone captures over 340M short messages,

or *tweets*, per day.¹ From such micro-blogging services' data streams, researchers have reported mining insights about a variety of domains, from election results (Tumasjan et al., 2010) and democracy movements (Starbird and Palen, 2012) to health issues and disease spreading (Paul and Dredze, 2011; Sadilek et al., 2012), as well as tracking product feedback and sentiment (Asur and Huberman, 2010).

A critical step in mining information from a micro-blogging service, such as Twitter, is the identification of entities in tweets. In order to mine the relationship between drugs, symptoms and side-effects, or track the popularity of politicians or sentiment about social issues, we must first be able to identify the topics and specific entities being discussed. The challenge is that messages on micro-blogs are short, noisy, and informal texts with little context, and often contain phrases with ambiguous meanings. For example, “one day” may be either a set phrase or a reference to a movie. Given such difficulties, current mining and analysis of micro-blogs lists limits its application to certain domains with easy-to-recognize, unambiguous entities in order to avoid noise in the extraction results.

We begin this paper with a thorough investigation of mention detection and entity disambiguation for social media, focused on the Twitter micro-blogging service. *Mention detection* is the task of extraction surface form candidates that can link to an entity in the domain of interest. *Entity disambiguation* is the task of linking an extracted mention to a specific definition or instance of an entity in a knowledge base.

¹<http://blog.twitter.com/2012/03/twitter-turns-six.html>

While mention detection and entity disambiguation are frequently cast as equally important but distinct and separate problems, we find that mention detection is where today’s systems and our baseline techniques incur the most failures. Detecting the correct entity mention is a significant challenge given mis-capitalizations, incorrect grammar, and ambiguous phrases. In (Ritter et al., 2011), the authors report their system achieves 0.64 to 0.67 F_1 on named entity segmentation results with 34K tokens of labeled examples. On the other hand, once the correct entity mention is detected, a trivial disambiguation that maps to the most popular entity² will achieve 85% accuracy in our set.

Our primary contribution in this paper is a recasting and merging of the tasks of mention detection and entity disambiguation into a single *end-to-end entity linking* task. We achieve significant improvements by applying structural learning techniques to jointly optimize the detection and disambiguation of entities. Treating detection and disambiguation as a single task also enables us to apply a large set of new features, conventionally used only for disambiguation, to the initial detection of mentions. These features, derived from external knowledge bases, include entity popularity and inter-entity relations from external knowledge bases, and are not well utilized in current mention detection systems. For example, consider the following partial tweet:

- (1) The town is so, so good. And don’t worry Ben, we already forgave you for Gigli. Really.

Determining whether or not “The town” is a mention of a location or other specific entity based solely on lexical and syntactic features is challenging. Knowing “The Town” is the name of a recent movie helps, and we can be more confident if we know that Ben Affleck is an actor in the movie, and Gigli is another of his movies.

To train and evaluate our system, we created three separate annotated data sets of approximately 500 tweets each. These data sets are hand annotated with entity links to Wikipedia. We evaluate our system by comparing its performance at detecting en-

ties to the performance of two state-of-the-art entity linking systems, Cucerzan (Cucerzan, 2007) and TagMe (Ferragina and Scaiella, 2010), and find that our system outperforms them significantly by 15% in absolute F_1 .

The rest of this paper describes related work, our structured learning approach to entity linking, and our experimental results.

2 Related Work

Building an entity linking system requires solving two interrelated sub-problems: mention detection and entity disambiguation. The significant portion of recent work in the literature (Ratinov et al., 2011; Davis et al., 2012; Sil et al., 2012; Demartini et al., 2012; Wang et al., 2012; Han and Sun, 2011; Han et al., 2011) focuses solely upon the entity linking problem. The entity linking systems of these studies assume that entity mentions are provided by a separate mention detection system. In contrast, our study jointly identifies and disambiguates entity mentions within tweets (short text fragments).

A subset of existing literature targets end-to-end linking (Cucerzan, 2007; Milne and Witten, 2008; Kulkarni et al., 2009; Ferragina and Scaiella, 2010; Han and Sun, 2011; Meij et al., 2012), but there are quite a few differences between our work and each of these systems. Some systems (Milne and Witten, 2008; Kulkarni et al., 2009; Han and Sun, 2011) heavily depend on Wikipedia text and might not work well in short and noisy tweets. Many systems (Mihalcea and Csomai, 2007; Cucerzan, 2007; Milne and Witten, 2008; Ferragina and Scaiella, 2010) treat mention detection and entity disambiguation as two different problems. (Meij et al., 2012) is the most related to our paper. While their system also considers mention detection and entity disambiguation together, they do not consider entity-to-entity relationships and do not incorporate contextual words from tweets.

An area of work closely related to the mention detection problem is the Named Entity Recognition (NER) problem, the identification of textual phrases which belong to core categories (Person, Location, Organization). It is well-known that NER systems trained on well-written documents perform very poorly on short, noisy text, such as tweets (Rit-

²What we mean here is “the most linked entity”. See Section 3 for details.

ter et al., 2011). There have been a few recent studies proposing Twitter-specific NER systems (Li et al., 2012; Ritter et al., 2011).

3 Preliminaries

For performing entity linking on Twitter, we choose Wikipedia as our external knowledge base of entities.

Entity We define an *entity* as a nonambiguous, terminal page (e.g., The Town (the film)) in Wikipedia (i.e., a Wikipedia page that is not a category, disambiguation, list, or redirect page). We define an *anchor phrase* (surface form) as the textual phrase (e.g., the town) which can potentially link to some entities. We define an *entity mention* as an anchor phrase *and* the context (“the town” in the example tweet in Section 1), where its semantic meaning unambiguously represents a specific entity. Note that an entity may be represented by multiple surface forms.

Wikipedia Lexicon Construction Following the assumptions used in most prior entity linking research, we assume that surface forms of entities can be found as anchor phrases in Wikipedia. In order to construct a Wikipedia lexicon, we first collect all anchors phases in Wikipedia. For each anchor phrase (surface form) s , we construct a lexicon entry by gathering the set of entities $\{e_1, e_2, \dots, e_K\}$ that can be linked from s . We also collect the number of times anchor a links to the entity e_i , $d(s, e_i)$. We define $P(e_i|s) = d(s, e_i)/d(s)$, where $d(s)$ represents the number of times s appears in Wikipedia. We refer e' as the *most linked entity* for anchor s if $e' = \arg \max_e P(e_i|s)$.

Candidate Generation Given a tweet t , we extract all k -grams of size $\leq k$. For each k -gram, we find all entities where this k -gram is an anchor phrase. If a k -gram is an anchor phrase for at least one entity, then the k -gram is a *candidate* entity mention. In general, we identify many candidate phrase per tweet; let $U(t) = \{c_1, c_2, \dots\}$ denote the set of candidates in tweet t . We refer to $s(c)$ as the surface form (e.g., the anchor phrase) of c . Compared to the anchor phrase, the candidate also carries the context and position information. Let $E(c_i) = \{e_1, e_2, \dots, \text{NIL}\}$ denote the set of entities

which candidate i may be linked to, plus the additional special token **NIL**. Note that the size of $E(c_i)$ is always at least 2.

Task Definition First, our system generates candidate entity mentions, textual phrases which can possibly be entity mentions. Our system then performs filtering and optimization to process the list of candidates. For each candidate, our system links the candidate to a special **NIL** token or links the candidate to its corresponding entity in Wikipedia. More formally, given a tweet t and its candidate set $U(t)$, the goal of the system is to predict $y_i \in E(c_i), \forall c_i \in U(t)$.

Comparison to the TAC KBP Competition It is important to state that our definition of the entity linking problem differs significantly from the entity linking problem as defined by the TAC KBP competition (Ji et al., 2010; Ji et al., 2011). In the TAC, there is no true mention detection problem; every candidate in the TAC is an entity mention that represents an entity. Another difference is that the TAC allows for an entity mention to map to an entity not in the external knowledge base (Wikipedia); our system does not provide special handling of this case.

Comparison to Named Entity Recognition There are also important differences between our task and the canonical NER task. For example, NER systems identify common names, such as “Robert,” as entities. In our task, we only consider a prediction as a success if the system can determine which person in Wikipedia “Robert” is referring to. In other words, our definition of entities depends on the given knowledge base, rather than human judgment. Hence, it is difficult to make a fair system comparison of our system to NER systems.

4 Entity Linking as Structural Learning

In our framework, we use structural learning as a tool to capture the relationship between entities. We define y_i as the output for c_i , where $y_i \in E(c_i)$. Let $T = |U(t)|$ and $\mathbf{y} = \{y_1, y_2, \dots, y_T\}$. The feature function for the whole assignment can be written as $\Phi(t, U(t), \mathbf{y})$. The score for the assignment \mathbf{y} can be obtained as the linear product between the weight vector \mathbf{w} and the feature vector. For an input example, the prediction can be found by solving the

inference problem:

$$\mathbf{y}' = \arg \max_{\mathbf{y}} \mathbf{w}^T \Phi(t, U(t), \mathbf{y}) \quad (1)$$

We use a Structural SVM (SSVM) (Taskar et al., 2004; Tsouchantidis et al., 2005; Chang et al., 2010) as our learning algorithm. To train the weight vector \mathbf{w} , we minimize the objective function of the SSVM

$$\min_{\mathbf{w}} \frac{\|\mathbf{w}\|^2}{2} + C \sum_{i=1}^l \xi_i^2 \quad (2)$$

where l is the number of labeled examples and

$$\begin{aligned} & \mathbf{w}^T \Phi(t_i, c(t_i), \mathbf{y}_i) \\ & \geq \Delta(\mathbf{y}_i, \mathbf{y}) + \mathbf{w}^T \Phi(t_i, c(t_i), \mathbf{y}) - \xi_i, \forall i, \mathbf{y} \end{aligned}$$

We denote \mathbf{y}_i as the gold assignment for \mathbf{x}_i and define $\Delta(\mathbf{y}_i, \mathbf{y})$ as the Hamming distance between two assignments \mathbf{y}_i and \mathbf{y} .

4.1 Features

Feature definitions are very important as they define the shapes of the structures. Our feature vector is defined as

$$\Phi(t, U(t), \mathbf{y}) = \sum_i \phi(t, c_i, y_i) + \sum_{i < j} \phi(t, c_i, y_i, c_j, y_j)$$

where c_i and c_j is the i -th and j -th candidates in $U(t)$, respectively.

First, we assign $\Phi(t, c_i, \mathbf{NIL})$ to be a special bias feature. The corresponding weight value behaves as a threshold to cut-off mentions. Recall in our definition that $y_i = \mathbf{NIL}$ represents that the candidate c_i is not a mention.

The first order features for $\Phi(t, c_i, e)$ are described as follows. In general, we can classify our features into two types: mention-specific features and entity-specific features. For a given candidate c_i , mention-specific features only consider the surface form of c_i and the tweet t . Entity-specific features also consider the knowledge base content of the entity e . Prior work in the entity linking literature has primarily focused on entity-specific features, as most prior work solves entity disambiguation with given mentions.

Base and Capitalization Rate Our base features are from two resources. Let $s(c)$ denote the surface form of candidate c . The link probability $P_l(s(c))$ and $P(e|s(c))$ features are extracted from Wikipedia. We explained $P(e|s(c))$ in Section 3. Link probability $P_l(s(c))$ is the probability that a phrase is used as an anchor in Wikipedia. We also add a third feature that captures normalized link count. Besides these three features, we also have a feature to indicate if a is a stop word, and a feature indicating the number of tokens in a . The view count and $P(e|s)$ features are entity-specific, while the other three features are mention-specific.

For each phrase $s(c)$, we also collect statistics about the probability that a phrase is capitalized in Wikipedia. We refer to this feature as the capitalization rate feature, $P_c(s(c))$.

Popularity Feature We have access to 300GBs of Wikipedia page view counts, representing one months worth of page view information, we use this as popularity data.³ As mentioned in Section 3, we find that the most often linked Wikipedia articles might not be the most popular ones on Twitter. Using page view statistics helps our system correct this bias. We define another probability based on page view statistics $P_v(e_i|c) = v(e_i)/(\sum_{e \in E(c)/\{\mathbf{NIL}\}} v(e))$, where $v(e)$ represents the view count for the page e .

Context Capitalization Our context capitalization features indicate if the current candidate, the word before, and the word after the candidate are capitalized.

Entity Type and Tf-idf We use the procedure proposed in (Ratinov et al., 2011) to extract keyword phrases from categories for each Wikipedia page, and then build a rule-based system using keyword phrases to classify if each entity page belongs to one of the following entity types: Person, Location, Organization, TV Show, Book/Magazine and Movie.⁴ For a given candidate c and an entity e , the associated binary feature becomes active if the entity belongs to a specific entity type. There are six entity type features in our system.

³<http://dammit.lt/wikistats>

⁴The entity type prediction accuracy of our rule-based system on the development set is around 95%.

Features	Descriptions
Base	$P_l(s_i)$, $P(e s)$, normalized link counts, stop word, # tokens
Cap. Rate	$P_c(s_i)$
Popularity	$P_v(e s)$, normalized page view count, $P_v(e s)P(e s)$
Context Cap.	Three features indicating if the current candidate and the words before and after are capitalized
Entity Type	Six binary features for each entity type
Tf-idf	Two features for the similarity between the word vectors of the entity and the tweet
Second-Order	$Jac(e_i, e_j)$, $P(e_i s_i)P(e_j s_j)$, $P_c(s_i)P_c(s_j)$, $P_l(s_i)P_l(s_j)$

Table 1: Summary of the features used in our structural learning systems.

We also include tf-idf features in our system. For each Wikipedia page, we collect the top 100 tf-idf words. We add one feature that is the dot product between the tf-idf word vector of e and the words of tweet t . We include a second feature that represents the average tf-idf score of all words that appear in both e and t .

Second-order features We include four very simple second-order features $\phi(t, c_i, e_i, c_j, e_j)$ to capture more complex relations between entities and candidates. The first feature is the Jaccard distance between two Wikipedia pages e_i and e_j . Let $\Gamma(e_i)$ denote the set of Wikipedia pages that contain a hyperlink to e_i . We define the Jaccard distance between e_i and e_j as:

$$Jac(e_i, e_j) = \frac{|\Gamma(e_i) \cap \Gamma(e_j)|}{|\Gamma(e_i) \cup \Gamma(e_j)|}$$

This feature has a similar effect as the normalized Google distance (Cilibrasi and Vitanyi, 2007), which has been used for many entity linking systems. Let us use the following shorthand: $s_i = s(c_i)$ and $s_j = s(c_j)$. We have also included three features $P(e_i|s_i)P(e_j|s_j)$, $P_c(s_i)P_c(s_j)$ and $P_l(s_i)P_l(s_j)$ to increase the expressivity of our model.

4.2 Mining Additional Contextual Words

Unlike mention detection systems used in other NLP tasks, there are no lexical features in our system. Lexical features are important as they can capture semantic meaning precisely. However, given that we do not have many labeled examples, lexical features can lead to overfitting. The diverse language

in tweets also make it more difficult to use lexical features.

Our solution for this problem is to use a very simple method to mine context words for different entities from a large, unlabeled tweet corpus. The algorithm works as follows:

1. Train an end-to-end entity linking system and then apply it to a large, unlabeled tweet corpus
2. Extract contextual words for each entity type based on the pseudo-labeled data.
3. Train the entity linking system again with new contextual features.

In this paper, we only use the word before and the word after as our contextual word for a candidate. Note that while there are ambiguous phrases on the surface (e.g., “friends” can be a TV show or just a regular phrase), certain phrases are unambiguous (e.g., “CSI : Miami”). As contextual words are often shared within the same entity type (e.g. “watching” is likely to appear before a tv show), those words can potentially improve our final system.

Let w_i denote the i -th word in the tweet and t_i denote the entity type for the i -th word.⁵ We use a very simple rule to select a set of left context words $Q(R)$ for entity type R .

$$Q(R) = \{w_i \mid P(t_{i+1} = R|w_i) > r, d(w_i) > z\}$$

where $d(w_i)$ represent the number of times the word w_i appears in the unlabeled set. The first rule is to simply find a word which is more likely to be followed by an entity. The second rule filter outs noisy words (e.g., Twitter handles) in the unlabeled set. The right context words are also extracted in a similar way.

To train the second end-to-end entity linking system, we add one additional feature for the contextual words. For the feature vector $\Phi(t, c_i, e)$, the context feature is active if the candidate c_i is capitalized⁶ and the context words around c_i belongs to $Q(R)$, given R is the entity type for the entity e .

⁵The tag t_i belongs to the entity type R if our system links a candidate c to an entity with type R and c covers the word w_i .

⁶The word “watching” can be a TV show while most of the time it is not. These common makes this contextual feature noisy. We found that the context feature can only be reliably applied when the candidate is capitalized.

4.3 Cohesiveness Score

There are several ways to consider entity-entity cohesiveness besides using the second-order features directly. In our model, we also consider a modified cohesiveness score proposed in (Ferragina and Scaiella, 2010). The idea behind the cohesiveness score is to estimate the correlations between different entities by using weighted Jaccard scores.⁷

There are two rounds in the procedure of computing the cohesiveness score. We first estimate approximately the most probable entity for each candidate given all the other candidates in the same tweet. In the second round, the cohesiveness score is then produced with respect to the most probable entity computed in the first round.

More formally, in the first round, we compute the relevance score for each candidate and entity pair:

$$Rel(e, c|t) = \frac{\sum_{c' \neq c} \sum_{e' \in E(c')} P(e'|c') Jac(e, e')}{|U(t)|}.$$

Then, the cohesiveness score is computed by

$$S_{coh}(e, c|t) = \frac{\sum_{c' \neq c} Jac(e, \bar{e}(c')) P(\bar{e}(c')|c')}{|U(t)|},$$

where the $\bar{e}(c') = \arg \max_{e \in E(c')} Rel(e, c'|t)$. We then put the cohesiveness score as a feature for each (e, c) pair. In practice, we found that the cohesiveness score in the model can significantly increase the disambiguation ability of the model without using the second-order information.

4.4 Inference

In order to train and test the SSVM model, one needs to solve both the inference problem Eq. (3) and the loss-augmented inference problem. Without second-order features, the inference and loss-augmented inference problems can be easily solved, given that each component can be solved independently by

$$y'_i = \arg \max_{y \in E(c_i)} \mathbf{w}^T \Phi(t, c_i, y) \quad (3)$$

While the inference problem can be solved independently, the training algorithm still considers the whole assignment together in the training procedure.

⁷In our experiments, we only apply the cohesiveness score technique on candidates which pass the filtering procedure. See section 5 for more details for our filtering process.

Data	#Tweets	#Cand	#Men.	P@1
Train	473	8212	218	85.3%
Test 1	500	8950	249	87.7%
Test 2	488	7781	332	89.6%

Table 2: Labeled example statistics. “#Cand” represents the total number of candidates we found in this dataset. “#Men.” is the total number of mentions that disambiguate to an entity. The top-1 rate (P@1) represents the proportion of the mentions that disambiguate to the most linked entity in Wikipedia.

With the second-order features, the inference problem becomes NP-hard. While one can resort to using integer linear programming to find the optimal solution, we choose not to do so. We instead use the beam search algorithm. Our beam search algorithm first arranges the candidates from left to right, and then solve the inference problems approximately.

5 Experiments

We collected unlabeled Twitter data from two resources and then asked human annotators to label each tweet with a set of entities present. Our annotators ignored the following: duplicate entities per tweet, ambiguous entity mentions, and entities not present in Wikipedia. We next describe the two sets of Twitter data used as our training data and testing data. In addition to these two datasets, we also randomly sampled another 200 tweets as our development set.

Ritter We sampled 473 and 500 tweets⁸ from the data used in (Ritter et al., 2011) to be our training data and test data, respectively. We did not use any labels generated by (Ritter et al., 2011); our annotators completely re-annotated each tweets with its set of entities. We refer to the first set as **Train** and the second set as **Test 1**.

Entertainment To check if our system has the ability to generalize across different domains, we sampled another 488 tweets related to entertainment entities. Our main focus was to extract tweets that contained TV shows, Movies, and

⁸We originally labeled 1000 tweets but then found 27 repeated tweets in the dataset. Therefore, we remove those 27 tweets in the training set.

Books/Magazines. Identifying tweets from a specific domain is a research topic on its own, so we followed (Dalvi et al., 2012), and used a keyword matching method.⁹ After sampling this set of tweets, we asked our annotators to label the data in the same way as before (all entities are labeled, not just entertainment entities). We refer to this tweet set as **Test 2**.

After sampling, all tweets were then normalized in the following way. First, we removed all retweet symbols (RT) and special symbols, as these are tokens that may easily confuse NER systems. We treated punctuation as separate tokens. Hashtags (#) play a very important role in tweets as they often carry critical information. We used the following web service¹⁰ to break the hashtags into tokens (e.g., the service will break “#TheCloneWars” into “the clone wars”) (Wang et al., 2011).

The statistics of our labeled examples are presented in Table 2. First, note that the average number of mentions per tweet is well below 1. In fact, many tweets are personal conversations and do not carry any entities that can be linked to Wikipedia. Still, many candidates are generated (such as “really”) for those tweets, given that those candidates can still potentially link to an entity (“really” could be a TV channel). Therefore, it is very important to include tweets without entities in the training set because we do not want our system to create unnecessary links to entities.

Another interesting thing to note is the percentage of entity mentions that disambiguate directly to their most often linked entities in Wikipedia. If we simply disambiguate each entity mention to its most linked entity in Wikipedia, we can already achieve 85% to 90% accuracy, if mention detection is perfectly accurate. However, mention detection is a difficult problem as only about 3% of candidates are valid entity mentions.

It is worthwhile to mention that, as per (Ferragina and Scaiella, 2010), for computational efficiency,

⁹We use the following word list :“movie”, “tv”, “episode”, “film”, “actor”, “actors”, “actress”, “director”, “directors”, “movies”, “episodes”, “book”, “novel”, “reading”, “read”, “watch”, “watching”, “show”, “books”, “novels”, “movies”, “author” and “authors”.

¹⁰<http://web-ngram.research.microsoft.com/info/break.html>

we apply several preprocessing steps before running our entity linking system. First, for each anchor in Wikipedia, we gather all entities it can disambiguate to and remove from that anchor’s entity set all entities that are linked less than 2% of the time. Second, we apply a modified filtering procedure similar to that proposed in (Ferragina and Scaiella, 2010) to filter the set of candidates per tweet.

Evaluation Our annotated datasets contain entities from many Wikipedia categories. For evaluation, we primarily focus on entities belonging to a set of six *core* categories (Person, Location, Organization, TV Show, Book/Magazine, Movie). We believe it is necessary to focus upon core entities, rather than considering all possible entities in Wikipedia. Most common words in the English language have their own Wikipedia page, but most words are not important enough to be considered entities. In general, there is a large degree of subjectivity when comparing different entity linking datasets; different researchers have their own interpretation of what constitutes an entity. For example, we examined the annotation used in (Meij et al., 2012) and found it to be extremely lenient, when compared to our own beliefs of what is an entity. Therefore, we believe evaluating performance on restricted entity types is the only fair way to compare different end-to-end entity linking systems.

We evaluate the performance of our system on a per-tweet basis, by comparing the set of annotated “gold” entities with the set of entities predicted by our system, and computing performance metrics (precision, recall, F_1). We choose to evaluate our system on a per-tweet basis, as opposed to a per-entity basis, because we wish to avoid the issue of matching segmentations. For example, it is quite common to observe multiple overlapping phrases in a tweet that should be linked to the same entity (e.g., “President Obama” and “Obama”). When evaluating our system, we compute performance metrics for both all entities and core entities.¹¹

Parameters In our implementation, we fixed the regularization parameter $C = 10$. When beam-

¹¹To decide if an entity is a core entity or not, we use the following procedure. For the gold entities, the annotators also annotate type of the entity. We decide the entity type of the predicted entities using the procedure described in Section 4.1.

Model	Test 1			Test 2		
	P	R	F_1	P	R	F_1
Cucerzan	64.8	42.2	51.1	64.9	39.7	49.5
TagMe	38.8	69.0	49.7	34.9	70.3	46.7
SSVM	78.8	59.9	68.0	75.0	57.7	65.2

Table 3: Comparisons between different end-to-end entity linking systems. We evaluate performance on core entities, as it is the only fair way to compare different systems.

search is used, the beam size is set to be 50, and we only consider the top 10 candidates for each candidate to speed the inference process. In the context word mining algorithm, $r = 0.5\%$ and $z = 1000$.

5.1 Results

In the following, we analyze the contributions of each component in our system and compare our final systems to other existing end-to-end entity linking systems.

System Comparison We compare our final system to other state-of-the-art systems in Table 3. CUCERZAN represents a modified implementation of the system in (Cucerzan, 2007). TagMe is an end-to-end linking system that focuses on short texts, including tweets. Our system significantly outperforms these two systems in both precision and recall. Note that CUCERZAN’s system is a state-of-the-art system on well-written documents with provided entity mentions. The system (Cucerzan, 2007) has been extended by the authors and won the TAC KBP competition in 2010 (Ji et al., 2010).

There are two possible reasons to explain why our system outperforms CUCERZAN. First, their mention detection is a carefully designed system targeted toward documents, not tweets. Their system has segmentation issues when applied to Twitter, as it relies heavily upon capitalization when identifying candidate entity mentions. Second, their system heavily depends on the fact that related entities should appear together within documents. However, given that tweets are very short, some of their most important features are not suitable for the Twitter domain. Our system outperforms TagMe because we use a more sophisticated machine learning approach, as compared to their system. TagMe links too many

spurious entity mentions for common words. This is a result of their algorithm’s over-emphasis on entity-entity co-occurrence features.

Feature Study We study the contributions of each feature group in our system in Table 4. We summarize our discoveries as follows:

First, we find collecting statistics from a large corpus helps the system significantly. In addition to $P(e|s)$, we find that capitalization rate features offer around 3% to 4% F_1 improvement in Test 1. Similarly, popularity features are also important, as it corrects bias existing in Wikipedia link statistics. Compared to lexical features, using statistical features offers a great advantage of reducing the need for large amounts of labeled data.

We also find entity related features (Popularity, Entity Type, Tf-idf) are crucial. Given that between 85% to 90% of our mentions should directly disambiguate to the most often linked entities, one might think entity-specific features are not important in our task. Interestingly, entity-specific features are among the most important features. The discovery confirms our hypothesis: it is critical to consider mention detection and entity disambiguation as a single problem, rather than as separate problems in a two staged approach used by many other entity linking systems. Note that capitalization rate and context capitalization features are mention-specific. Additionally, we find that mixing mention-specific features and entity-specific features results in a better model.

Entity Type	Words appearing before the mention	Words appearing after the mention
Person	wr, dominating, rip, quarterback, singer, featuring, defender, rb, minister, actress, twitition, secretary	tarde, format, noite, suffers, dire, admits, senators, urges, performs, joins
TV Show	sbs, assistir, assistindo, otm, watching, nw, watchn, viagra, watchin, ver	skit, performances, premieres, finale, parody, marathon, season, episodes, spoilers, sketch

Table 5: An example of context words that are automatically extracted from 20 million unlabeled tweets. For the sake of brevity, we only display context words for two categories. Note that there are misspelled words (such as “watchn”) and abbreviations (such as nw) that do not appear in well-written documents.

+Cohesiveness	55.6	66.5	59.7	65.1
+2nd order	58.1	68.0	60.6	65.2

Table 6: Evaluation results (F_1) of the advanced models. “+ Context” is the model that uses additional context features extracted from 20 millions unlabeled tweets. “+ Cohesiveness” is the model with both additional context and cohesiveness features. “+2nd order” is our final model (which incorporates context, cohesiveness, and second-order features).

Mining Context Words We verify the effectiveness of adding contextual features that are extracted automatically from large unlabeled data. We apply our system (with all first-order features) on a set of 20 million unlabeled tweets we collected. Context words are then extracted using the simple rules described in Section 4. We list the top 10 words we extracted in Table 5. Due to space limitations, we only list the words for the Person and TV Show categories. The results are interesting as we are able to find common misspelled words and abbreviations used in Twitter. For example, we find that “watchn” means “watching” and “nw” means “now watching,” and they are usually words found before TV shows. We also find tweeters frequently use abbreviations for people’s jobs. For example, “wr” means “wide receiver” and “rb” means “running back.” When mined context is added into our system, the performance improves significantly (Table 6). We note

that extending context mining algorithms in a large-scale, principled approach is an important next research topic.

Capturing Entity-Entity Relationships In this paper, we use two methods to capture the relationship between entities: adding the cohesiveness score and using second order information. Until now, we only considered features that can be extracted from only one entity. Past research has shown that considering features that involve multiple entities can improve entity linking performance, given that related entities are more likely to appear together in a document. When these type of features are added, we need to perform beamsearch, as the exact inference procedure can be prohibitively expensive.

As displayed in Table 6, we find that either adding the cohesiveness score or using second order information can improve prediction. Using both methods improves the model even more. Comparing computation overhead, computing cohesiveness is significantly more cost-effective than using second-order information.

6 Conclusion

In this paper, we propose a structural SVM method to address the problem of end-to-end entity linking on Twitter. By considering mention detection and entity disambiguation together, we build a end-to-end entity linking system that outperforms current state-of-the-art systems.

There are plenty of research problems left to be addressed. Developing a better algorithm for mining contextual words is an important research topic. It would also be interesting to design a method that jointly learns NER models and entity linking models.

Abstract

Threaded discussion forums provide an important social media platform. Its rich user generated content has served as an important source of public feedback. To automatically discover the viewpoints or stances on hot issues from forum threads is an important and useful task. In this paper, we propose a novel latent variable model for viewpoint discovery from threaded forum posts. Our model is a principled generative latent variable model which captures three important factors: viewpoint specific topic preference, user identity and user interactions. Evaluation results show that our model clearly outperforms a number of baseline models in terms of both clustering posts based on viewpoints and clustering users with different viewpoints.

1 Introduction

Threaded discussion forums provide an important social media platform that allows netizens to express their opinions, to ask for advice, and to form online communities. In particular, responses to major sociopolitical events and issues can often be found in discussion forums, which serve as an important source of public feedback. In such discussion threads, we often observe heated debates over a controversial issue, with different sides defending their viewpoints with different arguments. For example, after the presidential debate between Barack Obama and Mitt Romney, there were heated discussions in online forums like CreateDebate¹ where some people expressed their support for Obama while some

others have their opposition to him. For a user who is not closely following an event or issue, instead of going through all the existing posts in a long thread, she may want to quickly get an overview of the major viewpoints and arguments given by the different sides. For policy makers who want to obtain public feedback on social issues from social media, it is also desirable to automatically summarize the viewpoints on an issue from relevant threads. In this paper, we study the problem of modeling and discovering different viewpoints in forum threads.

Recently there has been some work on finding contrastive viewpoints from text. The model proposed by Paul et al. (2010) assumes viewpoints and topics are orthogonal dimensions. Another model proposed by Fang et al. (2012) assumes that documents are already grouped by viewpoints and it focus on identifying contrastive viewpoint words under the same topic. However, these existing studies are not based on interdependent documents like threaded forum posts. As a result, at least two important characteristics of threaded forum data are not considered in these models. (1) **User identity**: The user or publisher of each forum post is known, and a user may publish several posts in the same thread. Since the same user’s opinion on an issue usually remains unchanged, posts published by the same user are likely to contain the same viewpoint. (2) **User interactions**. A thread is like a conversation, where users not only directly comment on the issue under discussion but also comment on each other’s posts. Users having different viewpoints may express their disagreement or even attack each other while users having the same viewpoint often support each other.

¹<http://www.createdebate.com/>

The interaction expressions in forum posts may help us infer the relation between two users and subsequently infer the viewpoints of the corresponding posts.

In this paper, we propose a novel latent variable model for viewpoint discovery from threaded forum posts. Our model is based on the following observations: First, posts with different viewpoints tend to focus on different topics. To illustrate this point, we first apply the Latent Dirichlet Allocation (LDA) model (Blei et al., 2003) on a thread about “will you vote Obama” and obtain a set of topics. This thread comes from a data set that has each user’s viewpoint annotated. Using the ground truth viewpoint labels, we group all posts published by users with viewpoint 1 (or viewpoint 2) and compute the topic proportions. The two topic distributions are shown in Figure 1. We can see that indeed the two viewpoints each have some dominating topics. Our second observation is that the same user tends to hold the same viewpoint. In our model, we use a user-level viewpoint distribution to capture this observation, and the experiments show that it works better than assuming a global viewpoint distribution. Third, users with the same viewpoint are likely to have positive interactions while users with different viewpoints tend to have negative interactions. Using a sentiment lexicon, we can first predict the polarity of interaction expressions. We then propose a novel way to incorporate this information into the latent variable model. In summary, we capture the three observations above in a principled generative latent variable model. We present the details of our model in Section 3.

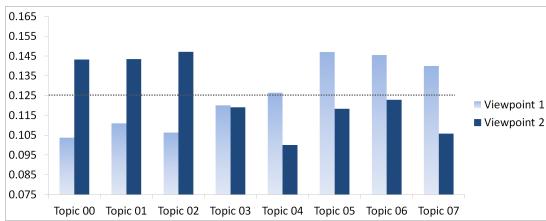

Figure 1: Topic distributions of two viewpoints for the thread “will you vote Obama?” The dotted line is the average topic probability.

We use two tasks to evaluate our model. In the first task, we evaluate how well posts with different viewpoints are separated. In the second task, we

evaluate how well our model is able to group users with different viewpoints. For both tasks, we compare our model with an existing model as well as a few degenerate versions of our model. The results show that our model can clearly outperform the baselines in terms of three evaluation metrics. The experiments are presented in Section 5.

The contributions of our work are threefold: (1) We identify the importance of using user interactions to help infer viewpoints in forum posts. (2) We propose a principled latent variable model to jointly model topics, viewpoints and user interactions. (3) We empirically verify the validity of the three assumptions in our model using real data sets.

2 Related Work

There are a few different lines of work that are related to our work. For discovering different viewpoints from general text, Paul et al. (2010) used the model proposed by Paul and Girju (2010) to jointly model topics and viewpoints. They assume these two concepts are orthogonal and they do not consider user identity. In comparison, our model has the notion of topics and viewpoints, but we explicitly model the dependency of topics on viewpoints, i.e. we assume each viewpoint has a topic distribution. We also consider author identities as an important factor of our model. Fang et al. (2012) proposed a model that also combines topics and viewpoints. But they assume that documents are already grouped by viewpoints, which is not the case for forum posts. Therefore, their model cannot be directly applied to forum posts.

There has also been some work on finding viewpoints from social media. Somasundaran and Wiebe (2010) studied how to identify stances in online debates. They used a supervised approach for classifying stances in ideological debates. In comparison, our model is an unsupervised method. The same authors proposed an unsupervised method which relies on associations of aspects with topics indicative of stances mined from the Web for the task (Somasundaran and Wiebe, 2009). In contrast, our model is also an unsupervised one but we do not rely on any external knowledge.

Part of our work is related to detecting agreement/disagreement from text. For this task, nor-

mally supervised methods are used (Galley et al., 2004; Abbott et al., 2011), which require sufficient labeled training data. In our work, since we deal with different languages, we use a lexicon-based approach that does not need training data. Recently, Mukherjee and Liu (2012) proposed an unsupervised model to extract different types of expressions including agreement/disagreement expressions. However, our focus is not to detect agreement/disagreement expressions but to model the interplay between agreement/disagreement expressions and viewpoints. The work by Mukherjee and Liu (2012) can potentially be combined with our model.

Another line of related work is subgroup detection, which aims to separate users holding different viewpoints. This problem has recently been studied by Abu-Jbara and Radev (2012), Dasigi et al. (2012), Abu-Jbara et al. (2012) and Hassan et al. (2012), where a clustering based approach is used. Lu et al. (2012) studied both textual content and social interactions to find opposing network from online forums. In our experiments we show that our model can also be used for subgroup detection, but meanwhile we also directly identify viewpoints, which is not the goal of existing work on subgroup finding or opposing network extraction.

3 Model

3.1 Motivation

Before we formally present our latent variable model for viewpoint discovery, let us first look at the assumptions we would like to capture in the model.

Viewpoint-based topic distribution: The first assumption we have is that different viewpoints tend to touch upon different topics. This is because to support a viewpoint, users need to provide evidence and arguments, and for different viewpoints the arguments are likely different. To capture this assumption, in our model, we let each viewpoint have its own distribution of topics. Given the viewpoint of a post, the hidden topic of each word in the post is chosen according to the corresponding topic distribution associated with that viewpoint.

User identify: The second assumption we have is that the same user tends to talk from the same viewpoint, although there are also users who do not

clearly have a viewpoint. In our model, we assume that there is a user-level viewpoint distribution. For each post by a user, its viewpoint is drawn from the corresponding viewpoint distribution.

User interaction: An important difference between threaded forum posts and regular document collections such as news articles is that posts in the same thread form a tree structure via the “reply-to” relations. Many reply posts start with an expression that comments on a previous post or directly addresses another user. These interaction expressions may carry positive or negative sentiment, indicating an agreement or a disagreement. For example, Table 1 shows the interaction expressions from a few sample posts with words such as “correct,” “agree,” and “delusional,” implying the polarity of the interaction expressions. The polarity of these interaction expressions can help us infer whether two posts or two users hold the same viewpoint or not. In our model, we assume that the polarity of each interaction expression can be detected. Details of how we perform this detection are in Section 3.4.

Post
+ You are correct . Obama got into office w/ everything ...
+ I agree with your post Dan. Obama is so ...
- Most of your post is delusional , especially the part ...
- Are you freaking nutz ? Palin is a BIMBO!

Table 1: Sample posts with positive (+) and negative(−) interactions.

While the way to capture the first two assumptions discussed above is fairly standard, modeling user interactions is something new. In our model, we assume that the polarity of an interaction expression is generated based on the viewpoint of the current post and the viewpoint of post(s) that the current post replies to. The intuition is that if the viewpoints are the same, we are more likely to see a positive interaction whereas if the viewpoints are different we are more likely to see a negative interaction.

3.2 Model description

We use the following notation to represent our data. We consider a set of forum posts published by U different users on the same event or issue, where user u ($1 \leq u \leq U$) has published N_u posts. Let $w_{u,n,l}$ ($1 \leq l \leq L_{u,n}$) denote the l -th word in the n -th post by user u , where $L_{u,n}$ is the number of words

in the n -th post by user u . $w_{u,n,l}$ is represented by an index between 1 and V where V is the vocabulary size. Furthermore, we assume that some of the posts have user interaction expressions, where the polarity of the expression is known. Without loss of generality, let $s_{u,n} \in \{0, 1\}$ denote the polarity of the interaction expression of the n -th post by user u . In addition, for each post that has an interaction expression, we assume we also know the previous post(s) it replies to. (In the case when the current post replies to a user, we assume all that user's existing posts are being replied to.) We refer to these posts as the *parent posts* of the current post.

We assume that there are T topics where each topic is essentially a word distribution, denoted as ψ^t . We also assume that there are Y different viewpoints expressed in the collection of posts. For most controversial issues, Y can be set to 2. Each viewpoint y has a topic distribution θ^y over the T topics. While these T topics are meant to capture the topical differences between viewpoints, since these viewpoints are all about the same issue, there are also some words commonly used by different viewpoints. We therefore introduce a background topic ψ^B to capture these words. Finally, each user u has a distribution over the Y viewpoints, denoted as φ^u .

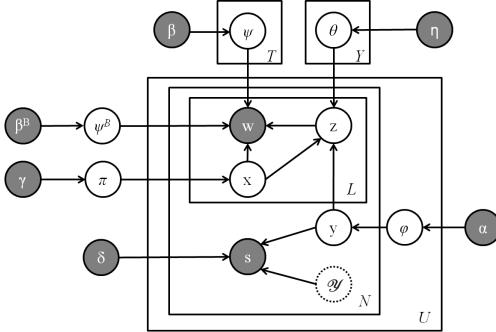

Figure 2: Plate notation of the Joint Viewpoint-Topic Model with User Interaction (JVTM-UI). The dotted circle for \mathcal{Y} means the variables represented by \mathcal{Y} are not new variables but a subset of the y variables.

Figure 2 shows the plate notation of the complete model. We assume the following generation process in our model. When user u generates her n -th post, she first samples a viewpoint from φ^u . Let this viewpoint be represented by a hidden variable $y_{u,n}$. For the l -th word in this post, she first samples an in-

dicator variable $x_{u,n,l}$ from a Bernoulli distribution parameterized by π . If $x_{u,n,l} = 0$, then she draws $w_{u,n,l}$ from ψ^B . Otherwise, she first samples a topic, denoted as $z_{u,n,l}$, according to $\theta^{y_{u,n}}$, and then draws $w_{u,n,l}$ from $\psi^{z_{u,n,l}}$.

Furthermore, if this post is a reply to a previous post or another user, she may first comment on the parent post(s). The polarity of the interaction expression in the post is dependent on the viewpoint $y_{u,n}$ and the viewpoints of the previous post(s). Let us use $\mathcal{Y}_{u,n}$ to denote the set of y variables associated with the parent posts of the current post. The user draws $s_{u,n}$ according to following distribution:

$$p(s_{u,n} = 1|y_{u,n}, \mathcal{Y}_{u,n}, \delta) = \frac{\sum_{y' \in \mathcal{Y}_{u,n}} \mathbb{I}(y_{u,n} == y') + \delta}{|\mathcal{Y}_{u,n}| + 2\delta},$$

$$p(s_{u,n} = 0|y_{u,n}, \mathcal{Y}_{u,n}, \delta) = 1 - p(s_{u,n} = 1|y_{u,n}, \mathcal{Y}_{u,n}, \delta), \quad (1)$$

where $\mathbb{I}(\cdot)$ is 1 if the statement inside is true and 0 otherwise, and $\delta > 0$ is a smoothing parameter.

Finally, we assume that ψ^B , ψ^t , φ^u , θ^y and π all have some uniform Dirichlet priors.

3.3 Inference

We use collapsed Gibbs sampling to estimate the model parameters. In the initialization stage of Gibbs sampling, for a reply post to a recipient, we initialize its corresponding reply polarity s according to all the labeled polarity of interaction words. Specifically, if the majority of labeled interaction words are positive, we set $s = 1$, otherwise we set $s = 0$.

Let \mathbf{Y} denote the set of all y variables, and $\mathbf{Y}_{-(u,n)}$ denote \mathbf{Y} excluding $y_{u,n}$. Similar notation is used for the other variables. We sample $y_{u,n}$ using the following formula.

$$\begin{aligned} & p(y_{u,n} = k | \mathbf{Y}_{-(u,n)}, \mathbf{Z}, \mathbf{S}, \mathbf{X}, \alpha, \eta, \delta) \\ & \propto \frac{p(y_{u,n} = k, \mathbf{Y}_{-(u,n)} | \alpha)}{p(\mathbf{Y}_{-(u,n)} | \alpha)} \cdot \frac{p(\mathbf{Z} | y_{u,n} = k, \mathbf{Y}_{-(u,n)}, \mathbf{X}, \eta)}{p(\mathbf{Z}_{-(u,n)} | \mathbf{Y}_{-(u,n)}, \mathbf{X}_{-(u,n)}, \eta)} \\ & \quad \cdot p(\mathbf{S} | y_{u,n} = k, \mathbf{Y}_{-(u,n)}, \delta) \\ & = \frac{C_{u,-n}^k + \alpha}{C_{u,-n}^{(\cdot)} + Y\alpha} \cdot \frac{\prod_{t=1}^T \prod_{a=0}^{C_{u,-n}^{t-1}-1} (C_{k,-(u,n)}^t + \eta + a)}{\prod_{b=0}^{C_{u,-n}^{(\cdot)}-1} (C_{k,-(u,n)}^{(\cdot)} + T\eta + b)} \\ & \quad \cdot p(\mathbf{S} | y_{u,n} = k, \mathbf{Y}_{-(u,n)}, \delta). \end{aligned} \quad (2)$$

Here all C s are counters. $C_{u,-n}^k$ is the number of times we observe the viewpoint k from u 's posts, excluding the n -th post, based on $\mathbf{Y}_{-(u,n)}$. $C_{u,n}^t$ is

the number of times we observe topic t from user u 's n -th post, based on $\mathbf{Z}_{u,n}$. And $C_{k,\neg(u,n)}^t$ is the number of times we observe topic t associated with viewpoint k , excluding user u 's n -th post. Note that we need \mathbf{X} to know which words are assigned to the background topic so we can exclude them for $C_{u,n}^t$ and $C_{k,\neg(u,n)}^t$. $C_{u,\neg n}^{(\cdot)}$ is the number of times we observe any viewpoint from u 's posts, excluding the n -th post. $C_{u,n}^{(\cdot)}$ and $C_{k,\neg(u,n)}^{(\cdot)}$ are defined similarly.

The last term is further expanded as follows:

$$p(\mathbf{S}|y_{u,n} = k, \mathbf{Y}_{\neg(u,n)}, \delta) = p(s_{u,n}|y_{u,n} = k, \mathcal{Y}_{u,n}, \delta) \cdot p(\mathbf{S}_{\neg(u,n)}|y_{u,n} = k, \mathbf{Y}_{\neg(u,n)}, \delta). \quad (3)$$

Here $p(s_{u,n}|y_{u,n} = k, \mathcal{Y}_{u,n}, \delta)$ is computed according to Eqn. (1). For the latter term, we need to consider posts which reply to user u 's n -th post because the value of $y_{u,n}$ affects these posts.

$$p(\mathbf{S}_{\neg(u,n)}|y_{u,n} = k, \mathbf{Y}_{\neg(u,n)}, \delta) \propto \prod_{(u',n'): y_{u,n} \in \mathcal{Y}_{u',n'}} p(s_{u',n'}|y_{u',n'}, \mathcal{Y}_{u',n'}, \delta). \quad (4)$$

Next, we show how we jointly sample $x_{u,n,l}$ and $z_{u,n,l}$. We jointly sample them because when $x_{u,n,l} = 0$, $z_{u,n,l}$ does not need a value. We have the following formulas:

$$\begin{aligned} & p(x_{u,n,l} = 1, z_{u,n,l} = t | \mathbf{X}_{\neg(u,n,l)}, \mathbf{Z}_{\neg(u,n,l)}, \mathbf{Y}, \mathbf{W}, \gamma, \eta, \beta, \beta^B) \\ & \propto \frac{C_{\neg(u,n,l)}^1 + \gamma}{C_{\neg(u,n,l)}^{(\cdot)} + 2\gamma} \cdot \frac{C_{y_{u,n,l}, \neg(u,n,l)}^t + \eta}{C_{y_{u,n,l}, \neg(u,n,l)}^{(\cdot)} + T\eta} \cdot \frac{C_{t,\neg(u,n,l)}^{w_{u,n,l}} + \beta}{C_{t,\neg(u,n,l)}^{(\cdot)} + V\beta}, \quad (5) \\ & p(x_{u,n,l} = 0 | \mathbf{X}_{\neg(u,n,l)}, \mathbf{Z}_{\neg(u,n,l)}, \mathbf{Y}, \mathbf{W}, \gamma, \eta, \beta, \beta^B) \\ & \propto \frac{C_{\neg(u,n,l)}^0 + \gamma}{C_{\neg(u,n,l)}^{(\cdot)} + 2\gamma} \cdot \frac{C_{B,\neg(u,n,l)}^{w_{u,n,l}} + \beta^B}{C_{B,\neg(u,n,l)}^{(\cdot)} + V\beta^B}. \quad (6) \end{aligned}$$

Here again the C s are counters defined in similar ways as before. For example, $C_{\neg(u,n,l)}^1$ is the number of times we observe 1 assigned to an x variable, excluding $x_{u,n,l}$.

3.4 Interaction polarity prediction

The problem of detecting agreement and disagreement from forum posts is relatively new. One possible solution is to use supervised learning, which requires training data (Galley et al., 2004; Abbott et al., 2011; Andreas et al., 2012). However, training

data are also likely domain and language dependent, which makes them hard for re-use. For our task, we take a simpler approach and use a sentiment lexicon together with some heuristics to predict the polarity of interaction expressions. Specifically, we first identify interaction sentences following the strategies from Hassan et al. (2012). We assume sentences containing mentions of the recipient of a post are interaction sentences. Next, we consider words within a text window of 8 words surrounding these mentions. We then use a subjectivity lexicon to label these words. To form an English lexicon, we combine three popular lexicons: the sentiment lexicon used by Hu and Liu (2004), Multi-Perspective Question Answering Subjectivity Lexicon by Wilson et al. (2005) and SentiWordNet by Baccianella et al. (2010). Since we also work with a Chinese data set, to form the Chinese sentiment lexicon, we use opinion words from HowNet² and NTUSD by Ku et al. (2007). To predict the polarity of an interaction expression, we simply check whether there are more positive sentiment words or more negative sentiment words in the expression, and label the interaction expression accordingly.

We would like to stress that since this interaction classification step is independent of the latent variable model, we can always apply a more accurate method, but this is not the focus of this work.

4 Models for Comparison

In our experiments, we compare our model, Joint Viewpoint-Topic Model with User Interaction (JVTM-UI), with the following baseline models.

JVTM: The model is shown in Figure 3(a), a variant of JVTM-UI that does not consider user interaction. Through comparison with it, we can check the effect of modeling user interactions.

JVTM-G: We consider JVTM-G in Figure 3(b), a variant of JVTM which assumes a global viewpoint distribution. Comparison with it allows us to check the usefulness of user identity in the task.

UIM: The third model we consider is a User Interaction Model (UIM) in Figure 3(c), where we rely on only the users' interactions to infer the viewpoints. We use it to check how well viewpoints can be discovered from only user interaction expressions.

²http://www.keenage.com/html/e_index.html

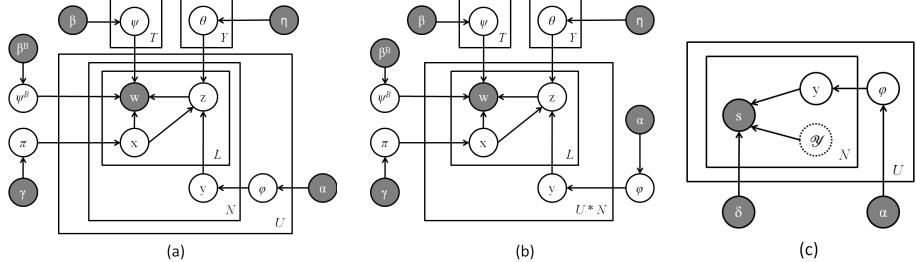

Figure 3: (a) JVTM: Joint Viewpoint-Topic Model. (b) JVTM-G: JVTM with a global viewpoint distribution. (c) UIM: User-Interaction Model.

TAM: The last model we consider is the one by Paul et al. (2010). As TAM is applied at document collections, we first concatenate all the posts by the same user into a pseudo document and then apply TAM.

5 Experiments and Analysis

In this section, we evaluate our model with a set of baseline models using two data sets.

Name	Issue	#Posts	#Users
EDS1	Vote for Obama	2599	197
EDS2	Arizona Immigration Law	738	59
EDS3	Tax Cuts	276	26
CDS1	Tencent and Qihoo dispute	30137	2507
CDS2	Fang Zhouzi questions Han Han	76934	1769
CDS3	Liu Xiang in London Olympics	29486	2774

Table 2: Some statistics of the data set.

5.1 Data Sets and Experimental Settings

We focus our work on finding users’ viewpoints on a controversial issue, where we assume that there are two contradictory viewpoints. We use two data sets on controversial issues. The first data set comes from Abu-Jbara et al. (2012) and Hassan et al. (2012). This data set originally was used for finding subgroups of users, so the annotations were done at user level, i.e. for each user there is a label indicating which subgroup he/she belongs to. We use the top-3 mostly discussed threads with two subgroups for our study.

In reality, controversial issues are often discussed across threads. We thus constructed another large data set which contains more than one thread for each issue. We chose three hot issues from one of the most popular Chinese online forums — TianYa

Club³. The three issues are “Fang Zhouzi questions Han Han”⁴, “Tencent and Qihoo dispute”⁵, and “Liu Xiang in London Olympics”⁶. All these issues triggered heated discussions on the forum and we found that most of the users were divided into two different groups.

We crawled the data set using the TianYa API⁷. The API allows users to issue queries and get threads most related to the queries. For each issue, we used entities involved in the event as queries and obtained 750 threads for each query. We then extracted all the posts in the threads. As there are users who posted irrelevant posts in the forum, we then filtered out those users who did not mention the entities or had fewer than 4 posts.

We refer to the first set of data in English as EDS1, EDS2 and EDS3, and the second set of data in Chinese as CDS1, CDS2 and CDS3. Some statistics of the resulting data set are shown in Table 2.

For all the models, we set $Y = 2$. We set $T = 10$ for the English data sets and $T = 40$ for the Chinese data sets. We run 400 iterations of Gibbs sampling as burn-in iterations and then take 100 samples with a gap of 5 to obtain our final results. We empirically set $\beta = 0.01$, $\beta^B = 0.1$, $\gamma = 10$ and $\delta = 0.1$ for our model on all the data sets. α and η are set through grid search where they take values in $\{0.01, 0.001\}$. For each data set, we choose the best setting for each model and report the corresponding results.

5.2 Identification of viewpoints

We first evaluate the models on the task of identifying viewpoints. For fair comparison, each model will output a viewpoint label for each post. For JVTM-UI, JVTM, JVTM-G and UIM, after we learn the model, each post will directly have a viewpoint assignment. For TAM we cannot directly get each post’s viewpoint as the model assumes a document-level viewpoint distribution. To estimate each post’s viewpoint in this model, we use viewpoint assignment at the word level learnt from the model. Then for each post, we label its viewpoint as the viewpoint that has the majority count in the post.

Ideally, we would like to manually label all the posts to obtain the ground truth for evaluation. Since there are too many posts, we only labeled a sample of them. For each issue, we randomly selected 150 posts to label their viewpoints. For each post, we asked two different annotators to label its viewpoint. We made sure that the annotators understand the issue and the two major viewpoints before they annotated the posts. Specifically, as the Chinese data sets are about some controversial issues around the entities involved, we then defined two major viewpoints as *support* and *not support* the entity who initiated the event. The entities of data set CDS1, CDS2 and CDS3 are *Fang Zhouzi*, *Tencent* and *Liu Xiang* respectively. For each given post, the annotators were asked to judge whether the post has expressed viewpoints and if so, what is its corresponding viewpoint. We measure the agreement score using Cohen’s kappa coefficient. The lowest agreement score for an issue is 0.61 in the data set, showing good agreement. We then used the set of posts that were labeled with the same viewpoint by the two annotators as our evaluation data for all the models.

Since our task is essentially a clustering problem, we use *purity* and *entropy* to measure the performance (Manning et al., 2008). Furthermore, we also use *accuracy* where we choose the better alignment of clusters with ground truth class labels and compute the percentage of posts that are “classified” correctly. For purity and accuracy, the higher the measure is the better the performance. For entropy, the lower the measure is the better the performance.

We give an overview of the all the averaged model results on the data sets in Figure 4. We observed that

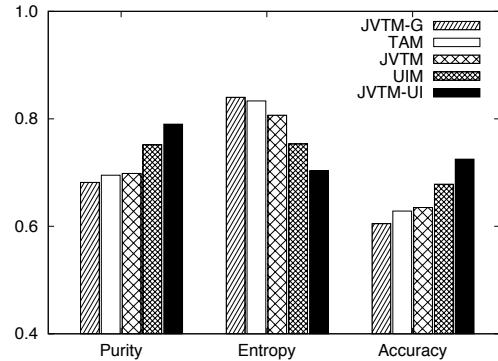

Figure 4: Averaged results of the models in identification of viewpoints.

UIM performs relatively better than other methods except our model. This shows user interactions are important features to identify post viewpoints. Overall, our model has a better performance as it is with higher purity and accuracy, and lower entropy.

	<i>A</i> 0.67	0.59	0.67	0.66	0.63

Table 3: Results on viewpoint identification on the all data sets.

Table 3 shows the detailed results on the data sets. We perform the 2-tailed paired t-test as used by Abu-Jbara et al. (2012) on the results. All the result differences are at 10% significance level if not with further clarification. First, JVTM has a better performance over JVTM-G, which shows it is important to consider user identity in the task. Second, JVTM and TAM have similar performance on

EDS1 and CDS2, but JVTM has a relatively better performance on EDS2, EDS3, CDS1 and CDS3. This shows it is helpful to consider each viewpoint’s topic preference. Although as studied by Paul et al. (2010), by only using unigram features, TAM may not be able to cluster viewpoints accurately, our study shows that the results can be improved when adding each viewpoint’s topic focus. Third, UIM has relatively better performance than the other models, which demonstrates that user interactions alone can do a decent job in inferring viewpoints. Finally, our proposed model has the best performance across the board in terms of all three evaluation metrics. Note that, our proposed model significantly outperforms other methods at 5% significance level except at 10% significance level over JVTM model. This shows by jointly modeling topics, viewpoints and user interactions, our model can better identify posts with different viewpoints.

5.3 Identification of user groups

We also use another task to evaluate our model. The task here is finding each user’s viewpoint and subsequently grouping users by their viewpoints. This task has been studied by Abu-Jbara and Radev (2012), Dasigi et al. (2012), Abu-Jbara et al. (2012) and Hassan et al. (2012). For the English data set, the user-level group labels are provided by the original data set. For the Chinese data set, we randomly selected 150 users for each issue and manually labeled them according to their viewpoints as reflected by their posts. If a user’s posts do not clearly suggest a viewpoint, we label her as neutral. Again we asked two human judges to do annotation. The agreement scores are above 0.70 for all issues, showing substantial agreement. This score is higher than viewpoint identification, which suggests that it is easier to judge a user’s viewpoint than a single post’s viewpoint. We use the set of users who have got the same labels by the two human judges for our experiments. Similarly we compute *purity*, *entropy* and *accuracy* to evaluate the clustering results.

Figure 5 shows the averaged results of all the models. Similar to previous experiment, our model has a better performance compared to the competing models.

The results on the each data set are shown in Table 4. The tables show that similar trends can be

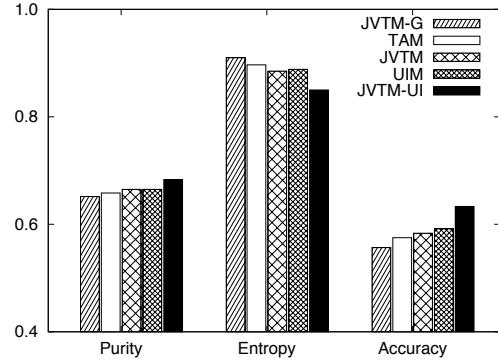

Figure 5: Averaged results of the models in identification of user groups.

	<i>A</i>	0.64	0.62	0.60	0.54

Table 4: Results on identification of user groups on the all the data sets.

observed for the task of user group identification. We also perform the 2-tailed paired t-test on the results. We find our model significantly outperforms other models in terms of accuracy at 5% significance level, and purity and entropy at 10% significance level. Overall speaking, our joint model performed the best among all the models for this task for all three metrics. This shows that it is important to consider the topical preference of individual viewpoint, user’s identify as well as the interactions between users.

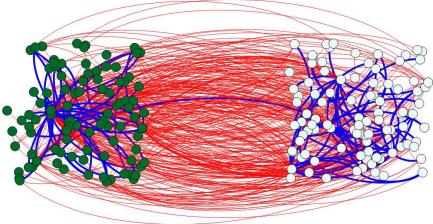

Figure 6: The user interaction network in a discussion thread about “will you vote obama.” Green (left) and white (right) nodes represent users with two different viewpoints. Red (thin) and blue(thick) edges represent negative and positive interactions.

5.4 User interaction network

To gain some direct insight into our results, we show the user interaction network from one thread in Figure 6. Here each node denotes a user, and its color denotes the predicted viewpoint of that user. A link between a pair of users means these users have interactions and the interaction types have a dominant polarity. The polarities of these links are predicted using the interaction expressions and a sentiment lexicon, whereas the viewpoints of different users are learned by JVTM-UI, making use of the interaction polarities. The figure shows that clearly there are mostly positive interactions between users with the same viewpoint and mostly negative interactions between users with different viewpoints. Note that, our method to identify user interaction polarity is rule-based. As this step serves as a preprocessing step for our latent variable model, we can always use a more accurate method to improve the performances.

6 Conclusion

In this work, we proposed a novel latent variable model for viewpoint discovery from threaded forum posts. Our model is based on the three important factors: viewpoint specific topic preference, user identity and user interactions. Our proposed model captures these observations in a principled way. In particular, to incorporate the user interaction information, we proposed a novel generative process. Empirical evaluation on the real forum data sets showed that our model could cluster both posts and users with different viewpoints more accurately than the baseline models we consider. To the best of our

knowledge, our work is the first to incorporate user interaction polarity into a generative model to discover viewpoints.

In this work, we only considered unigrams. As some previous work has shown, more complex lexical units such as n -grams (Mukherjee and Liu, 2012) and dependency triplets (Paul et al., 2010) may improve the performance of topic models. We will consider these strategies in our future work. Currently we use a simple heuristic-based classifier to predict interaction polarity. In our further work, we plan to consider more accurate methods using deeper linguistic analysis. We did not study how to summarize the discovered viewpoints in this work, which is also something we will look into in our future work.

Acknowledgments

We thank the reviewers for their valuable comments on this work. We also thank Shuang Xia for his help on processing and labeling the data sets.

Abstract

This paper proposes to study the problem of identifying intention posts in online discussion forums. For example, in a discussion forum, a user wrote “I plan to buy a camera,” which indicates a buying intention. This intention can be easily exploited by advertisers. To the best of our knowledge, there is still no reported study of this problem. Our research found that this problem is particularly suited to transfer learning because in different domains, people express the same intention in similar ways. We then propose a new transfer learning method which, unlike a general transfer learning algorithm, exploits several special characteristics of the problem. Experimental results show that the proposed method outperforms several strong baselines, including supervised learning in the target domain and a recent transfer learning method.

1 Introduction

Social media content is increasingly regarded as an information gold mine. Researchers have studied many problems in social media, e.g., sentiment analysis (Pang & Lee, 2008; Liu, 2010) and social network analysis (Easley & Kleinberg, 2010). In this paper, we study a novel problem which is also of great value, namely, *intention identification*, which aims to identify discussion posts expressing certain user intentions that can be exploited by businesses or other interested parties. For example, one user wrote, “*I am looking for a brand new car to replace my old Ford Focus*”. Identifying such intention automatically can help social media sites to decide what ads to display so

that the ads are more likely to be clicked.

This work focuses on identifying user posts with *explicit* intentions. By *explicit* we mean that the intention is explicitly stated in the text, no need to deduce (hidden or implicit intention). For example, in the above sentence, the author clearly expressed that he/she wanted to buy a car. On the other hand, an example of an implicit sentence is “*Anyone knows the battery life of iPhone?*” The person may or may not be thinking about buying an iPhone.

To our knowledge, there is no reported study of this problem in the context of text documents. The main related work is in Web search, where *user* (or *query*) *intent classification* is a major issue (Hu et al., 2009; Li, 2010; Li, Wang, & Acero, 2008). Its task is to determine what the user is searching for based on his/her keyword queries (2 to 3 words) and his/her click data. We will discuss this and other related work in Section 2.

We formulate the proposed problem as a two-class classification problem since an application may only be interested in a particular intention. We define *intention posts* (positive class) as the posts that explicitly express a particular intention of interest, e.g., the intention to buy a product. The other posts are *non-intention posts* (negative class). Note that we do not exploit intention specific knowledge since our aim is to propose a generic method applicable to different types of intentions.

There is an important feature about this problem which makes it amenable to transfer learning so that we do not need to label data in every domain. That is, for a particular kind of intention such as buying, the ways to express the intention in different domains are often very similar. This

fact can be exploited to build a classifier based on labeled data in some domains and apply it to a new/target domain without labeling any training data in the target domain. However, this problem also has some special difficulties that existing general transfer learning methods do not deal with. The two special difficulties of the proposed problem are as follows:

1. In an intention post, the intention is typically expressed in only one or two sentences while most sentences do not express intention, which provide very noisy data for classifiers. Furthermore, words/phrases used for expressing intention are quite limited compared to other types of expressions. These mean that the set of shared (or common) features in different domains is very small. Most of the existing advanced transfer learning methods all try to extract and exploit these shared features. The small number of such features in our task makes it hard for the existing methods to find them accurately, which in turn learn poorer classifiers.
2. As mentioned above, in different domains, the ways to express the same intention are often similar. This means that only the positive (intention) features are shared among different domains, while features indicating the negative class in different domains are very diverse. We then have an imbalance problem, i.e., the shared features are almost exclusively features indicating the positive class. To our knowledge, none of the existing transfer learning methods deals with this imbalance problem of shared features, which also results in inaccurate classifiers.

We thus propose a new transfer learning (or domain adaptation) method, called Co-Class, which, unlike a general transfer learning method, is able to deal with these difficulties in solving the problem. Co-Class works as follows: we first build a classifier h using the labeled data from existing domains, called the source data, and then apply the classifier to classify the target (domain) data (which is unlabeled). Based on the target data labeled by h , we perform a feature selection on the target data. The selected set of features is used to build two classifiers, one (h_S) from the labeled source data and one (h_T) from the target data which has been labeled by h . The two classifiers (h_S and h_T) then work together to perform classi-

fication of the target data. The process then runs iteratively until the labels assigned to the target data stabilize. Note that in each iteration both classifiers are built using the same set of features selected from the target domain in order to focus on the target domain. The proposed Co-Class explicitly deals with the difficulties mentioned above (see Section 3). Our experiments using four real-life data sets extracted from four forum discussion sites show that Co-Class outperforms several strong baselines. What is also interesting is that it works even better than fully supervised learning in the target domain itself, i.e., using both training and test data in the target domain. It also outperforms a recent state-of-the-art transfer learning method (Tan et al., 2009), which has been successfully applied to the NLP task of sentiment classification.

In summary, this paper makes two main contributions:

1. It proposes to study the novel problem of intention identification. User intention is an important type of information in social media with many applications. To our knowledge, there is still no reported study of this problem.
2. It proposes a new transfer learning method Co-Class which is able to exploit the above two key issues/characteristics of the problem in building cross-domain classifiers. Our experimental results demonstrate its effectiveness.

2 Related Work

Although we have not found any paper studying intention classification of social media posts, there are some related works in the domain of Web search, where user or query intent classification is a major issue (Hu et al., 2009; Li, 2010; Li et al., 2008). The task there is to classify a query submitted to a search engine to determine what the user is searching for. It is different from our problem because they classify based on the user-submitted keyword queries (often 2 to 3 words) together with the user's click-through data (which represent the user's behavior). Such intents are typically implicit because people usually do not issue a search query like "*I want to buy a digital camera.*" Instead, they may just type the keywords "*digital camera*". Our interest is to identify *explicit* intents expressed in full text documents (forum posts). Another related problem is online commercial intention (OCI) identification (Dai et al.,

2006; Hu et al., 2009), which focuses on capturing commercial intention based on a user query and web browsing history. In this sense, OCI is still a user query intent problem.

In NLP, (Kanayama & Nasukawa, 2008) studied users' needs and wants from opinions. For example, they aimed to identify the user needs from sentences such as "*I'd be happy if it is equipped with a crisp LCD.*" This is clearly different from our explicit intention to buy or to use a product/service, e.g., "*I plan to buy a new TV.*"

Our proposed Co-Class technique is related to transfer learning or domain adaptation. The proposed method belongs to "*feature representation transfer*" from source domain to target domain (Pan & Yang, 2010). Aue & Gamon (2005) tried training on a mixture of labeled reviews from other domains where such data are available and test on the target domain. This is basically one of our baseline methods 3TR-1TE in Section 4. Their work does not do multiple iterations and does not build two separate classifiers as we do. Some related methods were also proposed in (W. Dai, Xue, Yang & Yu, 2007; Tan et al., 2007; Yang, Si & Callan, 2006). More sophisticated transfer learning methods try to find common features in both the source and target domains and then try to map the differences of the two domains (Blitzer, Dredze, & Pereira, 2007; Pan, et al, 2010; Bollegala, Weir & Carroll, 2011; Tan et al., 2009). Some researchers also used topic modeling of both domains to transfer knowledge (Gao & Li, 2011; He, Lin & Alani, 2011). However, none of these methods deals with the two problems/difficulties of our task. Co-Class tackles them explicitly and effectively (Section 4).

The proposed Co-Class method is also related to Co-Training method in (Blum & Mitchell, 1998). We will compare them in detail in Section 3.3.

3 The Proposed Technique

We now present the proposed technique. Our objective is to perform classification in the target domain by utilizing labeled data from the source domains. We use the term "source domains" as we can combine labeled data from multiple source domains. The target domain has no labeled data. Only the source domain data are labeled.

To deal with the first problem in Section 1 (i.e.,

the difficulty of finding common features across different domains), Co-Class avoids it by using an EM-based method to iteratively transfer from the source domains to the target domain while exploiting feature selection in the target domain to focus on important features in the target domain.

Since our ideas are developed starting from the EM (Expectation Maximization) algorithm and its shortcomings, we now introduce EM.

3.1 EM Algorithm

EM (Dempster, Laird, & Rubin, 1977) is a popular class of iterative algorithms for maximum likelihood estimation in problems with incomplete data. It is often used to address missing values in the data by computing expected values using existing values. The EM algorithm consists of two steps, the Expectation step (E-step) and the Maximization step (M-step). E-step basically fills in the missing data, and M-step re-estimates the parameters. This process iterates until convergence. Since our target data have no labels, which can be treated as missing values/data, the EM algorithm naturally applies. For text classification, each iteration of EM (Nigam, McCallum, Thrun, & Mitchell, 2000) usually uses the naïve Bayes (NB) classifier. Below, we first introduce the NB classifier.

Given a set of training documents D , each document $d_i \in D$ is an ordered list of words. We use $w_{d_i,k}$ to denote the word in the position k of d_i , where each word is from the vocabulary $V = \{w_1, \dots, w_{|V|}\}$, which is the set of all words considered in classification. We also have a set of classes $C = \{+, -\}$ representing positive and negative classes. For classification, we compute the posterior probability $\Pr(c_j | d_i)$. Based on the Bayes rule and multinomial model, we have:

$$\Pr(c_j) = \frac{\sum_{i=1}^{|D|} \Pr(c_j | d_i)}{|D|} \quad (1)$$

and with Laplacian smoothing:

$$\Pr(w_t | c_j) = \frac{1 + \sum_{i=1}^{|D|} N(w_t, d_i) \Pr(c_j | d_i)}{|V| + \sum_{s=1}^{|V|} \sum_{i=1}^{|D|} N(w_s, d_i) \Pr(c_j | d_i)} \quad (2)$$

where $N(w_t, d_i)$ is the number of times that the word w_t occurs in document d_i , and $\Pr(c_j | d_i) \in [0, 1]$ is the probability of assigning class c_j to d_i . Assuming that word probabilities are independent given a class, we have the NB classifier:

$$\Pr(c_j | d_i) = \frac{\Pr(c_j) \prod_{k=1}^{|d_i|} \Pr(w_{d_i,k} | c_j)}{\sum_{r=1}^{|C|} \Pr(c_r) \prod_{k=1}^{|d_i|} \Pr(w_{d_i,k} | c_r)} \quad (3)$$

The EM algorithm basically builds a classifier iteratively using NB and both the labeled source data and the unlabeled target data. However, the major shortcoming is that the feature set, even with feature selection, may fit the labeled source data well but not the target data because the target data has no labels to be used in feature selection. Feature selection is shown to be very important for this application as we will see in Section 4.

3.2 FS-EM

Based on the discussion above, the key to solve the problem of EM is to find a way to reflect the features in the target domain during the iterations. We propose two alternatives, FS-EM (Feature Selection EM) and Co-Class (Co-Classification). This sub-section presents FS-EM.

EM can select features only before iterations using the labeled source data and keep using the same features in each iteration. However, these features only fit the labeled source data but not the target data. We then propose to select features during iterations, i.e., after each iteration, we redo feature selection. For this, we use the predicted classes of the target data. In naïve Bayes, we define the predicted class for document d_i as

$$c = \operatorname{argmax}_{c_j \in C} \Pr(c_j | d_i) \quad (4)$$

The detailed algorithm for FS-EM is given in Figure 1. First, we select a feature set from the labeled source data D_L and then build an initial NB classifier (lines 1 and 2). The feature selection is based on Information Gain, which will be introduced in Section 3.4. After that, we classify each document in the target data D_U to obtain its predicted class (lines 4-6). A new target data set D_P is produced in line 7, which is D_U with added classes (predicted in line 5). Line 8 selects a new feature set Δ from the data D' (which is discussed below), from which a new classifier h is built (line 9). The iteration stops when the predicted classes of D_U do not change any more (line 10).

We now turn to the data set D' , which can be formed with one of the two methods:

1. $D' = D_L \cup D_P$
2. $D' = D_P$

The first method (called FS-EM1) merges the labeled source data D_L and the target data D_P (with predicted classes). However, this method does not work well because the labeled source data can dominate D' and the target domain features are still not well represented.

The second method ($D' = D_P$), denoted as FS-EM2, selects features from the target domain data D_P only based on the predicted classes. The classifiers are built in iterations (lines 3-10) using only the target domain data. The weakness of this is that it completely ignores the labeled source data after initialization, but the source data does contain some valuable information. Our final proposed method Co-Class is able to solve this problem.

3.3 Co-Class

Co-Class is our final proposed algorithm. It considers both the source labeled data and the target data with predicted classes. It uses the idea of FS-EM, but is also inspired by Co-Training in (Blum & Mitchell, 1998). It additionally deals with the second issue identified in Section 1 (i.e., the imbalance of shared positive and negative features).

Co-Training is originally designed for semi-supervised learning to learn from a small labeled and a large unlabeled set of training examples, which assumes the set of features in the data can be partitioned into two subsets, and each subset is sufficient for building an accurate classifier. The proposed Co-Class model is similar to Co-Training in that it also builds two classifiers. However, unlike Co-Training, Co-Class does not partition the feature space. Instead, one classifier is built based on the target data with predicted classes (D_P), and the other classifier is built using only the source labeled data (D_L). Both classifiers use the same features (this is an important point) that are selected from the target data D_P only, in order to focus on the target domain. The final classification is based on both classifiers. Furthermore, Co-Training only uses the data from the same domain.

The detailed Co-Class algorithm is given in Figure 2. Lines 1-6 are the same as lines 1, 2 and 4-7 in FS-EM. Line 8 selects new features Δ from D_P . Two naïve Bayes classifiers, h_L and h_P , are then built using the source data D_L and predicted target data D_P respectively with the same set of

Algorithm FS-EM

```

Input: Labeled data  $D_L$  and unlabeled data  $D_U$ 
1 Select a feature set  $\Delta$  based on IG from  $D_L$ ;
2 Learn an initial naïve Bayes classifier  $h$  from  $D_L$ 
   based on  $\Delta$  (using Equations (1) and (2));
3 repeat
4   for each document  $d_i$  in  $D_U$  do
5      $c = h(d_i)$ ; // predict the class of  $d_i$  using  $h$ 
6   end
7   Produce data  $D_P$  based on predicted class of  $D_U$ ;
8   Select a new feature set  $\Delta$  from  $D'$ ;
9   Learn a new classifier  $h$  on  $D'$ 
   based on the new feature set  $\Delta$ ;
10 until the predicted classes of  $D_U$  stabilize
11 Return the classifier  $h$  from the last iteration.

```

Figure 1 – The FS-EM algorithm

features Δ (lines 9-10). Lines 11-13 classify each target domain document d_i using the two classifiers. $\Phi(h_L(d_i), h_P(d_i))$ is the aggregate function to combine the results of two classifiers. It is defined as:

$$\Phi(h_L(d_i), h_P(d_i)) = \begin{cases} + & h_L(d_i) = h_P(d_i) = + \\ - & \text{Otherwise} \end{cases}$$

This aims to deal with the imbalanced feature problem. As discussed before, the expressions for stating a particular intention (e.g., buying) are very similar across domains but the non-intention expressions across domains are highly diverse, which result in strong positive features and weak negative features. We then need to restrict the positive class by requiring both classifiers to give positive predictions. If we use the method in Co-Training (multiplying the probabilities of the two NB classifiers), the classification results deteriorate from iteration to iteration because the positive class recall gets higher and higher due to strong positive features, but the precision gets lower and lower.

Since we build and use two classifiers for the final classification, we call the method *Co-Class*, short for *Co-Classification*. Co-Class is different from EM (Nigam et al., 2000) in two main aspects. First, it integrates feature selection into the iterations, which has not been done before. Feature selection refines features to enhance the correlation between the features and classes. Second, two classifiers are built based on different domains and combined to improve the classification. Only one classifier is built in existing EM methods, which gives poorer results (Section 4).

Algorithm Co-Class

```

Input: Labeled data  $D_L$  and unlabeled data  $D_U$ 
1 Select a feature set  $\Delta$  based on IG from  $D_L$ ;
2 Learn an initial naïve Bayes classifier  $h$  from  $D_L$ 
   based on  $\Delta$  (using Equations (1) and (2));
3 for each document  $d_i$  in  $D_U$  do
4    $c = h(d_i)$ ; // predict the class of  $d_i$  using  $h$ 
5 end
6 Produce data  $D_P$  based on the predicted class of  $D_U$ ;
7 repeat
8   Select a new feature set  $\Delta$  from  $D_P$ ;
9   Build a naïve Bayes classifier  $h_L$  using  $\Delta$  and  $D_L$ ;
10  Build a naïve Bayes classifier  $h_P$  using  $\Delta$  and  $D_P$ ;
11  for each document  $d_i$  in  $D_U$  do
12     $c_i = \Phi(h_L(d_i), h_P(d_i))$ ; // Aggregate function
13  end
14  Produce data  $D_P$  based on predicted class of  $D_U$ ;
15 until the prediction classes of  $D_U$  stabilize
16 Return classifiers  $h_L$  and  $h_P$  from the last iteration.

```

Figure 2 – The Co-Class algorithm

3.4 Feature Selection

As feature selection is important for our task, we briefly introduce the Information Gain (IG) method given in (Yang & Pedersen, 1997), which is a popular feature selection algorithm for text classification. IG is based on entropy reflecting the purity of the categories or classes by knowing the presence or absence of each feature, which is defined as:

$$IG(f) = -\sum_{i=1}^m P(c_i) \log P(c_i) + \sum_{f,f} P(f) \sum_{i=1}^m P(c_i | f) \log P(c_i | f)$$

Using the IG value of each feature f , all features can be ranked. As in normal classification tasks, the common practice is to use a set of top ranked features for classification.

4 Evaluation

We have conducted a comprehensive set of experiments to compare the proposed Co-Class method with several strong baselines, including a state-of-the-art transfer learning method.

4.1 Experiment Settings

Datasets: We created 4 different domain datasets crawled from 4 different forum discussion sites:

Cellphone: <http://www.howardforums.com/forums.php>
 Electronics: <http://www.avsforsforum.com/avs-vb/>
 Camera: <http://forum.digitacamerareview.com/>

TV: <http://www.avforums.com/forums/tvs/>

For our experiments, we are interested in the intention to *buy*, which is our intention or positive class. For each dataset, we manually labeled 1000 posts.

Labeling: We initially labeled about one fifth of posts by two human annotators. We found their labels highly agreed. We then used only one annotator to complete the remaining labeling. The reason for the strong labeling agreement is that we are interested in only explicit buying intentions, which are clearly expressed in each post, e.g., “*I am in the market for a new smartphone.*” There is little ambiguity or subjectivity in labeling.

To ensure that the task is realistic, for all datasets we keep their original class distributions as they are extracted from their respective websites to reflect the real-life situation. The intention class is always the minority class, which makes it much harder to predict due to the imbalanced class distribution. Table 1 gives the statistics of each dataset. On average, each post contains about 7.5 sentences and 122 words. We have made the datasets used in this paper publically available at the websites of the first two authors.

Evaluation measures: For all experiments, we use *precision*, *recall* and *F1-score* as the evaluation measures. They are suitable because our objective is to identify intention posts.

4.2 One Domain Learning

The objective of our work is to classify the target domain instances without labeling any target domain data. To set the background, we first give the results of one domain learning, i.e., assuming that there is labeled training data in the target domain (which is the traditional fully supervised learning). We want to see how the results of Co-Class compare with the fully supervised learning.

For this set of experiments, we use naïve Bayes and SVM. For naïve Bayes, we use the *Lingpipe* implementation (<http://alias-i.com/lingpipe/>). For

Dataset	No. of Intention	No. of Non-Intention	Total No. of posts
Cellphone	184	816	1000
Electronics	280	720	1000
Camera	282	718	1000
TV	263	737	1000

Table 1: Datasets statistics with the buy intention

SVM, we use *SVM^{Light}* (Joachims, 1999) from (<http://svmlight.joachims.org/>) with the linear kernel as it has been shown by many researchers that linear kernel is sufficient for text classification (Joachims, 1998; Yang and Liu, 1999).

During labeling, we observed that the intention in an intention (positive) post is often expressed in the first few or the last few sentences. Hence, we tried to use the full post (denoted by Full), the first 5 sentences (denoted by (5, 0)), and first 5 and last 5 sentences (denoted by (5, 5)). We also experimented with the first 3 sentences, and first 3 and last 3 sentences but their results were poorer.

The experiments were done using 10-fold cross validation. For the number of selected features, we tried 500, 1000, 1500, 2000, 2500 and all. We also tried unigrams, bigrams, trigrams, and 4-grams. To compare naïve Bayes with SVM, we tried each combination, i.e. number of features and n-grams, and found the best model for each method. We found that naïve Bayes works best when using trigrams with 1500 selected features. Bigrams with 1000 features are the best combination for SVM. Figure 3 shows the comparison of the best results (F1-scores) of naïve Bayes and SVM.

From Figure 3, we make the following observations:

1. SVM does not do well for this task. We tuned the parameters of SVM, but the results were similar to the default setting, and all were worse than naïve Bayes. We believe the main reason is that the data for this application is highly noisy because apart from one or two intention sentences, other sentences in an intention post have little difference from those in a non-intention post. SVM does not perform well with very noisy data. When there are data points far away from their own classes, SVM

Table 3: F1-scores of 3TR-1TE with trigrams and different no. of features

tends to be strongly affected by such points (Wu & Liu, 2007). Naïve Bayes is more robust in the presence of noise due to its probabilistic nature.

2. SVM using only the first few and/or last few sentences performs better than using full posts because full posts have more noise. However, it is still worse than naïve Bayes.
3. For naïve Bayes, using full posts and the first 5 and last 5 (5, 5) sentences give similar results, which is not surprising as (5, 5) has almost all the information needed. Without using the last 5 sentence (5, 0), the results are poorer.

We also found that without feature selection (using all features), the results are markedly worse for both naïve Bayes and SVM. This is understandable (as we discussed earlier) because most words and sentences in both intention and non-intention posts are very similar. Thus, feature selection is highly desirable for this application.

Effect of different combinations: Table 2 gives the detailed F1-score results of naïve Bayes with best results in different n-grams (with best number of features). We can see that using trigrams produces the best results on average, but bigrams and 4-grams are quite similar. It turns out that using trigrams with 1500 selected features performs the best. SVM results are not shown as they are poorer.

In summary, we say that naïve Bayes is more suitable than SVM for our application and feature selection is crucial. In our experiments reported below, we will only use naïve Bayes with feature selection.

4.3 Evaluation of Co-Class

We now compare Co-Class with the baseline methods listed below. Note that for this set of experiments, the source data all contain labeled posts from three domains and the target data contain unlabeled posts in one domain. That is, for each target domain, we merge three other domains for training and the target domain for testing. For example, for the target of “Cellphone”, the model is built using the data from the other three domains (i.e., “Electronics”, “Camera” and “TV”). The results are the classification of the model on the target domain “Cellphone”. Several strong baselines are described as follows:

3TR-1TE: Use labeled data from three domains to train and then classify the target (test) domain. There is no iteration. This method was used in (Aue & Gamon, 2005).

EM: This is the algorithm in Section 3.1. The combined data from three domains are used as the labeled source data. The data of the remaining one domain are used as the unlabeled target data, which is also used as the test data (since it is unlabeled).

ANB: This is a recent transfer learning method (Tan et al., 2009). ANB uses *frequently co-occurring entropy* (FCE) to pick out generalizable (or shared) features that occur frequently in both the source and target domains. Then, a weighted transfer version of naïve Bayes classifier is applied. We chose this method for comparison as it is a recent method, also based on naïve Bayes, and has been applied to the NLP task of sentiment

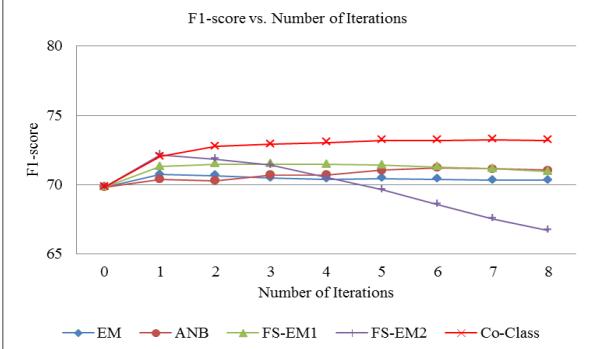

Figure 4 – Comparison EM, ANB, FS-EM1, FS-EM2, and Co-Class across iterations (0 is 3TR-1TE)

classification, which to some extent is related to the proposed task of intention classification. ANB was also shown to perform better than EM and naïve Bayes transfer learning method (Dai et al., 2007).

We look at the results of 3TR-1TE first, which are shown in Table 3. Due to space limitations, we only show the trigrams F1-scores as they perform the best on average. Table 3 gives the number of features with trigrams. We can observe that on average using 3000 features gives the best F1-score results. It has 1000 more features than one domain learning because we now combine three domains (3000 posts) for training and thus more useful features.

From Table 3, we observe that the F1-score results of 3TR-1TE are worse than those of one domain learning (Table 2), which is intuitive because no training data are used from the target domain. But the results are not dramatically worse which indicate that there are some common features in different domains, meaning people expressing the same intention in similar ways.

Since we found that trigrams with 3000 features perform the best on average, we run EM, FS-EM1, FS-EM2 and Co-Class based on trigrams with 3000 features. For the baseline ANB, we tuned the parameters using a development set (1/10 of the training data). We found that selecting 2000 generalizable/shared features gives the best results (the default is 500 in (Tan et al., 2009)). We kept ANB’s other original parameter values. The F1-scores (averages over all 4 datasets) with the number of iterations are shown in Figure 4. Iteration 0 is the result of 3TR-1TE. From Figure 4, we can make the following observations:

1. EM makes a little improvement in iteration 1. After that, the results deteriorate. The gain of iteration 1 shows that incorporating the target domain data (unlabeled) is helpful. However, the selected features from source domains can only fit the labeled source data but not the target data, which was explained in Section 3.1.
2. ANB improves slightly from iteration 1 to iteration 6, but the results are all worse than those of Co-Class. We checked the generalizable/shared features of ANB and found that they were not suitable for our problem since they were mainly adjectives, nouns and sentiment verbs, which do not have strong correlation with intentions. This shows that it is hard to find the truly shared features indicating intentions. Furthermore, ANB’s results are almost the same as those of EM.
3. FS-EM2 behaves similarly to FS-EM1. After two iterations, the results start to deteriorate. Selecting features only from the target domain makes sense since it can reflect target domain data well. However, it also becomes worse with the increased number of iterations, due to strong positive features. With increased iterations, positive features get stronger due to the imbalanced feature problem discussed in Section 1.
4. Co-Class performs much better than all other methods. With the increased number of iterations, the results actually improve. Starting from iteration 7, the results stabilize. Co-Class solves the problem of strong positive features by requiring strong conditions for positive classification and focusing on features in the target domain only. Although the detailed results of precision and recall are not shown, the Co-Class model actually improves the F1-score by improving both the precision and recall.

Significance of improvement: We now discuss the significance of improvements by comparing the results of Co-Class with other models. Table 4 summarizes the results among the models. For Co-Class, we use the converged models at iteration 7. We also include the One Domain learning results which are from fully supervised classification in the target domains with trigrams and 1500 features. The results of 3TR-1TE, EM, ANB, FS-EM1, and FS-EM2 are obtained based on their settings which give the best results in Figure 4.

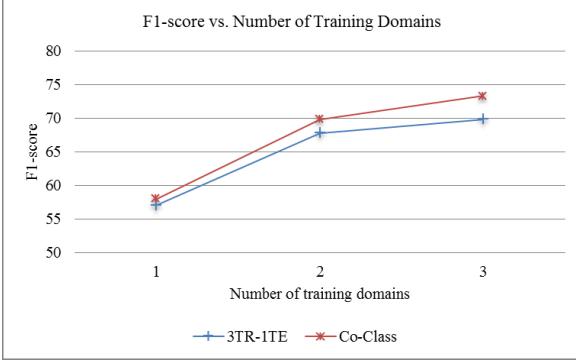

Figure 5 – Effect of number of source domains using 3TR-1TE and Co-Class.

It is clear from Table 4 that Co-Class is the best method in general. It is even better than the fully supervised One-Domain learning, although their results are not strictly comparable because One-Domain learning uses training and test data from the same domain via 10-fold cross validation, while all other methods use one domain as the test data (the labeled data are from the other three domains). One possible reason is that the labeled data are much bigger than those in One-Domain learning, which contain more expressions of buying intention. Note that FS-EM1 and FS-EM2 work slightly better than Co-Class in domain “Camera” because it is the least noisy domain with very short posts while other domains (as source data) are quite noisy. With good quality data, FS-EM1 and FS-EM2 (also proposed in this paper) can do slightly better than Co-Class. Statistical paired *t*-test shows that Co-Class performs significantly better than baseline methods 3TR-1TE, EM, ANB and FS-EM1 at the confidence level of 95%, and better than FS-EM2 at the confidence level of 94%.

Effect of the number of training domains: In our experiments above, we used 3 source domain data and tested on one target domain. We now show what happens if we use only one or two

source domain data and test on one target domain. We tried all possible combinations of source and target data. Figure 5 gives the average results over the four target/test domains. We can see that using more source domains is better due to more labeled data. With more domains, Co-Class also improves more over 3TR-1TE.

5 Conclusion

This paper studied the problem of identifying intention posts in discussion forums. The problem has not been studied in the social media context. Due to special characteristics of the problem, we found that it is particularly suited to transfer learning. A new transfer learning method, called Co-Class, was proposed to solve the problem. Unlike a general transfer learning method, Co-Class can deal with two specific difficulties of the problem to produce more accurate classifiers. Our experimental results show that Co-Class outperforms strong baselines including classifiers trained using labeled data in the target domains and classifiers from a state-of-the-art transfer learning method.

Abstract

We describe a novel approach to detecting empty categories (EC) as represented in dependency trees as well as a new metric for measuring EC detection accuracy. The new metric takes into account not only the position and type of an EC, but also the head it is a dependent of in a dependency tree. We also introduce a variety of new features that are more suited for this approach. Tested on a subset of the Chinese Treebank, our system improved significantly over the best previously reported results even when evaluated with this more stringent metric.

1 Introduction

In modern theoretical linguistics, empty categories (ECs) are an important piece of machinery in representing the syntactic structure of a sentence and they are used to represent phonologically null elements such as dropped pronouns and traces of dislocated elements. They have also found their way into large-scale treebanks which have played an important role in advancing the state of the art in syntactic parsing. In phrase-structure treebanks, ECs have been used to indicate long-distance dependencies, discontinuous constituents, and certain dropped elements (Marcus et al., 1993; Xue et al., 2005). Together with labeled brackets and function tags, they make up the full syntactic representation of a sentence.

The use of ECs captures some cross-linguistic commonalities and differences. For example, while both the Penn English TreeBank (PTB) (Marcus et al., 1993) and the Chinese TreeBank (CTB) (Xue

et al., 2005) use traces to represent the extraction site of a dislocated element, dropped pronouns (represented as *pro*s) are much more widespread in the CTB. This is because Chinese is a pro-drop language (Huang, 1984) that allows the subject to be dropped in more contexts than English does. While detecting and resolving traces is important to the interpretation of the syntactic structure of a sentence in both English and Chinese, the prevalence of dropped nouns in Chinese text gives EC detection added significance and urgency. They are not only an important component of the syntactic parse of a sentence, but are also essential to a wide range of NLP applications. For example, any meaningful tracking of entities and events in natural language text would have to include those represented by dropped pronouns. If Chinese is translated into a different language, it is also necessary to render these dropped pronouns explicit if the target language does not allow pro-drop. In fact, Chung and Gildea (2010) reported preliminary work that has shown a positive impact of automatic EC detection on statistical machine translation.

Some ECs can be resolved to an overt element in the same text while others only have a generic reference that cannot be linked to any specific entity. Still others have a plausible antecedent in the text, but are not annotated due to annotation limitations. A common practice is to resolve ECs in two separate stages (Johnson, 2002; Dienes and Dubey, 2003b; Dienes and Dubey, 2003a; Campbell, 2004; Gabard et al., 2006; Schmid, 2006; Cai et al., 2011). The first stage is *EC detection*, where empty categories are first located and typed. The second stage

is *EC resolution*, where empty categories are linked to an overt element if possible.

In this paper we describe a novel approach to detecting empty categories in Chinese, using the CTB as training and test data. More concretely, EC detection involves (i) identifying the position of the EC, relative to some overt word tokens in the same sentence, and (ii) determining the type of EC, e.g., whether it is a dropped pronoun or a trace. We focus on EC detection here because most of the ECs in the Chinese Treebank are either not resolved to an overt element or linked to another EC. For example, dropped pronouns (***pro***) are not resolved, and traces (***T***) in relative clauses are linked to an empty relative pronoun (***OP***).

In previous work, ECs are either represented linearly, where ECs are indexed to the following word (Yang and Xue, 2010) or attached to nodes in a phrase structure tree (Johnson, 2002; Dienes and Dubey, 2003b; Gabbard et al., 2006). In a linear representation where ECs are indexed to the following word, it is difficult to represent consecutive ECs because that will mean more than one EC will be indexed to the same word (making the classification task more complicated). While in English consecutive ECs are relatively rare, in Chinese this is very common. For example, it is often the case that an empty relative pronoun (***OP***) is followed immediately by a trace (***T***). Another issue with the linear representation of ECs is that it leaves unspecified where the EC should be attached, and crucial dependencies between ECs and other elements in the syntactic structure are not represented, thus limiting the utility of this task.

In a phrase structure representation, ECs are attached to a hierarchical structure and the problem of multiple ECs indexed to the same word token can be avoided because linearly consecutive ECs may be attached to different non-terminal nodes in a phrase structure tree. In a phrase structure framework, ECs are evaluated based on their linear position as well as on their contribution to the overall accuracy of the syntactic parse (Cai et al., 2011).

In the present work, we propose to look at EC detection in a dependency structure representation, where we define EC detection as (i) determining its linear position relative to the following word token, (ii) determining its head it is a dependent of, and (iii)

determining the type of EC. Framing EC detection this way also requires a new evaluation metric. An EC is considered to be correctly detected if its linear position, its head, and its type are all correctly determined. We report experimental results that show even using this more stringent measure, our EC detection system achieved performance that improved significantly over the state-of-the-art results.

The rest of the paper is organized as follows. In Section 2, we will describe how to represent ECs in a dependency structure in detail and present our approach to EC detection. In Section 3, we describe how linguistic information is encoded as features. In Section 4, we discuss our experimental setup and present our results. In Section 5, we describe related work. Section 6 concludes the paper.

2 Approach

In order to detect ECs anchored in a dependency tree, we first convert the phrase structure trees in the CTB into dependency trees. After the conversion, each word token in a dependency tree, including the ECs, will have one and only one head (or parent). We then train a classifier to predict the position and type of ECs in the dependency tree. Let W be a sequence of word tokens in a sentence, and T is syntactic parse tree for W , our task is to predict whether there is a tuple (h, t, e) , such that h and t are word tokens in W , e is an EC, h is the head of e , and t immediately follows e . When EC detection is formulated as a classification task, each classification instance is thus a tuple (h, t) . The input to our classifier is T , which can either be a phrase structure tree or a dependency tree. We choose to use a phrase structure tree because phrase structure parsers trained on the Chinese Treebank are readily available, and we also hypothesize that phrase structure trees have a richer hierarchical structure that can be exploited as features for EC detection.

2.1 Empty categories in the Chinese Treebank

According to the CTB bracketing guidelines (Xue and Xia, 2000), there are seven different types of ECs in the CTB. Below is a brief description of the empty categories:

1. ***pro***: small pro, used to represent dropped pronouns.

2. ***PRO***: big PRO, used to represent shared elements in control structures or elements that have generic references.
3. ***OP***: null operator, used to represent empty relative pronouns.
4. ***T***: trace left by movement such as topicalization and relativization.
5. ***RNR***: right node raising.
6. *****: trace left by passivization and raising.
7. ***?***: missing elements of unknown category.

An example parse tree with ECs is shown in Figure 1. In the example, there are two ECs, an empty relative pronoun (*OP*) and a trace (*T*), a common syntactic pattern for relative clauses in the CTB.

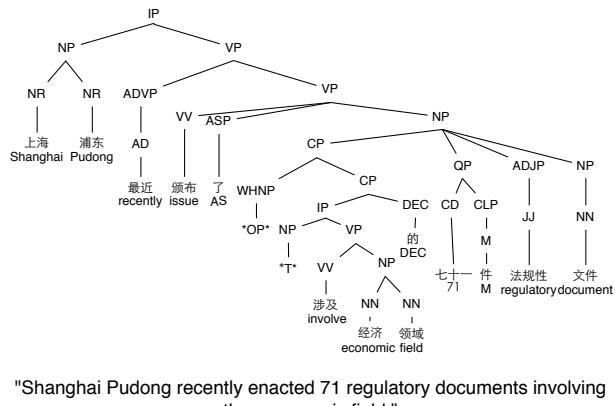

Figure 1: Empty categories in a phrase structure tree

2.2 Converting phrase structure to dependency structure

We convert the phrase structure parses in the CTB to dependency trees using the conversion tool that generated the Chinese data sets for the CoNLL 2009 Shared Task on multilingual dependency parsing and semantic role labeling (Hajíč et al., 2009)¹. While the Chinese data of CoNLL 2009 Shared Task does not include ECs, the tool has an option of preserving the ECs in the conversion process. As an example, the dependency tree in Figure 2 is converted from the phrase structure tree in Figure 1, with the ECs preserved.

¹The tool can be downloaded at <http://www.cs.brandeis.edu/clp/ctb/ctb.html>.

In previous work EC detection has been formulated as a classification problem with the target of the classification being word tokens (Yang and Xue, 2010; Chung and Gildea, 2010), or constituents in a parse tree (Gabbard et al., 2006). When word tokens are used as the target of classification, the task is to determine whether there is an EC before each word token, and what type EC it is. One shortcoming with that representation is that more than one EC can precede the same word token, as is the case in the example in Figure 1, where both *OP* and *T* precede 涉及 (“involve”). In fact, (Yang and Xue, 2010) takes the last EC when there is a sequence of ECs and as a result, some ECs will never get the chance to be detected. Notice that this problem can be avoided in a dependency structure representation if we make the target of classification a tuple that consists of the following word token and the head of the EC. From Figure 2, it should be clear that while *OP* and *T* both precede the same word token 涉及 (“involve”), they have different heads, which are 的 (DE) and 涉及 respectively.

Dependency-based EC detection also has other nice properties. For ECs that are arguments of their verbal head, when they are resolved to some overt element, the dependency between the referent of the EC and its head will be naturally established. This can be viewed as an alternative to the approach adopted by Levy and Manning (2004), where phrase structure parses are augmented to recover non-local dependencies. Dependency structures are also easily decomposable into head/dependency pairs and this makes the evaluation more straightforward. Each classification instance can be evaluated independently of other parts of the dependency structure.

2.3 One pass vs two passes

With pairs of tokens (h, t) as the classification target, all possible pairs in a sentence will have to be considered and there will be a large number of (h, t) tuples that are not associated with an EC, leading to a highly imbalanced data set. One can conceive a two-pass scenario where we first make a binary decision of whether there is an empty category associated with the head in the first pass and then determine whether there is an EC associated with the tuple as well as the EC type in the second pass. The alternative is to have a one-pass model in which we

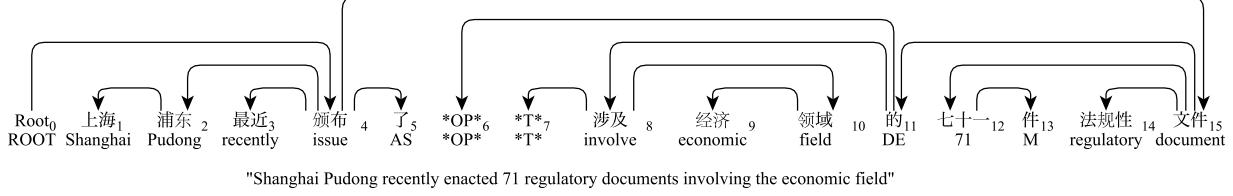

Figure 2: Empty categories in a dependency structure tree

add a NONE category indicating there is no EC associated with the tuple. With the seven EC types presented earlier in this section, this will be an eight-way classification problem. There are reasons for either model: the one-pass model is simpler but in the two-pass model we can bring different sources of information to bear on each sub-problem. Ultimately which model leads to better accuracy is an empirical question. We experimented with both models and it turned out that they led to very similar results. In this paper, we report results from the simpler one-pass model.

3 Features

We explored a wide range of features, all derived from the phrase structure parse tree (T). With each classification instance being a tuple (h, t) , the “pivots” for these features are h the head, t the word token following the EC, and p , the word token preceding the EC. The features we tried fall into six broad groups that are all empirically confirmed to have made a positive contribution to our classification task. These are (i) horizontal features, (ii) vertical features, (iii) targeted grammatical constructions, (iv) head information, (v) transitivity features, and (vi) semantic role features. We obviously have looked at features used in previous work on Chinese EC detection, most notably (Yang and Xue, 2010), which has also adopted a classification-based approach, but because we frame our classification task very differently, we have to use very different features. However, there is a subset of features we used here that has at least a partial overlap with their features, and such features are clearly indicated with *.

3.1 Horizontal features

The first group of features we use can be described as horizontal features that exploit lexical context of the head (h), the word token following the EC (t),

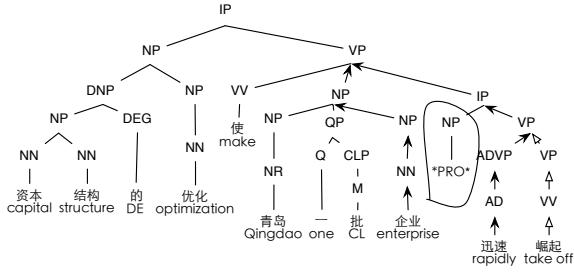

and the word token before the EC (p). These include different combinations of h , t and p , as well as their parts-of-speech. They also include various linear distance features between h and t . Below is the full list of lexical features:

1. *The token string representation of h , t and p , as well as their part-of-speech tag (POS).
2. *The POS combination of h and t , the POS combination of t and p .
3. The normalized word distance between h and t , with the values of this feature being *same*, *immediately before*, *immediately after*, *near before*, and *near after*, and *other*.
4. The verb distance between h and t , defined as the number of verbs that occur between h and t .
5. The comma distance between h and t , defined as the number of commas that occur between h and t .

3.2 Vertical features

Vertical features are designed to exploit the hierarchical structure of the syntactic tree. Our hierarchical features are based on the following observations. An empty category is always located between its *left frontier* and *right frontier*, anchored by t and p . Given the lowest common ancestor A of p and t , the right frontier is the path from t to A and the left frontier is the path from the p to A . We also define a path feature from h to t , which constrains the distance between the EC and its head, just as it constrains the distance between a predicate and its argument in the semantic role labeling task (Gildea and Jurafsky, 2002). Given the lowest common ancestor A' of h and t , the path from h to t is the path from h to A' and from A' to t .

In Figure 3, assuming that t is *迅速* (“rapidly”) and h is *崛起* (“take off”), the vertical features ex-

"The optimization of the capital structure has led to the rapid take-off of a host of enterprises in Qingdao."

Figure 3: Empty category on the right frontier

tracted include:

1. The string representation of the right frontier, $AD \uparrow ADVP \uparrow VP \uparrow IP \uparrow VP$
2. The path from the head t to h , $AD \uparrow ADVP \uparrow VP \downarrow VP \downarrow VV$
3. The path from the head h to A , $VV \uparrow VP \uparrow VP \uparrow IP \uparrow VP$. Notice there is not always a path from h to A .

The vertical features are really a condensed representation of a certain syntactic configuration that helps to predict the presence or absence of an empty category as well as the empty category type. For example, the right frontier of $*PRO*$ in Figure 3 $AD \uparrow ADVP \uparrow VP \uparrow IP \uparrow VP$ represents a subjectless IP. Had there been an overt subject in the place of the $*PRO*$, the right frontier would have been $AD \uparrow ADVP \uparrow VP \uparrow IP$. Therefore, the vertical features are discriminative features that can help detect the presence or absence of an empty category.

3.3 Targeted grammatical constructions

The third group of features target specific, linguistically motivated grammatical constructions. The majority of features in this group hinge on the immediate IP (roughly corresponds to S in the PTB) ancestor of t headed by h . These features are only invoked when t starts (or is on the left edge of) the immediate IP ancestor, and they are designed to capture the context in which the IP ancestor is located. This context can provide discriminative clues that may help identify the types of empty category. For example, both $*pro*$ s and $*PRO*$ s tend to occur in the subject position of an IP, but the larger context of the

IP often determines the exact empty category type. In Figure 3, the IP that has a $*PRO*$ subject is the complement of a verb in a canonical object-control construction. An IP can also be a sentential subject, the complement of a preposition or a localizer (also called postposition in the literature), or the complement in a CP (roughly SBAR in the PTB), etc. These different contexts tend to be associated with different types of empty categories. The full list of features that exploit these contexts include:

1. *Whether t starts an IP
2. *Whether t starts a subjectless IP
3. The left sisters of the immediate IP parent that t starts
4. The right sisters of the immediate IP parent that t starts
5. The string representation of the governing verb of the immediate IP parent that t starts
6. Whether the IP started by t is the complement of a localizer phrase
7. Whether the immediate IP parent that t starts is a sentential subject

3.4 Head information

Most ECs have a verb as its head, but when there is a coordination VP structure where more than one VP share an EC subject, only one such verb can be the head of this EC. The phrase structure to dependency structure conversion tool designates the first verb as the head of the coordinated VP and thus the head of the EC subject in the dependency structure. Other verbs have no chance of being the head. We use a VP head feature to capture this information. It is a binary feature indicating whether a verb can be a head.

3.5 Transitivity features

A transitivity lexicon has been extracted from the Chinese Treebank and it is used to determine the transitivity value of a word. A word can be *transitive*, *intransitive*, or *unknown* if it is not a verb. Ditransitive verbs are small in number and are folded into transitive verbs. Transitivity features are defined on h and constrained by word distance: it is only used when h immediately precedes t . This feature category is intended to capture transitive verbs that are missing an object.

3.6 Semantic role features

There are apparent connections between semantic role labeling and EC detection. The task of semantic role labeling is typically defined as one of detecting and classifying arguments for verbal or nominal predicates, with more work done so far on verbal than nominal predicates. Although empty categories are annotated as arguments to verbal predicates in linguistic resources such as the English (Palmer et al., 2005) and Chinese (Xue and Palmer, 2009) Propbanks, they are often left out in semantic role labeling systems trained on these resources. This is because the best performing semantic role labeling systems rely on syntactic features extracted from automatic parses (Gildea and Palmer, 2002; Punyakanok et al., 2005) and the parsers that produce them do not generally reproduce empty categories. As a result, current semantic role labeling systems can only recover explicit arguments. However, assuming that all the explicit arguments to a predicate are detected and classified, one can infer the empty arguments of a predicate from its explicit arguments, given a list of *expected* arguments for the predicate. The list of expected arguments can be found in the “frame files” that are used to guide probank annotation. We defined a semantic role feature category on h when it is a verb and the value of this feature is the semantic role labels for the EC arguments. Like transitivity features, this feature category is also constrained by word distance. It is only used when h immediately precedes t .

To extract semantic role features, we retrained a Chinese semantic role labeling system on the Chinese Propbank. We divided the Chinese Propbank data into 10 different subsets, and automatically assigned semantic roles to each subset with a system trained on the other nine subsets. Using the frame files for the Chinese Propbank, we are able to infer the semantic roles for the missing arguments and use them as features.

4 Experimental Results

4.1 Experimental setup

Our EC detection models are trained and evaluated on a subset of the Chinese TreeBank 6.0. The training/development/test data split in our experiments is recommended in the CTB documentation. The

CTB file IDs for training, development and testing are listed in Table 1. The development data is used for feature selection and tuning, and results are reported on the test set.

Train	Dev	Test
81-325, 400-454, 500-554	41-80	1-40
590-596, 600-885, 900		901-931

Table 1: Data set division.

As discussed in Section 2, the gold standard dependency structure parses are converted from the CTB parse trees, with the ECs preserved. From these gold standard parse trees, we extract triples of (e, h, t) where e is the EC type, h is (the position of) the head of the EC, and t is (the position of) the word token following the EC. During the training phrase, features are extracted from automatic phrase structure parses and paired with these triples. The automatic phrase structure parses are produced by the Berkeley parser² with a 10-fold cross-validation, which each fold parsed using a model trained on the other nine folds. Measured by the ParsEval metric (Black et al., 1991), the parsing accuracy on the CTB test set stands at 83.63% (F-score), with a precision of 85.66% and a recall of 81.69%. We chose to train a Maximum Entropy classifier using the Mallet toolkit³ (McCallum, 2002) to detect ECs.

4.2 Evaluation metric

We use standard metrics of precision, recall and F-measure in our evaluation. In a dependency structure representation, evaluation is very straightforward because individual arcs from the dependency tree can be easily decomposed. An EC is considered to be correctly detected if it is attached to the correct head h , correctly positioned relative to t , and correctly typed. This is a more stringent measure than metrics proposed in previous work, which evaluates EC detection based on its position and type without considering the head it is a dependent of.

4.3 Results

There are 1,838 total EC instances in the test set, and if we follow (Yang and Xue, 2010) and collapse all

²<http://code.google.com/p/berkeleyparser>

³<http://mallet.cs.umass.edu>

consecutive ECs before the same word token to one, we will end up with a total EC count of 1,352, and this is also the EC count used by (Cai et al., 2011) in their evaluation. On the dependency-based representation adopted here, after collapsing all consecutive ECs before the same word token AND attached to the same head to one, we end up with a total EC count of 1,765. The distribution of the ECs in the test set are presented in Table 2, with the EC count per type from (Yang and Xue, 2010) in parenthesis if it is different. The number of *OP*s, in particular, has increased dramatically from 134 to 527, and this is because a null relative pronoun (*OP*) immediately followed by a trace (*T*) in the subject position of a relative clause is a very common pattern in the Chinese Treebank, as illustrated in Figure 2. In (Yang and Xue, 2010), the *OP*-*T* sequences are collapsed into one, and only the *T*s are counted. That leads to the much smaller count of *OP*s.

type	count	type	count
pro	298 (290)	*PRO*	305 (299)
OP	527 (134)	*T*	584 (578)
*	19	*RNR*	32
?	0	total	(1352)/1765/(1838)

Table 2: EC distribution in the CTB test set

Our results are shown in Table 3. These results are achieved by using the full feature set presented in Section 3. The overall accuracy by F1-measure is 0.574 if we assume there can only be one EC associated with a given (h, t) tuple and hence the total EC count in the gold standard is 1,765, or 0.561 if we factor in all the EC instances and use the higher total count of 1,838, which lowers the recall. If instead we use the total EC count of 1,352 that was used in previous work (Yang and Xue, 2010; Cai et al., 2011), then the F1-measure is 0.660 because the lower total count greatly improves the recall. This is a significant improvement over the best previous result reported by Cai et al (2011), which is an F1 measure of 0.586 on the same test set but based on a less stringent metric of just comparing the EC position and type, without considering whether the EC is attached to the correct head.

There are several observations worth noting from these results. One is that our method performs particularly well on null relative pronouns (*OP*) and

class	correct	prec	rec	F1

CCG		.660	.545	.586

Table 3: EC detection results on the CTB test set and comparison with (Cai et al., 2011) [CCG]

traces (*T*), indicating that our features are effective in capturing information from relative clause constructions. This accounts for most of the gain compared with previous approaches. The *OP* category, in particular, benefits most from the dependency representation because it is collapsed to the immediately following *T* in previous approaches and does not even get a chance to be detected. On the other hand, our model did poorly on dropped pronouns (*pro*). One possible explanation is that *pro*s generally occupy subject positions in a sentence and is attached as an immediate child of an IP, which is the top-level structure of a sentence that an automatic parser tends to get wrong. Unlike *PRO*, it is not constrained to well-defined grammatical constructions such as subject- and object-control structures.

To evaluate the effectiveness of our features, we also did an ablation study on the contribution of different feature groups. The most effective features are the ones when taken out lead to the most drop in accuracy. As should be clear from Table 4, the most effective features are the horizontal features, followed by vertical structures. Features extracted from targeted grammatical constructions and features representing whether h is the head of a coordinated VP lead to modest improvement. Transitivity and semantic role features make virtually no difference at all. We believe it is premature to conclude that they are not useful. Possible explanations for their lack of effectiveness is that they are used in very limited context and the accuracy of the semantic role label-

ing system is not sufficient to make a difference.

5 Related Work

The work reported here follows a fruitful line of research on EC detection and resolution, mostly in English. Empty categories have initially been left behind in research on syntactic parsing (Collins, 1999; Charniak, 2001) for efficiency reasons, but more recent work has shown that EC detection can be effectively integrated into the parsing process (Schmid, 2006; Cai et al., 2011). In the meantime, both pre-processing and post-processing approaches have been explored in previous work as alternatives. Johnson (2002) has showed that empty categories can be added to the skeletal parses with reasonable accuracy with a simple pattern-matching algorithm in a postprocessing step. Dienes and Dubey (2003b; 2003a) achieved generally superior accuracy using a machine learning framework without having to refer to the syntactic structure in the skeletal parses. They described their approach as a pre-processing step for parsing because they only use as features morpho-syntactic clues (passives, gerunds and to-infinitives) that can be found in certain function words and part-of-speech tags. Even better results, however, were obtained by Campbell (2004) in a postprocessing step that makes use of rules inspired by work in theoretical linguistics. Gabbard et al (2006) reported further improvement largely by recasting the Campbell rules as features to seven different machine learning classifiers.

We adopted a machine-learning based postprocessing approach based on insights gained from prior work in English and on Chinese-specific considerations. All things being equal, we believe that a machine learning approach that can exploit partial

information is more likely to succeed than deterministic rules that have to make reference to morpho-syntactic clues such as to-infinitives and gerunds that are largely non-existent in Chinese. Without these clues, we believe a preprocessing approach that does not take advantage of skeletal parses is unlikely to succeed either. The work we report here also builds on emerging work in Chinese EC detection. Yang and Xue (2010) reported work on detecting just the presence and absence of empty categories without further classifying them. Chung and Gildea (2010) reported work on just detecting just a small subset of the empty categories posited in the Chinese TreeBank. Kong and Zhou (2010) worked on Chinese zero anaphora resolution, where empty category detection is a subtask. More recently, Cai et al (2011) has successfully integrated EC detection into phrase-structure based syntactic parsing and reported state-of-the-art results in both English and Chinese.

6 Conclusions and Future Work

We described a novel approach to detecting empty categories (EC) represented in dependency trees and a new metric for measuring EC detection accuracy. The new metric takes into account not only the position and type of an EC, but also the head it is a dependent of in a dependency structure. We also proposed new features that are more suited for this new approach. Tested on a subset of the Chinese Treebank, we show that our system improved significantly over the best previously reported results despite using a more stringent evaluation metric, with most of the gain coming from an improved representation. In the future, we intend to work toward resolving ECs to their antecedents when EC detection can be done with adequate accuracy. We also plan to test our approach on the Penn (English) Treebank, with the first step being converting the Penn Treebank to a dependency representation with the ECs preserved.

Abstract

We study multi-source transfer parsing for resource-poor target languages; specifically methods for target language adaptation of delexicalized discriminative graph-based dependency parsers. We first show how recent insights on selective parameter sharing, based on typological and language-family features, can be applied to a discriminative parser by carefully decomposing its model features. We then show how the parser can be relexicalized and adapted using unlabeled target language data and a learning method that can incorporate diverse knowledge sources through ambiguous labelings. In the latter scenario, we exploit two sources of knowledge: arc marginals derived from the base parser in a self-training algorithm, and arc predictions from multiple transfer parsers in an ensemble-training algorithm. Our final model outperforms the state of the art in multi-source transfer parsing on 15 out of 16 evaluated languages.

1 Introduction

Many languages still lack access to core NLP tools, such as part-of-speech taggers and syntactic parsers. This is largely due to the reliance on *fully supervised* learning methods, which require large quantities of manually annotated training data. Recently, methods for *cross-lingual transfer* have appeared as a promising avenue for overcoming this hurdle for both part-of-speech tagging (Yarowsky et al., 2001; Das and Petrov, 2011) and syntactic dependency parsing (Hwa et al., 2005; Zeman and Resnik, 2008; Ganchev et al., 2009; McDonald et al., 2011; Naseem et al.,

2012). While these methods do not yet compete with fully supervised approaches, they can drastically outperform both *unsupervised* methods (Klein and Manning, 2004) and *weakly supervised* methods (Naseem et al., 2010; Berg-Kirkpatrick and Klein, 2010).

A promising approach to cross-lingual transfer of syntactic dependency parsers is to use multiple source languages and to tie model parameters across related languages. This idea was first explored for weakly supervised learning (Cohen and Smith, 2009; Snyder et al., 2009; Berg-Kirkpatrick and Klein, 2010) and recently by Naseem et al. (2012) for multi-source cross-lingual transfer. In particular, Naseem et al. showed that by *selectively sharing* parameters based on typological features of each language, substantial improvements can be achieved, compared to using a single set of parameters for all languages. However, these methods all employ generative models with strong independence assumptions and weak feature representations, which upper bounds their accuracy far below that of feature-rich discriminative parsers (McDonald et al., 2005; Nivre, 2008).

In this paper, we improve upon the state of the art in cross-lingual transfer of dependency parsers from multiple source languages by adapting feature-rich discriminatively trained parsers to a specific target language. First, in §4 we show how selective sharing of model parameters based on typological traits can be incorporated into a delexicalized discriminative graph-based parsing model. This requires a careful decomposition of features into language-generic and language-specific sets in order to tie specific target language parameters to their relevant source language counterparts. The resulting parser outperforms the method of Naseem et al. (2012) on 12 out of 16 evaluated languages. Second, in §5 we introduce a train-

* Work primarily carried out while at Google, NY.

ing method that can incorporate diverse knowledge sources through ambiguously predicted labelings of unlabeled target language data. This permits effective relexicalization and target language adaptation of the transfer parser. Here, we experiment with two different knowledge sources: arc sets, which are filtered by marginal probabilities from the cross-lingual transfer parser, are used in an *ambiguity-aware self-training* algorithm (§5.2); these arc sets are then combined with the predictions of a different transfer parser in an *ambiguity-aware ensemble-training* algorithm (§5.3). The resulting parser provides significant improvements over a strong baseline parser and achieves a 13% relative error reduction on average with respect to the best model of Naseem et al. (2012), outperforming it on 15 out of the 16 evaluated languages.

2 Multi-Source Delexicalized Transfer

The methods proposed in this paper fall into the *delexicalized transfer* approach to multilingual syntactic parsing (Zeman and Resnik, 2008; McDonald et al., 2011; Cohen et al., 2011; Søgaard, 2011). In contrast to *annotation projection* approaches (Yarowsky et al., 2001; Hwa et al., 2005; Ganchev et al., 2009; Spreyer and Kuhn, 2009), delexicalized transfer methods do not rely on any bitext. Instead, a parser is trained on annotations in a source language, relying solely on features that are available in both the source and the target language, such as “universal” part-of-speech tags (Zeman and Resnik, 2008; Naseem et al., 2010; Petrov et al., 2012), cross-lingual word clusters (Täckström et al., 2012) or type-level features derived from bilingual dictionaries (Durrett et al., 2012).¹ This parser is then directly used to parse the target language. For languages with similar typology, this method can be quite accurate, especially when compared to purely unsupervised methods. For instance, a parser trained on English with only part-of-speech features can correctly parse the Greek sentence in Figure 1, even without knowledge of the lexical items since the sequence of part-of-speech tags determines the syntactic structure almost unambiguously.

Learning with multiple languages has been shown to benefit unsupervised learning (Cohen and Smith,

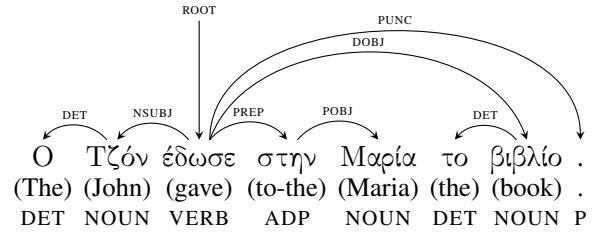

Figure 1: A Greek sentence which is correctly parsed by a delexicalized English parser, provided that part-of-speech tags are available in both the source and target language.

2009; Snyder et al., 2009; Berg-Kirkpatrick and Klein, 2010). Annotations in multiple languages can be combined in delexicalized transfer as well, as long as the parser features are available across the involved languages. This idea was explored by McDonald et al. (2011), who showed that target language accuracy can be improved by simply concatenating delexicalized treebanks in multiple languages. In similar work, Cohen et al. (2011) proposed a mixture model in which the parameters of a generative target language parser is expressed as a linear interpolation of source language parameters, whereas Søgaard (2011) showed that target side language models can be used to selectively subsample training sentences to improve accuracy. Recently, inspired by the phylogenetic prior of Berg-Kirkpatrick and Klein (2010), Søgaard and Wulff (2012) proposed — among other ideas — a typologically informed weighting heuristic for linearly interpolating source language parameters. However, this weighting did not provide significant improvements over uniform weighting.

The aforementioned approaches work well for transfer between similar languages. However, their assumptions cease to hold for typologically divergent languages; a target language can rarely be described as a linear combination of data or model parameters from a set of source languages, as languages tend to share varied typological traits; this critical insight is discussed further in §4. To account for this issue, Naseem et al. (2012) recently introduced a novel generative model of dependency parsing, in which the generative process is factored into separate steps for the *selection* of dependents and their *ordering*. The parameters used in the selection step are all language independent, capturing only head-dependent attachment preferences. In the ordering step, however, parameters are *selectively shared* between subsets of

¹Note that Täckström et al. (2012) and Durrett et al. (2012) do require bitext or a bilingual dictionary. The same holds for most cross-lingual representations, e.g., Klementiev et al. (2012).

Feature	Description
81A	Order of Subject, Object and Verb
85A	Order of Adposition and Noun
86A	Order of Genitive and Noun
87A	Order of Adjective and Noun
88A	Order of Demonstrative and Noun
89A	Order of Numeral and Noun

Table 1: Typological features from WALS (Dryer and Haspelmath, 2011), proposed for selective sharing by Naseem et al. (2012). Feature 89A has the same value for all studied languages, while 88A differs only for Basque. These features are therefore subsequently excluded.

source languages based on typological features of the languages extracted from WALS — the World Atlas of Language Structures (Dryer and Haspelmath, 2011) — as shown in Table 1. In the transfer scenario, where no supervision is available in the target language, this parser achieves the hitherto best published results across a number of languages; in particular for target languages with a word order divergent from the source languages.

However, the generative model of Naseem et al. is quite impoverished. In the fully supervised setting, it obtains substantially lower accuracies compared to a standard arc-factored graph-based parser (McDonald et al., 2005). Averaged across 16 languages,² the generative model trained with full supervision on the target language obtains an accuracy of 67.1%. A comparable lexicalized discriminative arc-factored model (McDonald et al., 2005) obtains 84.1%. Even when delexicalized, this model reaches 78.9%. This gap in supervised accuracy holds for all 16 languages. Thus, while selective sharing is a powerful device for transferring parsers across languages, the underlying generative model used by Naseem et al. (2012) restricts its potential performance.

3 Basic Models and Experimental Setup

Inspired by the superiority of discriminative graph-based parsing in the supervised scenario, we investigate whether the insights of Naseem et al. (2012) on selective parameter sharing can be incorporated into such models in the transfer scenario. We first review the basic graph-based parser framework and the

²Based on results in Naseem et al. (2012), excluding English.

experimental setup that we will use throughout. We then delve into details on how to incorporate selective sharing in this model in §4. In §5, we show how learning with ambiguous labelings in this parser can be used for further target language adaptation, both through self-training and through ensemble-training.

3.1 Discriminative Graph-Based Parser

Let x denote an input sentence and let $y \in \mathcal{Y}(x)$ denote a dependency tree, where $\mathcal{Y}(x)$ is the set of well-formed dependency trees spanning x . Henceforth, we restrict $\mathcal{Y}(x)$ to projective dependency trees, but all our methods are equally applicable in the non-projective case. Provided a vector of model parameters θ , the probability of a dependency tree $y \in \mathcal{Y}(x)$, conditioned on a sentence x , has the following form:

$$p_\theta(y | x) = \frac{\exp \{ \theta^\top \Phi(x, y) \}}{\sum_{y' \in \mathcal{Y}(x)} \exp \{ \theta^\top \Phi(x, y') \}}.$$

Without loss of generality, we restrict ourselves to first-order models, where the feature function $\Phi(x, y)$ factors over individual arcs (h, m) in y , such that

$$\Phi(x, y) = \sum_{(h, m) \in y} \phi(x, h, m),$$

where $h \in [0, |x|]$ and $m \in [1, |x|]$ are the indices of the head word and the dependent word of the arc; $h = 0$ represents a dummy ROOT token. The model parameters are estimated by maximizing the log-likelihood of the training data $\mathcal{D} = \{(x_i, y_i)\}_{i=1}^n$,

$$\mathcal{L}(\theta; \mathcal{D}) = \sum_{i=1}^n \log p_\theta(y_i | x_i).$$

We use the standard gradient-based L-BFGS algorithm (Liu and Nocedal, 1989) to maximize the log-likelihood. Eisner’s algorithm (Eisner, 1996) is used for inference of the Viterbi parse and arc-marginals.

3.2 Data Sets and Experimental Setup

To facilitate comparison with the state of the art, we use the same treebanks and experimental setup as Naseem et al. (2012). Notably, we use the mapping proposed by Naseem et al. (2010) to map from fine-grained treebank specific part-of-speech tags to coarse-grained “universal” tags, rather than the more recent mapping proposed by Petrov et al. (2012). For

Delexicalized MSTParser	Bare	Selectively shared
$d \otimes 1; [d \otimes 1] \otimes h.p; [d \otimes 1] \otimes m.p$ $[d \otimes 1] \otimes h.p \otimes m.p$ $[d \otimes 1] \otimes h.p \otimes h_{+1}.p \otimes m_{-1}.p \otimes m.p$ $[d \otimes 1] \otimes h_{-1}.p \otimes h.p \otimes m_{-1}.p \otimes m.p$ $[d \otimes 1] \otimes h.p \otimes h_{+1}.p \otimes m.p \otimes m_{+1}.p$ $[d \otimes 1] \otimes h_{-1}.p \otimes h.p \otimes m.p \otimes m_{+1}.p$ $h.p \otimes \text{between}.p \otimes m.p$	1 $[1] \otimes h.p$ $[1] \otimes m.p$ $[1] \otimes h.p \otimes m.p$	$d \otimes w.81A \otimes 1[h.p = \text{VERB} \wedge m.p = \text{NOUN}]$ $d \otimes w.81A \otimes 1[h.p = \text{VERB} \wedge m.p = \text{PRON}]$ $d \otimes w.85A \otimes 1[h.p = \text{ADP} \wedge m.p = \text{NOUN}]$ $d \otimes w.85A \otimes 1[h.p = \text{ADP} \wedge m.p = \text{PRON}]$ $d \otimes w.86A \otimes 1[h.p = \text{NOUN} \wedge m.p = \text{NOUN}]$ $d \otimes w.87A \otimes 1[h.p = \text{NOUN} \wedge m.p = \text{ADJ}]$

Figure 2: Arc-factored feature templates for graph-based parsing. Direction: $d \in \{\text{LEFT}, \text{RIGHT}\}$; dependency length: $1 \in \{1, 2, 3, 4, 5+\}$; part of speech of head / dependent / words between head and dependent: $h.p / m.p / \text{between}.p \in \{\text{NOUN}, \text{VERB}, \text{ADJ}, \text{ADV}, \text{PRON}, \text{DET}, \text{ADP}, \text{NUM}, \text{CONJ}, \text{PRT}, \text{PUNC}, \text{X}\}$; token to the left / right of z : z_{-1} / z_{+1} ; WALS features: $w.X$ for $X = 81A, 85A, 86A, 87A$ (see Table 1). $[.]$ denotes an optional template, e.g., $[d \otimes 1] \otimes h.p \otimes m.p$ expands to templates $d \otimes 1 \otimes h.p \otimes m.p$ and $h.p \otimes m.p$, so that the template also falls back on its undirectional variant.

each target language evaluated, the treebanks of the remaining languages are used as *labeled* training data, while the target language treebank is used for testing only (in §5 a different portion of the target language treebank is additionally used as *unlabeled* training data). We refer the reader to Naseem et al. (2012) for detailed information on the different treebanks. Due to divergent treebank annotation guidelines, which makes fine-grained evaluation difficult, all results are evaluated in terms of unlabeled attachment score (UAS). In line with Naseem et al. (2012), we use gold part-of-speech tags and evaluate only on sentences of length 50 or less excluding punctuation.

3.3 Baseline Models

We compare our models to two multi-source baseline models. The first baseline, *NBG*, is the generative model with selective parameter sharing from Naseem et al. (2012).³ This model is trained without target language data, but we investigate the use of such data in §5.4. The second baseline, *Delex*, is a delexicalized projective version of the well-known graph-based MSTParser (McDonald et al., 2005). The feature templates used by this model are shown to the left in Figure 2. Note that there is no selective sharing in this model.

The second and third columns of Table 2 show the unlabeled attachment scores of the baseline models for each target language. We see that *Delex* performs well on target languages that are related to the majority of the source languages. However, for languages

that diverge from the Indo-European majority family, the selective sharing model, *NBG*, achieves substantially higher accuracies.

4 Feature-Based Selective Sharing

The results for the baseline models are not surprising considering the feature templates used by *Delex*. There are two fundamental issues with these features when used for direct transfer. First, all but one template include the arc direction. Second, some features are sensitive to local word order; e.g., $[d \otimes 1] \otimes h.p \otimes h_{+1}.p \otimes m_{-1}.p \otimes m.p$, which models direction as well as word order in the local contexts of the head and the dependent. Such features do not transfer well across typologically different languages.

In order to verify that these issues are the cause of the poor performance of the *Delex* model, we remove all directional features and all features that model local word order from *Delex*. The feature templates of the resulting *Bare* model are shown in the center of Figure 2. These features only model selectional preferences and dependency length, analogously to the selection component of *NBG*. The performance of *Bare* is shown in the fourth column of Table 2. The removal of most of the features results in a performance drop on average. However, for languages outside of the Indo-European family, *Bare* is often more accurate, especially for Basque, Hungarian and Japanese, which supports our hypothesis.

4.1 Sharing Based on Typological Features

After removing all directional features, we now carefully reintroduce them. Inspired by Naseem et al.

Table 2: Unlabeled attachment scores of the multi-source transfer models. Boldface numbers indicate the best result per language. Underlined numbers indicate languages whose group is not represented in the training data (these default to *Share* under *Similarity* and *Family*). *NBG* is the “D-, T_o ” model in Table 2 from Naseem et al. (2012).

(2012), we make use of the typological features from WALS (Dryer and Haspelmath, 2011), listed in Table 1, to selectively share directional parameters between languages. As a natural first attempt at sharing parameters, one might consider forming the cross-product of all features of *Delex* with all WALS properties, similarly to a common domain adaptation technique (Daumé III, 2007; Finkel and Manning, 2009). However, this approach has two issues. First, it results in a huge number of features, making the model prone to overfitting. Second, and more critically, it ties together languages via features for which they are not typologically similar. Consider English and French, which are both prepositional and thus have the same value for WALS property 85A. These languages will end up sharing a parameter for the feature $[d \otimes 1] \otimes h.p = \text{NOUN} \otimes m.p = \text{ADJ} \otimes w.85A$; yet they have the exact opposite direction of attachment preference when it comes to nouns and adjectives. This problem applies to any method for parameter mixing

that treats all the parameters as equal.

Like Naseem et al. (2012), we instead share parameters more selectively. Our strategy is to use the relevant part-of-speech tags of the head and dependent to select which parameters to share, based on very basic linguistic knowledge. The resulting features are shown to the right in Figure 2. For example, there is a shared directional feature that models the order of Subject, Object and Verb by conjoining WALS feature 81A with the arc direction and an indicator feature that fires only if the head is a verb and the dependent is a noun. These features would not be very useful by themselves, so we combine them with the *Bare* features. The accuracy of the resulting *Share* model is shown in column five of Table 2. Although this model still performs worse than *NBG*, it is an improvement over the *Delex* baseline and actually outperforms the former on 5 out of the 16 languages.

4.2 Sharing Based on Language Groups

While *Share* models selectional preferences and arc directions for a subset of dependency relations, it does not capture the rich local word order information captured by *Delex*. We now consider two ways of selectively including such information based on language similarity. While more complex sharing could be explored (Berg-Kirkpatrick and Klein, 2010), we use a flat structure and consider two simple groupings of the source and target languages.

First, the *Similar* model consists of the features used by *Share* together with the features from *Delex* in Figure 2. The latter are conjoined with an indicator feature that fires only when the source and target languages share values for all the WALS features in Table 1. This is accomplished by adding the template

$$f \otimes [w.81A \otimes w.85A \otimes w.86A \otimes w.87A \otimes w.88A]$$

for each template *f* in *Delex*. This groups: 1) Catalan, Italian, Portuguese and Spanish; 2) Bulgarian, Czech and English; 3) Dutch, German and Greek; and 4) Japanese and Turkish. The remaining languages do not share all WALS properties with at least one source language and thus revert to *Share*, since they cannot exploit these grouped features.

Second, instead of grouping languages according to WALS, the *Family* model is based on a simple subdivision into Indo-European languages (Bulgarian, Catalan, Czech, Greek, English, Spanish, Italian,

Dutch, Portuguese, Swedish) and Altaic languages (Japanese, Turkish). This is accomplished with indicator features analogous to those used in *Similar*. The remaining languages are again treated as isolates and revert to *Similar*.

The results for these models are given in the last two columns of Table 2. We see that by adding these rich features back into the fold, but having them fire only for languages in the same group, we can significantly increase the performance — from 57.4% to 62.0% on average when considering *Family*. If we consider our original *Delex* baseline, we see an absolute improvement of 6.9% on average and a relative error reduction of 15%. Particular gains are seen for non-Indo-European languages; e.g., Japanese increases from 38.9% to 65.9%. Furthermore, *Family* achieves a 7% relative error reduction over the *NBG* baseline and outperforms it on 12 of the 16 languages. This shows that a discriminative graph-based parser can achieve higher accuracies compared to generative models when the features are carefully constructed.

5 Target Language Adaptation

While some higher-level linguistic properties of the target language have been incorporated through selective sharing, so far no features specific to the target language have been employed. Cohen et al. (2011) and Naseem et al. (2012) have shown that using expectation-maximization (EM) to this end can in some cases bring substantial accuracy gains. For discriminative models, self-training has been shown to be quite effective for adapting monolingual parsers to new domains (McClosky et al., 2006), as well as for *relexicalizing* delexicalized parsers using unlabeled target language data (Zeman and Resnik, 2008). Similarly Täckström (2012) used self-training to adapt a multi-source direct transfer named-entity recognizer (Täckström et al., 2012) to different target languages, “*relexicalizing*” the model with word cluster features. However, as discussed in §5.2, standard self-training is not optimal for target language adaptation.

5.1 Ambiguity-Aware Training

In this section, we propose a related training method: *ambiguity-aware training*. In this setting a discriminative probabilistic model is induced from automatically inferred *ambiguous labelings* over unlabeled

target language data, in place of gold-standard dependency trees. The ambiguous labelings can combine multiple sources of evidence to guide the estimation or simply encode the underlying uncertainty from the base parser. This uncertainty is marginalized out during training. The structure of the output space, e.g., projectivity and single-headedness constraints, along with regularities in the feature space, can together guide the estimation, similar to what occurs with the expectation-maximization algorithm.

Core to this method is the idea of an *ambiguous labeling* $\tilde{y}(x) \subseteq \mathcal{Y}(x)$, which encodes a set of possible dependency trees for an input sentence x . In subsequent sections we describe how to define such labelings. Critically, $\tilde{y}(x)$ should be large enough to capture the correct labeling, but on the other hand small enough to provide concrete guidance for model estimation. Ideally, $\tilde{y}(x)$ will capture heterogenous knowledge that can aid the parser in target language adaptation. In a first-order arc-factored model, we define $\tilde{y}(x)$ in terms of a collection of *ambiguous arc sets* $\mathcal{A}(x) = \{\mathcal{A}(x, m)\}_{m=1}^{|x|}$, where $\mathcal{A}(x, m)$ denotes the set of ambiguously specified heads for the m th token in x . Then, $\tilde{y}(x)$ is defined as the set of all projective dependency trees spanning x that can be assembled from the arcs in $\mathcal{A}(x)$.

Methods for learning with ambiguous labelings have previously been proposed in the context of multi-class classification (Jin and Ghahramani, 2002), sequence-labeling (Dredze et al., 2009), log-linear LFG parsing (Riezler et al., 2002), as well as for discriminative reranking of generative constituency parsers (Charniak and Johnson, 2005). In contrast to Dredze et al., who allow for weights to be assigned to partial labels, we assume that the ambiguous arcs are weighted uniformly. For target language adaptation, these weights would typically be derived from unreliable sources and we do not want to train the model to simply mimic their beliefs. Furthermore, with this assumption, learning is simply achieved by maximizing the *marginal* log-likelihood of the ambiguous training set $\tilde{\mathcal{D}} = \{(x_i, \tilde{y}(x_i))\}_{i=1}^n$,

$$\mathcal{L}(\theta; \tilde{\mathcal{D}}) = \sum_{i=1}^n \log \left\{ \sum_{y \in \tilde{y}(x_i)} p_\theta(y | x_i) \right\} - \lambda \|\theta\|_2^2 .$$

In maximizing the marginal log-likelihood, the model is free to distribute probability mass among the trees

in the ambiguous labeling to its liking, as long as the marginal log-likelihood improves. The same objective function is used by Riezler et al. (2002) and Charniak and Johnson (2005). A key difference is that in these works, the ambiguity is constrained through a supervised signal, while we use ambiguity as a way to achieve self-training, using the base-parser itself, or some other potentially noisy knowledge source as the sole constraints. Note that we have introduced an ℓ_2 -regularizer, weighted by λ . This is important as we are now training *lexicalized* target language models which can easily overfit. In all experiments, we optimize parameters with L-BFGS. Note also that the marginal likelihood is non-concave, so that we are only guaranteed to find a local maximum.

5.2 Ambiguity-Aware Self-Training

In standard self-training — hereafter referred to as *Viterbi self-training* — a base parser is used to label each unlabeled sentence with its most probable parse tree to create a self-labeled data set, which is subsequently used to train a supervised parser. There are two reasons why this simple approach may work. First, if the base parser’s errors are not too systematic and if the self-training model is not too expressive, self-training can reduce the variance on the new domain. Second, self-training allows for features in the new domain with low support — or no support in the case of lexicalized features — in the base parser to be “filled in” by exploiting correlations in the feature representation. However, a potential pitfall of this approach is that the self-trained parser is encouraged to blindly mimic the base parser, which leads to error reinforcement. This may be particularly problematic when relexic平izing a transfer parser, since the lexical features provide the parser with increased power and thereby an increased risk of overfitting to the noise. To overcome this potential problem, we propose an *ambiguity-aware self-training* (AAST) method that is able to take the noise of the base parser into account.

We use the arc-marginals of the base parser to construct the ambiguous labeling $\tilde{y}(x)$ for a sentence x . For each token $m \in [1, |x|]$, we first sort the set of arcs in which m is the dependent, $\{(h, m)\}_{h=0}^{|x|}$, by the marginal probabilities of the arcs:

$$p_\theta(h, m | x) = \sum_{\{y \in \mathcal{Y}(x) | (h, m) \in y\}} p_\theta(y | x)$$

We next construct the ambiguous arc set $\mathcal{A}(x, m)$ by adding arcs (h, m) in order of decreasing probability, until their cumulative probability exceeds σ , i.e. until

$$\sum_{(h, m) \in \mathcal{A}(x, m)} p_\theta(h, m | x) \geq \sigma.$$

Lower values of σ result in more aggressive pruning, with $\sigma = 0$ corresponding to including no arc and $\sigma = 1$ corresponding to including all arcs. We always add the highest scoring tree \hat{y} to $\tilde{y}(x)$ to ensure that it contains at least one complete projective tree.

Figure 3 outlines an example of how (and why) AAST works. In the Greek example, the genitive phrase Η παραμονή σκαφών (*the stay of vessels*) is incorrectly analyzed as a flat noun phrase. This is not surprising given that the base parser simply observes this phrase as DET NOUN NOUN. However, looking at the arc marginals we can see that the correct analysis is available during AAST, although the actual marginal probabilities are quite misleading. Furthermore, the genitive noun σκαφών also appears in other less ambiguous contexts, where the base parser correctly predicts it to modify a noun and not a verb. This allows the training process to add weight to the corresponding lexical feature pairing σκαφών with a noun head and away from the feature pairing it with a verb. The resulting parser correctly predicts the genitive construction.

5.3 Ambiguity-Aware Ensemble-Training

While ambiguous labelings can be used as a means to improve self-training, any information that can be expressed as hard arc-factored constraints can be incorporated, including linguistic expert knowledge and annotation projected via bitext. Here we explore another natural source of information: the predictions of other transfer parsers. It is well known that combining several diverse predictions in an ensemble often leads to improved predictions. However, in most ensemble methods there is typically no learning involved once the base learners have been trained (Sagae and Lavie, 2006). An exception is the method of Sagae and Tsujii (2007), who combine the outputs of many parsers on unlabeled data to train a parser for a new domain. However, in that work the learner is not exposed to the underlying ambiguity of the base parsers; it is only given the Viterbi parse of the combination system as the gold standard. In contrast,

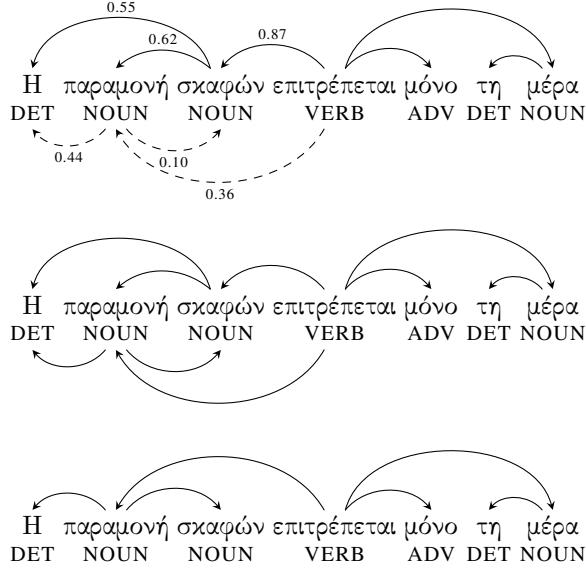

Figure 3: An example of ambiguity-aware self-training (AAST) on a sentence from the Greek self-training data. The sentence roughly translates to *The stay of vessels is permitted only for the day*. **Top:** Arcs from the base model’s Viterbi parse are shown above the sentence. When only the part-of-speech tags are observed, the parser tends to treat everything to the left of the verb as a head-final noun phrase. The dashed arcs below the sentence are the arcs for the true genitive construction *stay of vessels*. These arcs and the corresponding incorrect arcs in the Viterbi parse are marked with their marginal probabilities. **Middle:** The ambiguous labeling $\tilde{y}(x)$, which is used as supervision in AAST. Additional non-Viterbi arcs are present in $\tilde{y}(x)$; for clarity, these are not shown. When learning with AAST, probability mass will be pushed towards any tree consistent with $\tilde{y}(x)$. Marginal probabilities are ignored at this stage, so that all arcs in $\tilde{y}(x)$ are treated as equals. **Bottom:** The Viterbi parse of the AAST model, which has selected the correct arcs from $\tilde{y}(x)$.

we propose an *ambiguity-aware ensemble-training* (AAET) method that treats the union of the ensemble predictions for a sentence x as an ambiguous labeling $\tilde{y}(x)$. An additional advantage of this approach is that the ensemble is compiled into a single model and therefore does not require multiple models to be stored and used at runtime.

It is straightforward to construct $\tilde{y}(x)$ from multiple parsers. Let $\mathcal{A}_k(x, m)$ be the set of arcs for the m th token in x according to the k th parser in the ensemble. When arc-marginals are used to construct the ambiguity set, $|\mathcal{A}_k(x, m)| \geq 1$, but when the Viterbi-parse is used, $\mathcal{A}_k(x, m)$ is a singleton. We next form

$\mathcal{A}(x, m) = \bigcup_k \mathcal{A}_k(x, m)$ as the ensemble arc ambiguity set from which $\tilde{y}(x)$ is assembled. In this study, we combine the arc sets of two base parsers: first, the arc-marginal ambiguity set of the base parser (§5.2); and second, the Viterbi arc set from the *NBG* parser of Naseem et al. (2012) in Table 2.⁴ Thus, the latter will have singleton arc ambiguity sets, but when combined with the arc-marginal ambiguity sets of our base parser, the result will encode uncertainty derived from both parsers.

5.4 Adaptation Experiments

We now study the different approaches to target language adaptation empirically. As in Naseem et al. (2012), we use the CoNLL training sets, stripped of all dependency information, as the unlabeled target language data in our experiments. We use the *Family* model as the base parser, which is used to label the unlabeled target data with the Viterbi parses as well as with the ambiguous labelings. The final model is then trained on this data using standard lexicalized features (McDonald et al., 2005). Since labeled training data is unavailable in the target language, we cannot tune any hyper-parameters and simply set $\lambda = 1$ and $\sigma = 0.95$ throughout. Although the latter may suggest that $\tilde{y}(x)$ contains a high degree of ambiguity, in reality, the marginal distributions of the base model have low entropy and after filtering with $\sigma = 0.95$, the average number of potential heads per dependent ranges from 1.4 to 3.2, depending on the target language.

The ambiguity-aware training methods, that is ambiguity-aware self-training (AAST) and ambiguity-aware ensemble-training (AAET), are compared to three baseline systems. First, *NBG+EM* is the generative model of Naseem et al. (2012) trained with expectation-maximization on additional unlabeled target language text. Second, *Family* is the best discriminative model from the previous section. Third, *Viterbi* is the basic Viterbi self-training model. The results of each of these models are shown in Table 3.

There are a number of things that can be observed. First, *Viterbi* self-training helps slightly on average, but the gains are not consistent and there are even drops in accuracy for some languages. Second, *AAST* outperforms the *Viterbi* variant on all languages and

⁴We do not have access to the marginals of *NBG*.

Lang.	NBG+EM	Family	Target Adaptation		
			Viterbi	AAST	AAET

Table 3: Target language adaptation using unlabeled target data. *AAST*: ambiguity-aware self-training. *AAET*: ambiguity-aware ensemble-training. Boldface numbers indicate the best result per language. Underlined numbers indicate the best result, excluding *AAET*. *NBG+EM* is the “D+, T_o ” model from Naseem et al. (2012).

nearly always improves on the base parser, although it sees a slight drop for Italian. *AAST* improves the accuracy over the base model by 2% absolute on average and by as much as 5% absolute for Turkish. Comparing this model to the *NBG+EM* baseline, we observe an improvement by 3.6% absolute, outperforming it on 14 of the 16 languages. Furthermore, ambiguity-aware self-training appears to help more than expectation-maximization for generative (unlexicalized) models. Naseem et al. observed an increase from 59.3% to 60.4% on average by adding unlabeled target language data and the gains were not consistent across languages. *AAST*, on the other hand, achieves consistent gains, rising from 62.0% to 64.0% on average. Third, as shown in the rightmost column of Table 3, ambiguity-aware ensemble-training is indeed a successful strategy; *AAET* outperforms the previous best self-trained model on 13 and *NB&G+EM* on 15 out of 16 languages. The relative error reduction with respect to the base *Family* model is 9% on

average, while the average reduction with respect to *NBG+EM* is 13%.

Before concluding, two additional points are worth making. First, further gains may potentially be achievable with feature-rich discriminative models. While the best generative transfer model of Naseem et al. (2012) approaches its upper-bounding supervised accuracy (60.4% vs. 67.1%), our relaxed self-training model is still far below its supervised counterpart (64.0% vs. 84.1%). One promising statistic along these lines is that the oracle accuracy for the ambiguous labelings of *AAST* is 75.7%, averaged across languages, which suggests that other training algorithms, priors or constraints could improve the accuracy substantially. Second, relexicalization is a key component of self-training. If we use delexicalized features during self-training, we only observe a small average improvement from 62.0% to 62.1%.

6 Conclusions

We contributed to the understanding of multi-source syntactic transfer in several complementary ways. First, we showed how selective parameter sharing, based on typological features and language family membership, can be incorporated in a discriminative graph-based model of dependency parsing. We then showed how ambiguous labelings can be used to integrate heterogenous knowledge sources in parser training. Two instantiations of this framework were explored. First, an ambiguity-aware self-training method that can be used to effectively relexicalize and adapt a delexicalized transfer parser using unlabeled target language data. Second, an ambiguity-aware ensemble-training method, in which predictions from different parsers can be incorporated and further adapted. On average, our best model provides a relative error reduction of 13% over the state-of-the-art model of Naseem et al. (2012), outperforming it on 15 out of 16 evaluated languages.

Acknowledgments We thank Alexander Rush for help with the hypergraph framework used for inference. Tahira Naseem kindly provided us with her data sets and the predictions of her systems. This work benefited from many discussions with Yoav Goldberg and members of the Google parsing team. We finally thank the three anonymous reviewers for their valuable feedback. The work of the first author was partly funded by the Swedish National Graduate School of Language Technology (GSLT).

Emergence of Gricean Maxims from Multi-Agent Decision Theory

Adam Vogel, Max Bodoia, Christopher Potts, and Dan Jurafsky

Abstract

Grice characterized communication in terms of the *cooperative principle*, which enjoins speakers to make only contributions that serve the evolving conversational goals. We show that the cooperative principle and the associated maxims of relevance, quality, and quantity emerge from multi-agent decision theory. We utilize the Decentralized Partially Observable Markov Decision Process (Dec-POMDP) model of multi-agent decision making which relies only on basic definitions of rationality and the ability of agents to reason about each other's beliefs in maximizing joint utility. Our model uses cognitively-inspired heuristics to simplify the otherwise intractable task of reasoning jointly about actions, the environment, and the nested beliefs of other actors. Our experiments on a cooperative language task show that reasoning about others' belief states, and the resulting emergent Gricean communicative behavior, leads to significantly improved task performance.

1 Introduction

Grice (1975) famously characterized communication among rational agents in terms of an overarching *cooperative principle* and a set of more specific maxims, which enjoin speakers to make contributions that are truthful, informative, relevant, clear, and concise. Since then, there have been many attempts to derive the maxims (or perhaps just their effects) from more basic cognitive principles concerning how people make decisions, formulate plans, and collaborate to achieve goals. This research

traces to early work by Lewis (1969) on signaling systems. It has recently been the subject of extensive theoretical discussion (Clark, 1996; Merin, 1997; Blutner, 1998; Parikh, 2001; Beaver, 2002; van Rooy, 2003; Benz et al., 2005; Franke, 2009) and has been tested experimentally using one-step games in which the speaker produces a message and the hearer ventures a guess as to its intended referent (Rosenberg and Cohen, 1964; Dale and Reiter, 1995; Golland et al., 2010; Stiller et al., 2011; Frank and Goodman, 2012; Krahmer and van Deemter, 2012; Degen and Franke, 2012; Rohde et al., 2012).

To date, however, these theoretical models and experiments have not been extended to multi-step interactions extending over time and involving both language and action together, which leaves this work relatively disconnected from research on planning and goal-orientation in artificial agents (Perrault and Allen, 1980; Allen, 1991; Grosz and Sidner, 1986; Bratman, 1987; Hobbs et al., 1993; Allen et al., 2007; DeVault et al., 2005; Stone et al., 2007; DeVault, 2008). We attribute this in large part to the complexity of Gricean reasoning itself, which requires agents to model each other's belief states. Tracking these as they evolve over time in response to experiences is extremely demanding. Our approach complements slot-filling dialog systems, where the focus is on managing speech recognition uncertainty (Young et al., 2010; Thomson and Young, 2010).

However, recent years have seen significant advances in multi-agent decision-theoretic models and their efficient implementation. With the current paper, we seek to show that the Decentralized Par-

cially Observable Markov Decision Process (Dec-POMDP) provides a robust, flexible foundation for implementing agents that communicate in a Gricean manner. Dec-POMDPs are multi-agent, partially-observable models in which agents maintain belief distributions over the underlying, hidden world state, including the beliefs of the other players, and speech actions change those beliefs. In this setting, informative, relevant communication emerges as the best way to maximize joint utility.

The complexity of pragmatic reasoning is still forbidding, though. Correspondingly, optimal decision making in Dec-POMDPs is NEXP complete (Bernstein et al., 2002). To manage this issue, we introduce several cognitively-plausible approximations which allow us to simplify the Dec-POMDP to a single-agent POMDP, for which relatively efficient solvers exist (Spaan and Vlassis, 2005). We demonstrate our algorithms on a variation of the Cards task, a partially-observable collaborative search problem (Potts, 2012). Spatial language comprises the bulk of communication in the Cards task, and we discuss a model of spatial semantics in Section 3. Using this task and a model of the meaning of spatial language, we next discuss two agents that play the game: *ListenerBot* (Section 4) makes decisions using a single-agent POMDP that does not take into account the beliefs or actions of its partner, whereas *DialogBot* (Section 5) maintains a model of its partner’s beliefs. As a result of the cooperative structure of the underlying model and the effects of communication within it, DialogBot’s contributions are relevant, truthful, and informative, which leads to significantly improved task performance.

2 The Cards Task and Corpus

The Cards corpus consists of 1,266 transcripts¹ from an online, two-person collaborative game in which two players explore a maze-like environment, communicating with each other via a text chat window (Figure 1). A deck of playing cards has been distributed randomly around the environment, and the players’ task is to find six consecutive cards of the same suit. Our implemented agents solve a simplified version of this task in which the two agents

¹Released by Potts (2012) at <http://cardscorpus.christopherpotts.net>

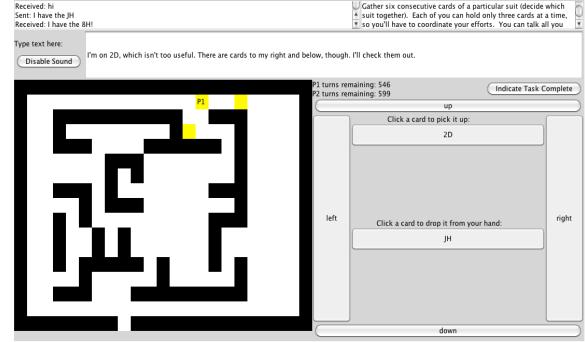

Figure 1: The Cards corpus gameboard. Player 1’s location is marked “P1”. The nearby yellow boxes mark card locations. The dialogue history and chat window are at the top. This board, the one we use throughout, consists of 231 open grid squares.

must both end up co-located with a single card, the Ace of Spades (AS). This is much simpler than the six-card version from the human–human corpus, but it involves the same kind of collaborative goal and forces our agents to deal with the same kind of partial knowledge about the world as the humans did. Each agent knows its own location, but not his partner’s, and a player can see the AS only when co-located with it. The agents use (simplified) English to communicate with each other.

3 Spatial Semantics

Much of the communication in the Cards task involves referring to spatial locations on the board. Accordingly, we focus on spatial language for our artificial agents. In this section, we present a model of spatial semantics, which we create by leveraging the human–human Cards transcripts. We discuss the spatial semantic representation, how we classify the semantics of new locative expressions, and our use of spatial semantics to form a high-level state space for decision making.

3.1 Semantic Representation

Potts (2012) released annotations, derived from the Cards corpus, which reduce 599 of the players’ statements about their locations to formulae of the form $\delta(\varphi_1 \wedge \dots \wedge \varphi_k)$, where δ is a *domain* and $\varphi_1, \dots, \varphi_k$ are semantic literals. For example, the utterance “(I’m) at the top right of the board” is annotated as $\text{BOARD}(\text{top} \wedge \text{right})$, and “(I’m) in bottom

of the C room” is annotated as C_room(bottom). Table 1 lists the full set of semantic primitives that appear as domain expressions and literals.

Because the Cards transcripts are so highly structured, we can interpret these expressions in terms of the Cards world itself. For a given formula $\sigma = \delta(\varphi_1 \wedge \dots \wedge \varphi_k)$, we compute the number of times that a player identified its location with (an utterance translated as) σ while standing on grid square (x, y) . These counts are smoothed using a simple 2D-smoothing scheme, detailed in (Potts, 2012), and normalized in the usual manner to form a distribution over board squares $\Pr((x, y) | \sigma)$. These grounded interpretations are the basis for communication between the artificial agents we define in Section 4.

--

Table 1: The spatial semantic primitives.

3.2 Semantics Classifier

Using the corpus examples of utterances paired with their spatial semantic representations, we learn a set of classifiers to predict a spatial utterance’s semantic representation. We train a binary classifier for each semantic primitive φ_i using a log-linear model with simple bag of words features. The words are not normalized or stemmed and we use whitespace tokenization. We additionally train a multi-class classifier for all possible domains δ . At test time, we use the domain classifier and each primitive binary classifier to produce a semantic representation.

3.3 Semantic State Space

The decision making algorithms that we discuss in Section 4 are highly sensitive to the size of the state space. The full representation of the game board consists of 231 squares. Representing the location of both players and the location of the card requires $323^3 = 12,326,391$ states, well beyond the capabilities of current decision-making algorithms.

To ameliorate this difficulty, we cluster squares together using the spatial referring expression cor-

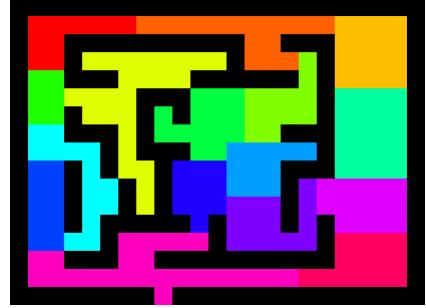

Figure 2: Semantic state space clusters with $k = 16$.

pus. This approach follows from research that shows that humans’ mental spatial representations are influenced by their language (Hayward and Tarr, 1995). Our intuition is that human players do not consider all possible locations of the card and players, but instead lump them into semantically coherent states, such as “the card is in the top right corner.” Following this intuition, we cluster states together which have similar referring expressions, allowing our agents to use language as a *cognitive technology* and not just a tool for communication.

For each board square (x, y) we form a vector $\phi(x, y)$ with $\phi_i(x, y) = \Pr((x, y) | \sigma_i)$, where σ_i is the i^{th} distinct semantic representation in the corpus. This forms a 136-dimensional vector for each board square. We then use k-means clustering with a Euclidean distance metric in this semantic space to cluster states which are referred to similarly.

Figure 2 shows a clustering for $k = 16$ which we utilize for the remainder of the paper. Denoting the board regions by $\{1, \dots, N_{\text{regions}}\}$, we compute the probability of an expression σ referring to a region r by averaging over the squares in the region:

$$\Pr(r | \sigma_i) \propto \sum_{(x,y) \in \text{region } r} \frac{\Pr((x,y) | \sigma_i)}{|\{(x,y) | (x,y) \in \text{region } r\}|}$$

4 ListenerBot

We first introduce ListenerBot, an agent that does not take into account the actions or beliefs of its partner. ListenerBot decides what actions to take using a *Partially Observable Markov Decision Process* (POMDP). This allows ListenerBot to track its beliefs about the location of the card and to incorporate linguistic advice. However, ListenerBot does not produce utterances.

A POMDP is defined by a tuple $(S, A, T, O, \Omega, R, b_0, \gamma)$. We explicate each component with examples from our task. Figure 3(a) provides the POMDP influence diagram.

States S is the finite state space of the world. The state space S of ListenerBot consists of the location of the player p and the location of the card c . As discussed above in Section 3.3, we cluster squares of the board into N_{regions} semantically coherent regions, denoted by $\{1, \dots, N_{\text{regions}}\}$. The state space over these regions is defined as

$$S := \{(p, c) | p, c \in \{1, \dots, N_{\text{regions}}\}\}$$

Two regions r_1 and r_2 are called *adjacent*, written $\text{adj}(r_1, r_2)$, if any of their constituent squares touch.

Actions A is the set of actions available to the agent. ListenerBot can only take physical actions and has no communicative ability. Physical actions in our region-based state space are composed of two types: traveling to a region and searching a region.

- $\text{travel}(r)$: travel to region r
- search : player exhaustively searches the current region

Transition Distributions The transition distribution $T(s'|a, s)$ models the dynamics of the world. This represents the ramifications of physical actions such as moving around the map. For a state $s = (p, c)$ and action $a = \text{travel}(r)$, the player moves to region r if it is adjacent to p , and otherwise stays in the same place:

$$T((p', c')|\text{travel}(r), (p, c)) = \begin{cases} 1 & \text{adj}(r, p) \wedge p' = r \\ & \wedge c = c' \\ 1 & \neg \text{adj}(r, p) \wedge p = p' \\ & \wedge c = c' \\ 0 & \text{otherwise} \end{cases}$$

Search actions are only concerned with observations and do not change the state of the world:²

$$T((p', c')|\text{search}, (p, c)) = \mathbb{1}[p' = p \wedge c' = c]$$

The travel and search high-level actions are translated into low-level (up, down, left, right) actions using a simple A* path planner.

Observations Agents receive observations from a set O according to an observation distribution

² $\mathbb{1}[Q]$ is the indicator function, which is 1 if proposition Q is true and 0 otherwise.

$\Omega(o|s', a)$. Observations include properties of the physical world, such as the location of the card, and also natural language utterances, which serve to indirectly change agents' beliefs about the world and the beliefs of their interlocutors.

Search actions generate two possible observations: o_{here} and $o_{\neg \text{here}}$, which denote the presence or absence of the card from the current region.

$$\begin{aligned} \Omega(o_{\text{here}}|(p', c'), \text{search}) &= \mathbb{1}[p' = c'] \\ \Omega(o_{\neg \text{here}}|(p', c'), \text{search}) &= \mathbb{1}[p' \neq c'] \end{aligned}$$

Travel actions do not generate meaningful observations:

$$\Omega(o_{\neg \text{here}}|(p', c'), \text{travel}) = 1$$

Linguistic Advice We model linguistic advice as another form of observation. Agents receive messages from a finite set Σ , and each message $\sigma \in \Sigma$ has a *semantics*, or distribution over the state space $\Pr(s|\sigma)$. In the Cards task, we use the semantic distributions defined in Section 3. To combine the semantics of language with the standard POMDP observation model, we apply Bayes' rule:

$$\Pr(\sigma|s) = \frac{\Pr(s|\sigma)\Pr(\sigma)}{\sum_{\sigma'} \Pr(s|\sigma')\Pr(\sigma')} \quad (1)$$

The prior, $\Pr(\sigma)$, can be derived from corpus data. By treating language as just another form of observation, we are able to leverage existing POMDP solution algorithms. This approach contrasts with previous work on communication in Dec-POMDPs, where agents directly share their perceptual observations (Pynadath and Tambe, 2002; Spaan et al., 2008), an assumption which does not fit natural language.

Reward The reward function $R(s, a) : S \rightarrow \mathbb{R}$ represents the goals of the agent, who chooses actions to maximize reward. The goal of the Cards task is for both players to be on top of the card, so any action that leads to this state receives a high reward R^+ . All other actions receive a small negative reward R^- , which gives agents an incentive to finish the task as quickly as possible.

$$R((p, c), a) = \begin{cases} R^+ & p = c \\ R^- & p \neq c \end{cases}$$

Lastly, $\gamma \in [0, 1)$ is the discount factor, specifying the trade-off between immediate and future rewards.

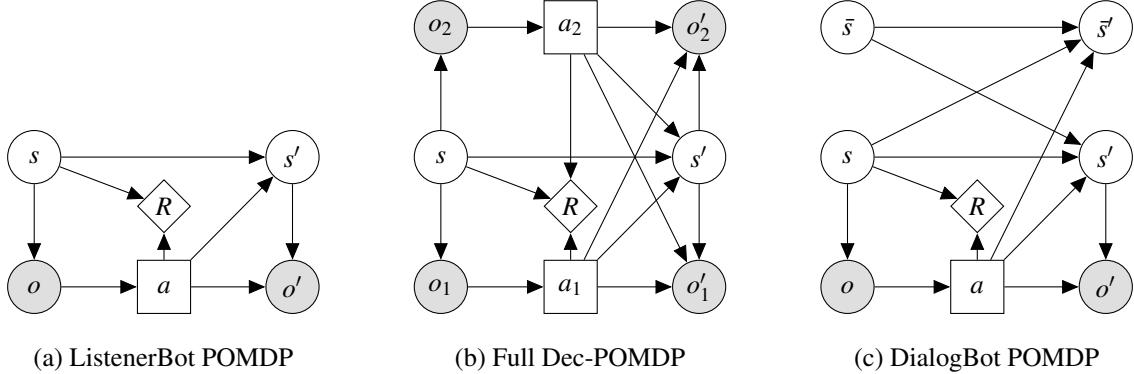

Figure 3: The decision diagram for the ListenerBot POMDP, the full Dec-POMDP, and the DialogBot approximation POMDP. The ListenerBot (a) only considers his own location p and the card location c . In the full Dec-POMDP (b), both agents receive individual observations and choose actions independently. Optimal decision making requires tracking all possible histories of beliefs of the other agent. In diagram (c), DialogBot approximates the full Dec-POMDP as single-agent POMDP. At each time step, DialogBot marginalizes out the possible observations \bar{o} that ListenerBot received, yielding an *expected belief state* \bar{b} .

Initial Belief State The initial belief state, $b_0 \in \Delta(S)$, is a distribution over the state space S . ListenerBot begins each game with a known initial location p_0 but a uniform distribution over the location of the card c :

$$b_0(p, c) \propto \begin{cases} \frac{1}{N_{\text{regions}}} & p = p_0 \\ 0 & \text{otherwise} \end{cases}$$

Belief Update and Decision Making The key decision making problem in POMDPs is the construction of a policy $\pi : \Delta(S) \rightarrow A$, a function from beliefs to actions which dictates how the agent acts. Decision making in POMDPs proceeds as follows. The world starts in a hidden state $s_0 \sim b_0$. The agent executes action $a_0 = \pi(b_0)$. The underlying hidden world state transitions to $s_1 \sim T(s'|a_0, s_0)$, the world generates observation $o_0 \sim \Omega(o|s_1, a_0)$, and the agent receives reward $R(s_0, a_0)$. Using the observation o_0 , the agent constructs a new belief $b_1 \in \Delta(S)$ using Bayes' rule:

$$\begin{aligned} b_{t+1}^{a_t, o_t}(s') &= \Pr(s'|a_t, o_t, b_t) \\ &= \frac{\Pr(o_t|a_t, s', b_t) \Pr(s'|a_t, b_t)}{\Pr(o_t|b_t, a_t)} \\ &= \frac{\Omega(o_t|s', a_t) \sum_{s \in S} T(s'|a_t, s) b_t(s)}{\sum_{s''} \Omega(o_t|s'', a_t) \sum_{s \in S} T(s''|a_t, s) b_t(s)} \end{aligned}$$

This process is referred to as *belief update* and is analogous to the forward algorithm in HMMs. To incorporate communication into the standard POMDP

model, we consider observations $(o, \sigma) \in O \times \Sigma$ which are a combination of a perceptual observation o and a received message σ . The semantics of the message σ is included in the belief update equation using $\Pr(s|\sigma)$, derived in Equation 1:

$$\begin{aligned} b_{t+1}^{a_t, o_t, \sigma_t}(s') &= \\ &\frac{\Omega(o|s', a) \frac{\Pr(s'|\sigma) \Pr(\sigma)}{\sum_{\sigma' \in \Sigma} \Pr(s'|\sigma') \Pr(\sigma')}}{\sum_{s'' \in S} \Omega(o|s'', a) \frac{\Pr(s''|\sigma) \Pr(\sigma)}{\sum_{\sigma' \in \Sigma} \Pr(s''|\sigma') \Pr(\sigma')}} \sum_{s \in S} T(s'|a, s) b_t(s) \end{aligned}$$

Using this new belief state b_1 , the agent selects an action $a_1 = \pi(b_1)$, and the process continues.

An initial belief state b_0 and a policy π together define a Markov chain over pairs of states and actions. For a given policy π , we define a *value function* $V^\pi : \Delta(S) \rightarrow \mathbb{R}$ which represents the expected discounted reward with respect to that Markov chain:

$$V^\pi(b_0) = \sum_{t=0}^{\infty} \gamma^t \mathbb{E}[R(b_t, a_t)|b_0, \pi]$$

The goal of the agent is find a policy π^* which maximizes the value of the initial belief state:

$$\pi^* = \arg \max_{\pi} V^\pi(b_0)$$

Exact computation of π^* is PSPACE-complete (Papadimitriou and Tsitsiklis, 1987), making approximation algorithms necessary for all but the simplest problems. We use Perseus (Spaan and Vlassis, 2005), an anytime approximate point-based value it-

eration algorithm.

5 DialogBot

We now introduce DialogBot, a Cards agent which is capable of producing linguistic advice. To decide when and how to speak, DialogBot maintains a distribution over its partner’s beliefs and reasons about the effects his utterances will have on those beliefs. To handle these complexities, DialogBot models the world as a *Decentralized Partially Observable Markov Decision Process* (Dec-POMDP) (Bernstein et al., 2002). See Figure 3(b) for the influence diagram. The definition of Dec-POMDPs mirrors that of the POMDP, with the following changes.

There is a finite set I of agents, which we restrict to two. Each agent takes an action a_i at each time step, forming a joint action $\bar{a} = (a_1, a_2)$. Each agent receives its own observation o_i according to $\Omega(o_1, o_2 | a_1, a_2, s')$. The transition distributions $T(s'|a_1, a_2, s)$ and the reward $R(s, a_1, a_2)$ both depend on both agents’ actions.

Optimal decision making in Dec-POMDPs requires maintaining a probability distribution over all possible sequences of actions and observations $(\bar{a}_1, \bar{o}_1, \dots, \bar{a}_t, \bar{o}_t)$ that the other player might have received. As t increases, we have an exponential increase in the belief states an agent must consider. Confirming this informal intuition, decision making in Dec-POMDPs is NEXP-complete, a complexity class above P-SPACE (Bernstein et al., 2002). This computational complexity limits the application of Dec-POMDPs to very small problems. To address this difficulty we make several simplifying assumptions, allowing us to construct a single-agent POMDP which approximates the full Dec-POMDP.

Firstly, we assume that other agents do not take into account our own beliefs, i.e., the other agent acts like a ListenerBot. This bypasses the infinitely nested belief problem by assuming that other agents track one less level of nested beliefs, a common approach (Goodman and Stuhlmüller, 2012; Gmytrasiewicz and Doshi, 2005).

Secondly, instead of tracking the full tree of possible observation histories, we maintain a point estimate \bar{b} of the other agent’s beliefs, which we term the *expected belief state*. Rather than tracking each possible observation/action history of the

other agent, at each time step we marginalize out the observations they could have received. Figure 4 compares this approach with exact belief update.

Thirdly, we assume that the other agent acts according to a variant of the Q_{MDP} approximation (Littman et al., 1995). Under this approximation, the other agent solves a fully-observable MDP version of the ListenerBot POMDP, yielding an MDP policy $\bar{\pi} : S \rightarrow A$. This critically allows us to approximate the other agent’s belief update using a specially formed POMDP, which we detail next.

State Space To construct the approximate single-agent POMDP from the full Dec-POMDP problem, we formulate the state space as $S \times S$. (See Figure 3(c) for the influence diagram.) We write a state $(s, \bar{s}) \in S \times S$, where s is DialogBot’s beliefs about the true state of the world, and \bar{s} is DialogBot’s estimate of the other agent’s beliefs.

Transition Distribution The main difficulty in constructing the approximate single-agent POMDP is specifying the transition distribution $T((s', \bar{s}') | a, (s, \bar{s}))$. To address this, we break this distribution into two components: $T((s', \bar{s}') | a, (s, \bar{s})) = \bar{T}(\bar{s}' | s', a, (s, \bar{s}))T(s' | a, s, \bar{s})$. The first term dictates how DialogBot updates its beliefs about the other agent’s beliefs:

$$\begin{aligned} \bar{T}(\bar{s}' | s', a, (s, \bar{s})) &= \Pr(\bar{s}' | s', a, (s, \bar{s})) \\ &= \sum_{\bar{o} \in O} \Pr(\bar{s}' | a, \bar{o}, \bar{s}, s) \Pr(\bar{o} | s', a, \bar{\pi}(\bar{s})) \\ &= \sum_{\bar{o} \in O} \left(\frac{\Omega(\bar{o} | \bar{s}', a, \bar{\pi}(\bar{s})) T(\bar{s}' | a, \bar{\pi}(\bar{s}), \bar{s})}{\sum_{\bar{s}''} \Omega(\bar{o} | \bar{s}'', a, \bar{\pi}(\bar{s})) T(\bar{s}'' | a, \bar{\pi}(\bar{s}), \bar{s})} \right. \\ &\quad \left. \times \Omega(\bar{o} | s', a, \bar{\pi}(\bar{s})) \right) \end{aligned}$$

We sum over all observations \bar{o} the other agent could have received, updating our probability of \bar{s}' as ListenerBot would have, multiplied by the probability that ListenerBot would have received that observation, $\Omega(\bar{o} | s', \bar{\pi}(\bar{s}))$. The Q_{MDP} approximation allows us to simulate ListenerBot’s belief update in $\bar{T}(\bar{s}' | s', a, (s, \bar{s}))$. Exact belief update would require access to \bar{b} : by using $\bar{\pi}(\bar{s})$ we can estimate the action that ListenerBot would have taken.

In cases where \bar{s} contradicts s such that for all \bar{o} either $\Omega(\bar{o} | s', \bar{\pi}(\bar{s})) = 0$ or $\Omega(\bar{o} | \bar{s}', \bar{\pi}(\bar{s})) = 0$, we redistribute the belief mass uniformly: $\bar{T}(\bar{s}' | s', a, (s, \bar{s})) \propto$

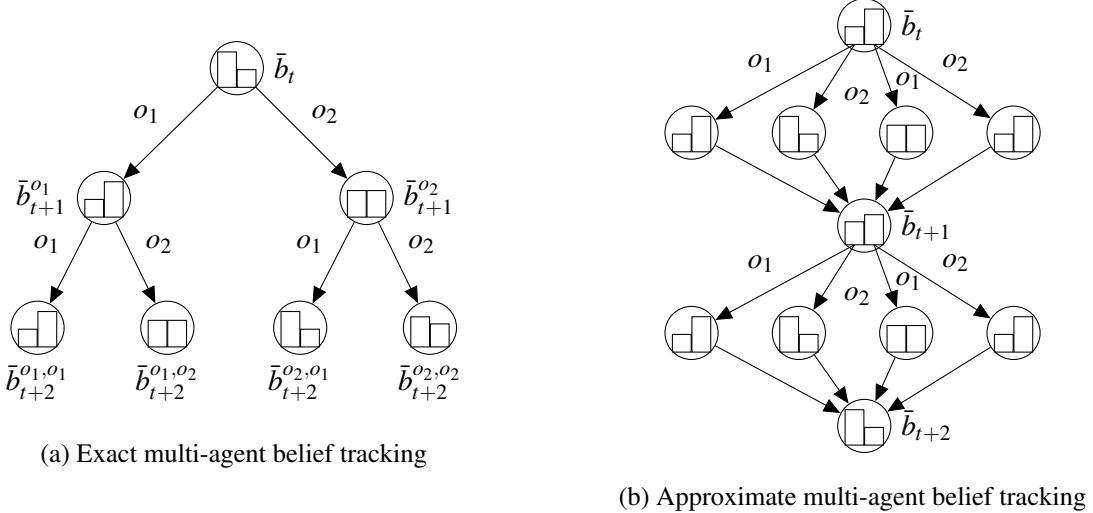

Figure 4: Exact multi-agent belief tracking compared with our approximate approach. Each node represents a belief state. In exact tracking (a), the agent tracks every possible history of observations that its partner could have received, which grows exponentially in time. In approximate update (b), the agent considers each possible observation and then averages the resulting belief states, weighted by the probability the other agent received that observation, resulting in a single summary belief state \bar{b}_{t+1} . Under the Q_{MDP} approximation, the agent considers what action the other agent would have taken if it completely believed the world was in a certain state. Thus, there are four belief states resulting from \bar{b}_t , as opposed to two in the exact case.

$1 \forall \bar{s}' \neq \bar{s}$. This approach to managing contradiction is analogous to logical belief revision (Alchourrón et al., 1985; Gärdenfors, 1988; Fermé and Hansson, 2011).

Speech Actions Speech actions are modeled by how they change the beliefs of the other agent. The effects of a speech actions are modeled in $\bar{T}(\bar{s}'|s', a, (s, \bar{s}))$, our model of how ListenerBot’s beliefs change. For a speech action $a = \text{say}(\sigma)$ with $\sigma \in \Sigma$,

$$\begin{aligned} \bar{T}(\bar{s}'|s', a, (s, \bar{s})) &= \\ &\sum_{\bar{o} \in O} \left(\frac{\Omega(\bar{o}|\bar{s}', a, \bar{\pi}(\bar{s})) \Pr(\sigma|\bar{s}') T(\bar{s}'|a, \bar{\pi}(\bar{s}), \bar{s})}{\sum_{\bar{s}''} \Omega(\bar{o}|\bar{s}'', a, \bar{\pi}(\bar{s})) \Pr(\sigma|\bar{s}'') T(\bar{s}''|a, \bar{\pi}(\bar{s}), \bar{s})} \right. \\ &\quad \times \left. \Omega(\bar{o}|s', a, \bar{\pi}(\bar{s})) \right) \end{aligned}$$

DialogBot is equipped with the five most frequent speech actions: BOARD(middle), BOARD(top), BOARD(bottom), BOARD(left), and BOARD(right). It produces concrete utterances by selecting a sentence from the training corpus with the desired semantics.

Reward DialogBot receives a large reward when both it and its partner are located on the card, and a negative cost when moving or speaking:

$$R((p, c, \bar{p}, \bar{c}), a) = \begin{cases} R^+ & p = c \wedge \bar{p} = \bar{c} \\ R^- & p \neq c \vee \bar{p} \neq \bar{c} \end{cases}$$

DialogBot’s reward is not dependent on the beliefs of the other player, only the true underlying state of the world.

6 Experimental Results

We now experimentally evaluate our semantic classifiers and the agents’ task performance.

6.1 Spatial Semantics Classifiers

We report the performance of our spatial semantics classifiers, although their accuracy is not the focus of this paper. We use 10-fold cross validation on a corpus of 577 annotated utterances. We used simple bag-of-words features, so overfitting the data with cross validation is not a pressing concern. Of the 577 utterances, our classifiers perfectly labeled 325 (56.3% accuracy). The classifiers correctly predicted the domain δ of 515 (89.3%) utterances. The

precision of our binary semantic primitive classifiers was $\frac{969}{1126} = .861$ and recall $\frac{969}{1242} = .780$, yielding F_1 measure .818.

6.2 Cards Task Evaluation

We evaluated our ListenerBot and DialogBot agents in the Cards task. Using 500 randomly generated initial player and card locations, we tested each combination of ListenerBot and DialogBot partners. Agents succeeded at a given initial position if they both reached the card within 50 moves. Table 2 shows how many trials each dyad won and how many high-level actions they took to do so.

Agents	% Success	Moves
LB & LB	84.4%	19.8
LB & DB	87.2%	17.5
DB & DB	90.6%	16.6

Table 2: The evaluation for each combination of agents. LB = ListenerBot; DB = DialogBot.

Collaborating DialogBots performed the best, completing more trials and using fewer moves than the ListenerBots. The DialogBots initially explore the space in a similar manner to the ListenerBots, but then share card location information. This leads to shorter interactions, as once the DialogBot finds the card, the other player can find it more quickly. In the combination of ListenerBot and DialogBot, we see about half of the improvement over two ListenerBots. Roughly 50% of the time, the ListenerBot finds the card first, which doesn't help the DialogBot find the card any faster.

7 Emergent Pragmatics

Grice's original model of pragmatics (Grice, 1975) involves the cooperative principle and four maxims: quality ("say only what you know to be true"), relation ("be relevant"), quantity ("be as informative as is required; do not say more than is required"), and manner (roughly, be clear and concise).

In most interactions, DialogBot searches for the card and then reports its location to the other agent. These reports obey quality in that they are made only when based on actual observations. The behavior is not hard-coded, but rather emerges, because only

accurate information serves the agents' goals. In contrast, sub-optimal policies generated early in the POMDP solving process sometimes lie about card locations. Since this behavior confuses the other agent and thus has a lower utility, it gets replaced by truthful communication as the policies improve.

We also capture the effects of relation and the first clause of quantity, because the nature of the reward function and the nested belief structures ensure that DialogBot offers only relevant, informative information. For instance, when DialogBot finds the card in the lower left corner, it alternates saying "left" and "bottom", effectively overcoming its limited generation capabilities. Again, early sub-optimal policies sometimes do not report the location of the card at all, thereby failing to fulfill these maxims.

We expect these models to produce behavior consistent with manner and the second clause of quantity, but evaluating this claim will require a richer experimental paradigm. For example, if DialogBot had a larger and more structured vocabulary, it would have to choose between levels of specificity as well as more or less economical forms.

8 Conclusion

We have shown that cooperative pragmatic behavior can arise from multi-agent decision-theoretic models in which the agents share a joint utility function and reason about each other's belief states. Decision-making in these models is intractable, which has been a major obstacle to achieving experimental results in this area. We introduced a series of approximations to manage this intractability: (i) combining low-level states into semantically coherent high-level ones; (ii) tracking only an averaged summary of the other agent's potential beliefs; (iii) limiting belief state nesting to one level, and (iv) simplifying each agent's model of the other's beliefs so as to reduce uncertainty. These approximations bring the problems under sufficient control that they can be solved with current POMDP approximation algorithms. Our experimental results highlight the rich pragmatic behavior this gives rise to and quantify the communicative value of such behavior. While there remain insights from earlier theoretical proposals and logic-based methods that we have not fully captured, our current results support

the notion that probabilistic decision-making methods can yield robust, widely applicable models that address the real-world difficulties of partial observability and uncertainty.

Abstract

We present open dialogue management and its application to relational databases. An open dialogue manager generates dialogue states, actions, and default strategies from the semantics of its application domain. We define three open dialogue management tasks. First, vocabulary selection finds the intelligible attributes in each database table. Second, focus discovery selects candidate dialogue foci, tables that have the most potential to address basic user goals. Third, a focus agent is instantiated for each dialogue focus with a default dialogue strategy governed by efficiency. We demonstrate the portability of open dialogue management on three very different databases. Evaluation of our system with simulated users shows that users with realistically limited domain knowledge have dialogues nearly as efficient as those of users with complete domain knowledge.

1 Introduction

This paper presents *open dialogue management*. An open dialogue manager (ODM) generates dialogue states, actions, and strategies from knowledge it computes about the semantics of its domain. A *dialogue strategy* is the procedure by which a system chooses its next action given the current state of the dialogue. The system's *dialogue policy* completely specifies which strategy to use in any dialogue state. Strategies can be handcrafted or learned. Reinforcement learning, the leading method for dialogue strategy learning, can yield powerful results but relies on small sets of states and actions predefined by the researcher. This reliance on domain expertise limits machine

learned dialogue managers to the domains for which they were specifically designed, and contributes to the prevalence of handcrafted strategies over machine learning approaches for dialogue management in commercial applications (Paek & Pieraccini, 2008). We argue that open dialogue management, which exploits the semantics and contents of its database to generate actions, states and default strategies, is a step towards a dialogue manager that operates across domains.

As a first step to open dialogue management we present ODDMER (OPEN-DOMAIN DIALOGUE MANAGER), the first dialogue system to generate its own dialogue strategy from relational databases. ODDMER's vocabulary selection module uses supervised learning to determine each table's *intelligible* attributes, those most likely to be in the user's vocabulary. Its focus discovery module finds *candidate dialogue foci*, tables that have the most potential to address basic user goals. Foci are identified with *schema summarization* through a random walk over the database schema that ranks tables by size, linguistic information, and connectivity. For each candidate focus, ODDMER instantiates a *focus agent* that prompts users for values of intelligible attributes ordered by efficiency.

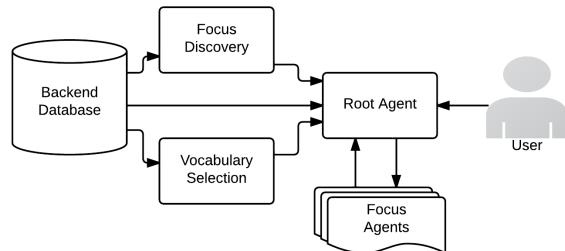

Figure 1. ODDMER uses focus discovery and vocabulary selection to choose its states, actions, and strategy.

This paper addresses a particular type of information-seeking dialogue in which the user’s goal is to select a tuple from a table. Tuples are identified by *constraints*, attribute-value pairs elicited from a user during the dialogue. A typical user, however, cannot supply all values with equal readiness. For example, attributes such as primary or foreign keys are irrelevant or unintelligible to users. This results in a *vocabulary problem*, a mismatch between system and user vocabulary (Furnas et al., 1987). Furthermore, tables differ in their relevance to users. Tables that contain little semantic information have less potential to address user goals. Dialogue systems for relational databases often rely on manual pre-processing to select the attributes a typical user can most readily supply and identify the tables with the most relevance to basic user goals. An open dialogue system obviates this manual step by exploiting the database semantics.

For example, *Heiskell* is a library database that includes a table for books (BOOK) and a table for book subject headings (HEADING). A typical patron wants a book, not a heading. Due to BOOK’s larger size, its greater number of intelligible attributes, and its higher connectivity to other tables, ODDMER recognizes that a BOOK tuple satisfies a more basic user goal. BOOK has 32 attributes, most of which are numeric fields familiar to a librarian but arcane to the user. ODDMER selects the table’s intelligible attributes as its vocabulary. It recognizes that a book’s author and title are intelligible, but the book’s ISBN is not. Consequently, ODDMER will not ask the user for the ISBN.

ODDMER assumes a user of the Heiskell database will be likely to know one or more intelligible attributes of books. ODDMER ranks intelligible attribute-value pairs by their *semantic specificity*, the degree to which they uniquely identify a tuple. To demonstrate the benefit of pre-computing this semantic information, we test ODDMER on three databases with simulated users of two knowledge levels. *Complete-knowledge* users know all attribute values. They have no vocabulary problem, will always be able to supply a requested constraint, and require no vocabulary selection to achieve maximum dialogue efficiency. *Incomplete-knowledge* users have a more realistic vocabulary. They know values for different attributes with different probabilities. Without vocabulary selection, these users have long, inefficient dialogues. Given ODDMER’s vocabulary selection and efficient

dialogue strategy, these users achieve their goals nearly as efficiently as complete-knowledge users.

2 Related Work

ODDMER is the first dialogue system to examine a database and choose which tables and attributes to use in dialogue. We envision open dialogue management as a suite of domain-independent procedures through which a dialogue manager can exploit its knowledge base. Hastie, Liu, and Lemon (2009) also generate policies from databases. They do not consider multiple tables, and they depend on handcrafted Business Process Models that explicitly specify the dialogue flow for the domain. This limits their method to domains with available models. Polifroni, Chung, and Seneff (2003) also argue for the importance of generic, domain-independent dialogue managers. Their portable information presentation strategies cluster attribute values to summarize database contents for users. Neither of these works considers how to choose attributes or find which domain entities are likely objects of dialogue goals. Chotimongkol and Rudnicky (2008) use unsupervised learning to automatically acquire task-specific information from a corpus of in-domain human-human dialogue transcripts. They require a large corpus whereas we need only the underlying database.

The vocabulary problem has received relatively little attention in dialogue research, and no method to automatically identify intelligible constraints has been previously demonstrated. Demberg and Moore (2006) choose constraints with a user model that records user importance, such as ‘price’ for a student in a restaurant domain. They require a manually crafted user model and must match model to user. Polifroni and Walker (2006) use attribute entropy to order system initiative prompts, but assume that both the table and the relevant attributes are known a priori. Varges, Weng, and Pon-Barry (2006) develop a WOZ system in which a wizard recommends to real users what constraint to provide that will best narrow down results. Each of these works assumes all constraints are intelligible.

Two recent works concentrate more closely on the vocabulary problem. Janarthanam and Lemon (2010) build a system that determines a user’s level of referring expression expertise, but manually determine the set of possible expressions. Selfridge and Heeman (2010) simulate users with different

levels of domain knowledge. A novice has a 10% chance to know any constraint, and an expert a 90% chance. They do not consider users who know different constraints with different probabilities as we do, and do not consider databases that contain attributes likely to be unintelligible to most users.

Reinforcement learning, the leading approach for learning a dialogue strategy, demonstrates powerful results. For example, Rieser and Lemon (2009) find the optimal size of a list of tuples that match a user’s constraints and when to display it in different user environments. A dialogue strategy is treated as a *policy*, a function that maps states to actions. Policy optimization is a Markov decision process. Paek and Pieraccini (2008) argue that reinforcement learning is limited by its reliance upon small sets of manually defined states and actions, with no standard method to determine these. ODDMER identifies dialogue states and actions automatically. Its default strategy could be optimized with reinforcement learning.

Portability is an important research area in natural-language interfaces to databases (NLIDBs). An NLIDB parses a user utterance into a logical form, which is transformed into a database query. Users typically know the database structure and contents. TEAM (Grosz, 1983), the first portable NLIDB, questions a domain expert to acquire linguistic knowledge for new databases. More recently, the ORAKEL interface (Cimiano et al., 2008) partially derives a domain-specific lexicon from a generic ontology. Here we do not focus on parsing of user questions, but on the acquisition of dialogue states, actions, and strategies from a database.

3 The ODDMER Dialogue System

ODDMER’s *vocabulary selection* module finds each table’s intelligible attributes. Its *focus discovery* module identifies candidate foci. A *focus agent* module instantiates dialogue agents for each focus. Their default strategy elicits attribute values from users in order of semantic specificity.

3.1 Vocabulary Selection

A *vocabulary* is the set of words and expressions used to discuss a domain. Domain entities can be identified by their *descriptions*, or sets of attribute-value pairs. In order for a system and a user to profitably engage in a natural language dialogue about database items, descriptions should consist

of attributes and values understood by both system and user. We define the *vocabulary selection task* as the automatic selection of attribute-value pairs that the system expects its users will use to describe domain entities.

Successful vocabulary selection solves the vocabulary problem. The vocabulary problem is a bottleneck to portability because the attributes a user is likely to know must be predetermined for existing systems. ODDMER learns a classifier to determine a table’s intelligible attributes. An attribute is *intelligible* if its values are in a user’s vocabulary. A user interested in a particular item but unfamiliar with the structure of a database is more likely to recognize an intelligible attribute, and to know all or part of the relevant value.

To determine intelligible attributes, ODDMER currently relies on a binary classifier that takes as input the values of each attribute found in a particular instantiation of a relational database. To train the classifier, we labeled a set of 84 attributes belonging to tables taken from the Microsoft AdventureWorks Cycle Company database, a benchmark database packaged with Microsoft SQL Server. An attribute was labeled as intelligible if its values were likely to be known to a user. Four annotators worked independently to label the attributes. Pairwise agreement was 69%, and Krippendorff’s alpha (Krippendorff, 1980) was 0.42. The low agreement can be attributed in part to the many ways to interpret the question annotators were to answer. The instructions indicated that the goal was to identify attributes corresponding to common-sense knowledge, but for a given table, annotators were shown all the attributes and asked whether they would know a value. For an employee table, annotators disagreed on attributes such as birthdate, hire date, and organization level. If they had instead been asked whether anyone without access to the table might know a value, there may have been more agreement.

Ratio of unique to total characters in all values
Mean ratio of unique to total characters per value
Ratio of numeric to total characters in all values
Ratio of unique to total values
Ratio of unique to total words in all values
Total number of characters in all values

Table 1. Representative features for attribute classification used in the best-performing intelligibility classifier.

The training data for the classifier consisted of 67 attributes that at least three annotators agreed on (22 intelligible, 45 not intelligible); pairwise agreement was 0.81 and Krippendorff's alpha was 0.61. They represented 8 tables and contained a total of 393,520 values, 123,901 of which were unique. For each attribute we extracted 17 features to represent the linguistic *expressiveness* of the attributes' values. An attribute whose values are more like natural language is more intelligible. Table 1 lists the features of the best classifier.

We tested several binary classifiers in Weka (Hall et al., 2009). ADTree (Freund & Mason, 1999) with ten boosting iterations performed best, with 91% recall and 91% precision under 10-fold cross-validation. However, the ADTree models were overfitted to the AdventureWorks domain. The RIPPER rule-learning algorithm (Cohen, 1995) achieved 77% precision and 78% recall. Because its learned model of three simple rules generalizes better to our domains, ODDMER uses the RIPPER intelligibility classifier.

Given a table, the vocabulary selection module returns which of its attributes should be in the system's vocabulary. For the Heiskell Library domain, the 32 attributes of the BOOK table include many internal codes understood by librarians but not by users. Only the seven attributes shown in Table 2 are classified as intelligible. Dialogues with only intelligible attributes should be more efficient for users with incomplete domain knowledge, because they will be more likely to know their values.

ODDMER's vocabulary selection module also computes the *semantic specificity* score of each attribute (Hixon, Passonneau, & Epstein, 2012). Semantic specificity rates an attribute on a scale from 0 to 1 according to how unambiguously its values map to rows in the database. More specific attributes are expected to be more efficient prompts. Table 2 lists the specificity values of the intelligible attributes for BOOK.

Intelligible Attributes	Specificity
ANNOTATION	0.958
TITLE	0.878
SORTTITLE	0.878
AUTHOR	0.300
NARRATOR	0.018
PUBLISHER	0.016
SERIES	0.003

Table 2. Intelligible attributes for BOOK sorted by specificity. (SORTTITLE is a duplicate of TITLE.)

3.2 Candidate Dialogue Focus Discovery

Information-seeking dialogues address diverse dialogue goals. For example, users may want to identify a tuple in a table ("I want a certain book by Stephen King."), retrieve the value of an attribute for a given tuple ("Is my plane on time?" "Who wrote *Moby Dick*?"), aggregate over a set of tuples ("How many Italian restaurants are in this neighborhood?"), or compare values of different tuples ("Which restaurant is more expensive?"). Each of these dialogue goals represents a distinct information need. However, not all possible information needs in a domain are equally likely. For example, a user is unlikely to ask for the value of a primary key attribute, or to select a tuple from a table that contains only primary and foreign keys. A dialogue system should place less priority on addressing these peripheral dialogue goals.

Given a particular domain, we assume that some goals are more *basic* than others. For example, the basic function of a library is to provide books to borrowers. Some libraries will also provide other material, or perform reference functions, but these are less basic. This notion of a basic goal is related to the basic categories proposed by Rosch (1978), who claimed that not all categories are equally useful for cognition. Basic categories are more differentiated from other categories, and have attributes that are common to all or most members of the category, thus provide us with more information (the principle of *cognitive economy*). Basic categories also mirror the structure of the perceptual and functional attributes of the natural world, thus serve us better in our daily activities. Typically a domain expert will identify the basic dialogue goals in a domain, but we suggest that the basic dialogue goals are *discoverable* in the underlying database. While a difficult problem, we are motivated by work in the database literature to identify and rank the most likely queries for an arbitrary database (Jayapandian & Jagadish, 2008).

We approach the problem of recovering dialogue goals from a database by restricting our attention to the tuple selection task, a commonly studied type of information-seeking dialogue in which the user's goal is to select a tuple from a table. A relational database typically consists of multiple tables, and each table can satisfy different user goals. Given a database composed of multiple tables, an open dialogue system calculates which

tables are larger, have more natural language content, and greater connectivity to other tables. We refer to these tables as *candidate dialogue foci*. This notion of candidate focus for a dialogue is similar to focus of attention (Grosz & Sidner, 1986) in that information-seeking dialogues can be segmented to reflect the table both participants focus their attention on at a given time. We denote the task of identifying candidate foci in a relational database as *focus discovery*.

ODDMER's focus discovery module returns an ordered list of candidate foci, the *focal summary*. The highest ranked focus is the most relevant to basic user goals, those goals that pertain to the most information-rich and intelligible table. For our tuple-selection task, the highest-ranked focus is the table from which the system predicts a user will most likely want to select a tuple. A system that begins a dialogue by first mentioning the most relevant tables communicates the structure of the database better than does a system that lists all tables in a random order. Users with more specialized goals may be interested in more peripheral tables. For these users, more effort will be required to establish a dialogue focus: several tables may be proposed by the system and rejected before the user agrees to consider a given table. In tests with real users, we would expect them to find it acceptable for a specialized goal to take more effort than a basic goal.

We use *schema summarization* to find candidate focus tables. According to Yu and Jagadish (2006), a schema summary should convey a concise understanding of the underlying database schema. They identify table importance and coverage as criteria for good schema summaries. Their summaries for XML databases rank entities with higher cardinality (number of rows) and connectivity (number of joins) as more important. Yang, Procopiuc, and Srivastava (2009) extend schema summarization to relational databases. We closely follow the Yang algorithm but make modifications for dialogue to account for attribute intelligibility.

A database *schema* is an undirected graph $G = \langle R, E \rangle$ where each node $r \in R$ corresponds to a table in a database and each edge $e \in E$ denotes a join between two tables. A *schema summary* is a set of the most important nodes in the schema. Yang and colleagues compute the importance of a table as a function of its size, total entropy of its attributes, and connectivity to other tables. To in-

corporate connectivity, they employ a random walk over the schema graph. The most important tables maintain the highest information content in the steady state of a random walk over the schema.

A significant feature of their algorithm is that a table's high-entropy attributes largely determine its importance. It is possible to artificially inflate a table's importance under the Yang algorithm by introducing a new column of distinct integer values; numeric and linguistic values contribute equally to importance. For dialogue applications, this is undesirable. A table with more intelligible attributes is a more likely candidate focus because it can more readily be discussed. We therefore modify the Yang algorithm to compute table *verbality*. Verbality is similar to importance except that where Yang and colleagues use all attributes, we use intelligible attributes identified by vocabulary selection.

A table's verbality score is a function of its cardinality, the entropy of its intelligible attributes, and its connectivity to other tables. We apply vocabulary selection to find natural language attributes. To calculate the verbality of a table T , let A be the attributes of T and let $A' \subseteq A$ be those attributes of T whose values are intelligible, found by the classifier described previously. For BOOK, A' consists of the attributes shown in Table 2. Define V , the verbal information content of a table, as

$$V(T) = \log(|T|) + \sum_{a \in A'} H(a)$$

where $|T|$ is the cardinality of the table and $H(a)$ is the entropy of the attribute a in A' . The entropy of a is given by $H(a) = -\sum_{k \in K} p_k \log p_k$ where K is the set of distinct values of a and p_k is the fraction of rows in T for which $a=k$. If table T has no joins, $V(T)$ is the final verbality score of T . Table 3 shows $V(T)$ for each T in Heiskell.

To incorporate connectivity into verbality, we create a matrix of transition probabilities between every pair of nodes in the schema and determine which table maintains the highest information. Let $J \subseteq A$ be the attributes of T that join to other tables. The *information transfer* (IT) over the join $j \in J$ is

$$IT(j) = \frac{H(j)}{V(T) + \sum_{a \in A} q_a H(a)}$$

where q_a is the number of joins in which attribute a participates. Let $P(T, R)$ be the transition probability from table T to table R . For $T \neq R$, $P(T, R)$ is the sum of $IT(j)$ for all joins j between T and R . These

probabilities represent the flow of information between tables over their joins. The diagonal entries of the transition matrix are given by

$$P(T, T) = 1 - \sum_{T \neq R} P(T, R),$$

the information that stays within table T . We then define the *verbality* of table T_i to be the i^{th} element in the stable distribution of a random walk over the $N \times N$ matrix whose elements are $P(T_i, T_j)$ for $i, j \in N$. We follow Yang and colleagues and use power iteration to find the stable distribution.

T	V(T)	Verbality(T)

Table 3. Verbalities of *Heiskell*. $V(T)$ is the verbal information of T . Verbality(T) incorporates connectivity.

Table 3 illustrates the verbalities of *Heiskell* before and after information transfer. *BOOK* clearly dominates. Before information transfer there is more verbal information V in *BOOK* than in the next four tables combined. After information transfer reaches a steady state, its connectivity with other tables increases their verbality, but *BOOK* remains the leading candidate by a large margin. *HEADING*'s verbality decreases sharply after information transfer because of its low connectivity.

The focus discovery module returns a *focal summary*, a list of the top k tables with the highest verbalities. The focal summary is similar to the intensional summary described by Polifroni and Walker (2008), which communicates the contents of a single table to a user. A key difference is that the focal summary pertains to the entire database.

ODDMER is currently limited to the table and attribute labels assigned by the database designer. For example, the Heiskell ‘BOOK’ table was labeled ‘BIBREC’ by the database designers, for Bibliographic Record. We renamed this table prior to its use as a backend for the dialogue system. But ODDMER has no way to determine if labels are meaningful. In many cases there is a disincentive towards meaningful table names to avoid conflicts with SQL keywords. Future work will explore how to infer more meaningful table and attribute labels

from a database instantiation, for example by consulting external knowledge bases to predict the entity a table represents.

3.3 Focus agent generation

Focus discovery fits naturally into an agent-based or agenda-based approach to dialogue management (Bohus & Rudnicky, 2009; Nguyen & Wobcke, 2005). At the onset of a dialogue, ODDMER’s root agent announces the focal summary and prompts the user for her goal. Upon receipt of a user reply, it launches the appropriate *focus agent*, a finite state machine based on Information State Update (Traum & Larsson, 2003), whose parameters are a table, its list of intelligible attributes, and their computed specificity scores. The agent elicits constraints from the user until the current goal is satisfied or the user abandons the focus. Control over the dialogue then returns to the root, which queries the user for a new focus or ends the dialogue. Figure 2 shows a sample dialogue.

1. S: Hello, I can help you find a Book. Would you like to find a Book?
2. U: I'd like a Book.
3. S: Do you know the annotation?
4. U: No.
5. S: Do you know the title?
6. U: It's *Gone with the Wind*

Figure 2. ODDMER’s root agent gives the focal summary ($k=1$) in line 1. The *BOOK* focus agent launches in line 3 and prompts for the value of the most specific intelligible attribute.

The default strategy of the focus agent is to elicit the most specific, intelligible constraints first. While intelligible attributes are more likely to be known by users, they are not equally valuable as item descriptions. As shown in Table 2, the specificities of *NARRATOR*, *PUBLISHER*, and *SERIES* are so low that a strategy involving them will likely lead to inefficient dialogues and unsatisfied users. The focus agent therefore orders its prompts for constraints by their specificity, and requests the most specific attributes first. Because specificity is a function of the database instantiation and not user knowledge, we expect that this strategy will lead to shorter, more efficient dialogues for all users.

The dialogue starts with the root agent in control of the dialogue. The root agent announces the focal summary, the k tables with highest verbality.

Here we let $k=1$. The root agent parses the user's reply to determine the focus of interest and launches the appropriate agent. The agent interacts with the user to find a tuple from the table. Its default strategy elicits constraints from the user in order of semantic specificity. Because semantic specificity can apply to combinations of attributes, future work will investigate tradeoffs between efficiency and user effort in prompts for multiple attributes.

The focus agent queries the database upon receipt of each new constraint. If the return size is small enough (here, a single tuple) it announces the result. Otherwise it continues to elicit constraints until all intelligible attributes have elicited values, at which point it announces all matching results.

ODDMER deals with three goal setbacks: (1) disambiguation, in which a query is under-constrained and matches multiple tuples; (2) over-constrained queries that have no matching tuple; and (3) attributes whose values are unknown to the user. The third setback is particularly prevalent in real-world databases. Our system addresses these setbacks with specific, intelligible vocabulary.

4 Evaluation

ODDMER finds foci and vocabulary for any relational database. We evaluate it on three very different domains. These databases were chosen for their variety, and are not equally suitable for dialogue. Our primary domain of consideration is *Heiskell*, the database of the Heiskell Library. *Heiskell* has eight tables. The largest table is CIRCULATION HISTORY, which contains 16 attributes with 244,072 rows. However, focus discovery identifies BOOK as the top candidate focus, which matches our intuition. Though BOOK is smaller at only 71,166 rows, it has 32 attributes of which seven are classified as intelligible. The classifier finds none of CIRCULATION HISTORY's attributes intelligible. Manual inspection revealed CIRCULATION HISTORY to consist primarily of alphanumeric codes relevant to the library rather than to users.

The second domain we consider is *Grocery*, a small supermarket database used as a teaching tool in an undergraduate class at Hunter College. *Grocery* has 20 tables. Their cardinalities range from 7 to 197 rows. The top focus in *Grocery* represents the products sold in the store. It was the largest table with the greatest connectivity, and makes

intuitive sense; it is the table a supermarket customer would most likely want to talk about.

To challenge our system we consider *Eve*, a freely available database for the virtual game Eve Online, a massively multiplayer online role-playing game with over 400,000 subscribers. *Eve* has 78 tables and the game's active community regularly accesses it to determine in-game goals and objects of interest. *Eve* is a challenge for ODDMER because it primarily contains numeric data for objects in the game world. These numeric attributes are of great interest to players but confound our assumption that dialogue goals correlate with high verbosity. Moreover, connectivity plays no role in table verbosity because *Eve* contains no joins. Focus discovery on *Eve* identifies INV TYPES, a table that represents in-game inventory items, as the best focus, even though vocabulary selection identifies only three of its 15 attributes as intelligible. The 12 unintelligible attributes were all numeric. In general, focus discovery and vocabulary selection proved less effective on *Eve* than on *Heiskell*. In *Eve* the verbosity scores of the top tables were close together without one outstanding focus candidate.

4.1 Simulating the vocabulary problem

A typical evaluation of a spoken dialogue system provides users with all the information needed to carry out a dialogue. Such a *completely knowledgeable* user can unrealistically describe objects in the domain with the same vocabulary that the system uses. This means it does not experience the vocabulary problem. To test vocabulary selection, we simulate users with *incomplete* domain knowledge. In contrast with Selfridge and Heeman (2010), our limited-knowledge users are more likely to know some attributes than others.

User simulation is often used to stand in for real user dialogues, but it is a concern whether the dialogues are sufficiently realistic (Schatzmann, Georgila, & Young, 2005). Here, we use simulation to exercise each dialogue system with a large number of cases in a highly controlled fashion. For simulated users, we can specify exactly what each user knows about the domain, thus simulation makes it possible to hold everything else the same while contrasting users with complete versus incomplete domain knowledge. We view this as a preliminary step towards evaluation with real users, which we hope to do in future work.

	<i>Heiskell</i>	<i>Grocery</i>	<i>Eve</i>

L/V/S	11.3 ± 0.2	9.7 ± 0.1	9.0 ± 0.0

Table 4. Mean dialogue length across domains. C/*/*: complete-knowledge user; L/*/*: incomplete-knowledge user; */N/*: no vocabulary selection; */V/*: with vocabulary selection; */*/R: random order; */*/S: order by specificity. Intervals are 95% confidence.

Our simulated user knows each attribute’s value with a different probability. Ideally we might estimate these probabilities from a language model of a corpus in the domain. Unfortunately our domains contain many obscure names and non-verbal values for which we need non-zero probabilities. Instead, we estimate a probability for attribute value knowledge by calculating the frequency of total value occurrences in a subset of the New York Times portion of the English Gigaword corpus (Parker et al., 2011), a 4 million word corpus of news articles. These frequency values could have been used during vocabulary selection but we chose to reserve them for evaluation.

The probability that the limited-knowledge user knows a particular value is the normalized frequency that the attribute’s values appear in Gigaword. We tokenized attribute values in our databases to remove punctuation and case. We ignored word order so that, for example, the author values “King, Stephen” and “Stephen King” are equivalent. For each value, we counted the articles in which all the value’s tokens co-occurred. For each attribute, we took the sum of these counts over all its values, and took its log to represent the probability that the user knows that attribute. We then normalized by the log of the highest-frequency attribute to enforce our assumption that the user usually knows at least one piece of information about her goal. This method is robust to attributes with missing values. Probabilities for the BOOK attributes were 100% for TITLE, 78% for AUTHOR, 75% for PLACE PUBLISHED, and 73% for PUBLISHER. ISBN has a 0% probability because none of its values occur in the corpus. ANNOTATIONS, whose values are brief plot descriptions of each

book, has a low 37%. Although its values contained many common words, the words in a single annotation rarely co-occurred in one article.

4.2 Testing the impact of domain knowledge

We evaluate dialogue efficiency with two simulated users as measured by number of turns. The first user, C, has complete domain knowledge and always knows every constraint. The second, L, has limited, incomplete domain knowledge. When confronted with the focal summary, the simulated user always chooses the top suggested focus. The dialogue ends when either a single tuple matching the constraints is found, or all constraints have been requested, in which case all matching tuples are announced. We measure average dialogue length of 1000 simulated dialogues for each user with vocabulary selection (V) and without (N), and with prompts ordered randomly (R) or by specificity (S). Table 4 shows the results. ANOVAs of all pairs of comparisons were highly significant.

The longest dialogues for both users occur without vocabulary selection and with prompts in random order (*N/R). The more attributes there are, the longer it takes a random order to achieve a constraint combination that forms a key, so C has long dialogues even though it knows every constraint. L experiences much longer dialogues because it is prompted for inefficient constraints, and is unlikely to know most of them. This difference is particularly noticeable in *Heiskell*. On average, L’s dialogues are ten turns longer.

Ordering prompts by specificity without vocabulary selection (*N/S) yields a sharp increase in efficiency for both users. C’s dialogues achieve the minimum number of turns because it is immediately asked for the most specific constraint, which it always knows. In *Heiskell*, specificity decreases L’s average length from 25.3 to 16.5, a large increase in efficiency but still much worse than C. For *Eve*, L performs better in the absence of vocabulary selection. Specificity alone brings its average efficiency near optimum. This is because for *Eve*’s INV TYPES table, the most specific intelligible attribute is the item’s NAME, which our domain knowledge model predicts L will always know.

Vocabulary selection is more effective than specificity for L on *Heiskell*. L is much more likely to know the selected attributes and its efficiency increases even when prompted for intelligible attributes in a random order. Vocabulary selection is

less effective than specificity for C because C knows every attribute, but in general the intelligible attributes are also more specific, so selection increases C’s efficiency even with random prompts. Vocabulary selection combined with specificity (*/V/S) leads to a small *decrease* in efficiency for C on *Heiskell* over specificity alone. This is because the most specific intelligible attribute is slightly ambiguous, and C must occasionally supply extra constraints to disambiguate. However, with both specificity and vocabulary selection, L achieves a mean dialogue length of 11.3, requiring only two turns more than C to order a book.

For *Eve*, vocabulary selection and order-by-specificity are each effective individually, and yield similar dialogues for both L and C. This is because INV TYPES has only three intelligible attributes, so the dialogue ends after at most three prompts. Our domain knowledge model predicts close to 100% knowledge for two of these.

A comparison of the order-by-specificity strategy used here with the order-by-entropy strategy described by Polifroni and Walker (2006) yielded no significant difference in dialogue length. The two strategies produce similar attribute orders.

5 Conclusion and Open Questions

We have demonstrated an open dialogue management system, ODDMER, which formulates a dialogue strategy by computing *metaknowledge* about its database: table verbosity, attribute intelligibility, and attribute specificity. Candidate dialogue foci are the tables with high verbosity. For each candidate focus, ODDMER chooses an intelligible domain vocabulary and generates a default strategy that orders prompts by specificity. A simulated user facing the vocabulary problem achieves more efficient dialogues with vocabulary selection. Our method works well on the Heiskell Library database, which has a particularly prominent candidate focus showing a clear separation between intelligible and unintelligible attributes. Focus discovery and vocabulary selection are less effective for numeric databases without clear dialogue goals. For example, *Eve*’s top focus scored the highest verbosity, even though the table contained only three intelligible attributes.

Questions that arise from this work include how to extend focus discovery and vocabulary selection to numerical databases, how to extract strategies

for goals other than tuple-selection from a database, and how to automatically infer intelligible table and attribute labels. We are also interested in discovery of less rigid dialogue goals, for example, a library patron who would be satisfied by an alternative book, and goals involving information aggregation where user utterances map to sophisticated queries. We would like to investigate how optimal policies learned through reinforcement learning vary across domains. Future work will also scale to mixed-initiative open dialogue management, explore more sophisticated models of user domain knowledge, and evaluate portability on more databases.

ODDMER uses the semantics of its domain representation to discover what to talk about and how to talk about it. We envision a rich toolkit that enables a system to explore its database for knowledge to exploit in collaborative dialogues with its users.

Abstract

This paper explores the relationship between explicit and predictive models of incremental speech understanding in a dialogue system that supports a finite set of user utterance meanings. We present a method that enables the approximation of explicit understanding using information implicit in a predictive understanding model for the same domain. We show promising performance for this method in a corpus evaluation, and discuss its practical application and annotation costs in relation to some alternative approaches.

1 Introduction

In recent years, there has been a growing interest among researchers in methods for incremental natural language understanding (NLU) for spoken dialogue systems; see e.g. (Skantze and Schlangen, 2009; Sagae et al., 2009; Schlangen et al., 2009; Heintze et al., 2010; DeVault et al., 2011a; Selfridge et al., 2012). This work has generally been motivated by a desire to make dialogue systems more efficient and more natural, by enabling them to provide lower latency responses (Skantze and Schlangen, 2009), human-like feedback such as backchannels that indicate how well the system is understanding user speech (DeVault et al., 2011b; Traum et al., 2012), and more interactive response capabilities such as collaborative completions of user utterances (DeVault et al., 2011a), more adaptive handling of interruptions (Buschmeier et al., 2012), and others.

This paper builds on techniques developed in previous work that has adopted a *predictive* approach to incremental NLU (DeVault et al., 2011a). On this approach, at specific moments while a user’s speech is in progress, an attempt is made to predict what the full meaning of the complete user utterance will be. Predictive models can be contrasted with *explicit* approaches to incremental NLU. We use the term *explicit* understanding to refer

to approaches that attempt to determine the meaning that has been expressed explicitly in the user’s partial utterance so far (without predicting further aspects of meaning to come). Explicit understanding of partial utterances can be implemented using statistical classification or sequential tagging models (Heintze et al., 2010).

Both predictive and explicit incremental NLU capabilities can be valuable in a dialogue system. Prediction can support specific response capabilities, such as system completion of user utterances (DeVault et al., 2011a) and reduced response latency.¹ However, explicit models support additional and complementary capabilities. For instance, depending on the application domain (Heintze et al., 2010) and on the individual utterance (DeVault et al., 2011b), it may be difficult for a system to predict a user’s impending meaning with confidence. Nevertheless, it may often be possible for systems to determine the meaning of what a user has said so far, and to take action based on this partial understanding. As one example, items in a user interface could be highlighted when mentioned by a user (Buß and Schlangen, 2011). Another capability would be to provide grounding feedback, such as verbal back-channels or head nods (in embodied systems), to indicate when the system is understanding the user’s meaning (Traum et al., 2012). Explicit utterance meanings also allow a system to distinguish between meaning that has been expressed and meaning that is merely implied or inferred, which may be less reliable. In the near future, as incremental processing capabilities in dialogue systems grow, it may prove valuable for dialogue systems to combine both predictive and explicit incremental understanding capabilities.

In this paper, we present a technique for approximating a user’s explicit meaning using an existing predictive understanding framework (DeVault et al., 2011a). The specific new contributions in this paper are (1) to show that

¹A simple approach to reducing response latency is to begin to plan a response to the predicted meaning while the user is still speaking.

an estimate of a user’s explicit utterance meaning can be derived from this kind of predictive understanding model (Section 2); (2) to quantify the performance of this new method in a corpus evaluation (Section 3); (3) to provide concrete examples and discussion of the annotation costs associated with implementing this technique, in relation to some alternative approaches to explicit understanding (Section 4). Our results and discussion show that the proposed method offers promising performance, has relatively low annotation costs, and enables explicit and predictive understanding to be easily combined within a dialogue system. It may therefore be a useful incremental understanding technique for some dialogue systems.

2 Technical Approach and Data Set

In Sections 2.1-2.3, we briefly summarize the data set and approach to predictive incremental NLU (DeVault et al., 2011a) that serves as the starting point for the new work in this paper. Sections 2.4 and 2.5 present our new approach to explicit understanding based on this approach.

2.1 Data set

For the experiments reported here, we use a corpus of user utterances collected with the SASO-EN spoken dialogue system (Hartholt et al., 2008; Traum et al., 2008). Briefly, this system is designed to allow a trainee to practice multi-party negotiation skills by engaging in face to face negotiation with virtual humans. The scenario involves a negotiation about the possible re-location of a medical clinic in an Iraqi village. A human trainee plays the role of a US Army captain, and there are two virtual humans that he negotiates with: Doctor Perez, the head of an NGO clinic, and a local village elder, al-Hassan. The captain’s main objective is to convince the doctor and the elder to move the clinic out of an unsafe marketplace area.

The corpus used for the experiments in this paper includes 3,826 training and 449 testing utterances drawn from user dialogues in this domain. The corpus and its semantic annotation are described in (DeVault et al., 2010; DeVault et al., 2011a). All user utterances have been audio recorded, transcribed, and manually annotated with the correct NLU output frame for the entire utterance. (We discuss the cost of this annotation in Section 4.) Each NLU output frame contains a set of attributes and values that represent semantic information linked to a domain-specific ontology and task model (Traum, 2003). Examples of the NLU output frames are included in Figures 2, 3, and 5.

2.2 Predictive incremental NLU

This approach uses a predictive incremental NLU module, mxNLU (Sagae et al., 2009; DeVault et al., 2011a), which is based on maximum entropy classification. The

approach treats entire individual frames as output classes, and extracts input features from partial ASR results. To define the incremental understanding problem, the audio of the utterances in the training data were fed through an ASR module, PocketSphinx (Huggins-Daines et al., 2006), in 200 millisecond chunks, and each partial ASR result produced by the ASR was recorded. Each partial ASR result then serves as an incremental input to mxNLU. NLU is predictive in the sense that, for each partial ASR result, the task of mxNLU is to produce as output the *complete* frame that has been associated by a human annotator with the user’s *complete* utterance, even if that utterance has not yet been fully processed by the ASR.

The human annotation defines a finite set $\mathcal{S} = \{S_1, \dots, S_N\}$ of possible NLU output frames, where each frame $S_i = \{e_1, \dots, e_n\}$ is a set of key-value pairs or *frame elements*. For notation, a user utterance u generally creates a sequence of m partial ASR results $\langle r_1, \dots, r_m \rangle$, where each ASR result r_j is a partial text such as *we need to move*. Let G_u denote the correct (or “gold”) frame for the complete utterance u . For each result r_j and for each complete frame S_i , the maximum entropy model provides $P(G_u = S_i | r_j)$. The NLU output frame S_j^{NLU} is the complete frame for which this probability is highest.

2.3 Performance of predictive incremental NLU

The performance of this predictive incremental NLU framework has been evaluated using the training and test portions of the SASO-EN data set described in Section 2.1. Performance is quantified by looking at precision, recall, and F-score of the frame elements that compose the predicted (S_j^{NLU}) and correct (G_u) frames for each partial ASR result. When evaluated over all the 5,736 partial ASR results for the 449 test utterances, the precision/recall/F-Score of this predictive NLU, in relation to the complete frames, are 0.67/0.47/0.56, respectively. When evaluated on only the ASR results for complete test utterances, these scores increase to 0.81/0.71/0.76, respectively.

2.4 Assigning probability to frame elements

An interesting question is whether we can use this model to attach useful probabilities not only to complete predicted frames but also to the individual frame elements that make up those frames. To explore this, for each partial ASR result r_j in each utterance u , and for each frame element e in SASO-EN, let us model the probability that e will be part of the correct frame for the complete utterance as:

$$P(e \in G_u | r_j) = \sum_{S_i: e \in S_i} P(G_u = S_i | r_j) \quad (1)$$

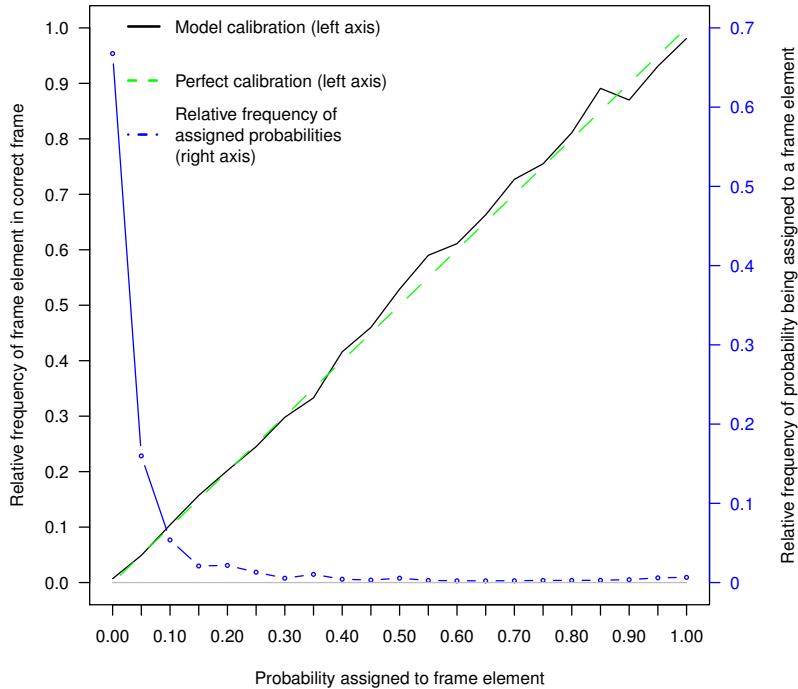

Figure 1: Calibration of frame element probabilities.

This method derives the probability of frame elements from the probabilities assigned to the possible frames that contain them. Computing this sum is straightforward in a finite semantic domain such as SASO-EN.

We computed this probability for all frame elements e and all partial ASR results r_j in our test set, yielding approximately 478,000 probability values. We grouped these probability values into bins of size 0.05, and calculated the frequency with which the frame elements in each bin were indeed present in the correct frame G_u for the relevant utterance u . The results are presented in Figure 1, which shows that the probability values derived from Equation (1) are relatively “well calibrated”, in the sense that the relative frequency with which a frame element is in the final frame is very close to the numeric probability assigned by Equation (1). The figure also shows how frequently the model assigns various probability ranges to frame elements (blue dotted line, plotted against the secondary right axis). Note that most frame elements are assigned very little probability for most partial ASR results.

We conclude from these observations that the probabilities assigned by (1) could indeed carry useful information about the likelihood that individual key values will be present in the complete utterance meaning.

2.5 Selecting probable frame elements

In exploring the model of frame element probabilities given in Equation (1), we observed that often the reason

a frame element has lower probability, at a given point within a user utterance, is that it is a *prediction* rather than something that has been expressed explicitly. Building on this observation, our technique for estimating the user’s explicit meaning uses a probability threshold to select those individual frame elements which are most likely to be in the frame for a complete utterance, according to the predictive model. That is, at each partial result r_j , we estimate the user’s explicit meaning using a constructed frame:

$$S_j^{\text{SUB}} = \{e | P(e \in G_u | r_j) \geq \tau\} \quad (2)$$

This approximation could work well if, in practice, the most probable frame elements prove to match fairly closely the user’s non-incremental utterance meaning at the point this frame is constructed. We evaluate this in the next section.

Note that, in general, the returned subset of frame elements may not be identical to any complete frame $S_i \in \mathcal{S}$; rather it will correspond to parts of these complete frames or “subframes”.

3 Performance Evaluation

To evaluate this technique, we constructed subsets of frame elements or “explicit subframes” using Equation (2) and various minimum probability thresholds τ for partial ASR results in our test set. We then compared the resulting subframes both to the final complete frame G_u for each utterance u , and also to manually annotated sub-

Explicit subframe (with frame element probabilities)	Predicted complete frame	Annotated subframe
Partial ASR result: <i>hello</i> 0.813 <S>.sem.speechact.type greeting	<S>.sem.speechact.type greeting <S>.addressee doctor-perez	<S>.sem.speechact.type greeting
Partial ASR result: <i>hello elder</i> 0.945 <S>.sem.speechact.type greeting 0.934 <S>.addressee elder-al-hassan	<S>.sem.speechact.type greeting <S>.addressee elder-al-hassan	<S>.sem.speechact.type greeting <S>.addressee elder-al-hassan

Figure 2: Explicit subframes and predicted complete frames for two partial ASR results in a user utterance of *hello elder*.

frames that represent human judgments of explicit incremental utterance meaning.

To collect these judgments, we hand-annotated a word-meaning alignment for 50 random utterances in our test set.² To perform this annotation, successively larger prefixes of each utterance transcript were mapped to successively larger subframes of the full frame for the complete utterance. The annotated subframes for each utterance prefix were selected to be *explicit*; they include only those frame elements that are explicitly expressed in the corresponding prefix of the user’s utterance. (We discuss the cost of this annotation in Section 4.)

We provide a simple concrete example in Figure 2. This example shows two partial ASR results during an utterance of *hello elder* by a user. For each partial ASR result, three frames are indicated horizontally. At the right, labeled “Annotated subframe”, we show the human judgment of explicit incremental utterance meaning for this partial utterance. Our human judge has indicated that the word *hello* corresponds to the frame element <S>.sem.speechact.type greeting, and that the words *hello elder* correspond to an expanded frame that includes the frame element <S>.addressee elder-al-hassan.

At the left, labeled “Explicit subframe”, we show the subframe selected by Equation (2) for each partial ASR result, with threshold $\tau = 0.5$. A relevant background fact for this example is that in this scenario, the user can generally address either of two virtual humans who are present, Doctor Perez or Elder Al-Hassan. After the user has said *hello*, the frame element <S>.sem.speechact.type greeting is assigned probability 0.813 by Equation (1), and only this frame element appears in the explicit subframe.

In the middle, labeled “Predicted complete frame”, the figure also shows the full predicted frame from mxNLU at each point. After the user has said *hello*, the full predicted output includes an additional frame element, <S>.addressee doctor-perez, indicating a prediction that the addressee of this user utterance will be Doctor Perez rather than Elder al-Hassan. However, the

probability assigned to this prediction by Equation (1) is less than 0.5, and so this predicted frame element is excluded from the explicit subframe. And indeed, this is the correct *explicit* representation of the meaning of *hello* in this system.

This simple example illustrates how our proposed technique can enable a dialogue system to have access to both explicit and predicted utterance meaning as a user’s utterance progresses. An excerpt from a more complex utterance is given in Figure 3. This example shows incremental outputs for two partial ASR results during a user utterance of *we will provide transportation at no cost*. In this example, the explicit subframe for *we will* includes frame elements that convey that the captain (i.e. the user) is promising to do something. This subframe does not exactly match the human judgment of explicit meaning at the right, which does not include at this point the <S>.sem.agent captain-kirk and <S>.sem.type event frame elements. However, the explicit subframe more closely matches the human judgment than does the predicted complete frame from mxNLU (middle column), which includes an incorrect prediction that the captain is promising to deliver medical supplies (represented by the key values <S>.sem.event deliver and <S>.sem.theme medical-supplies). For the next partial ASR result shown in the figure, the explicit subframe correctly adds several additional frame elements which formalize the meaning of the phrase *provide transportation* in this scenario as having the army move the clinic out of the market area.

To understand more quantitatively how well this technique works, we evaluated this technique in the SASO-EN test corpus, using different probability thresholds in the range [0.5,1.0). We present the results in Figure 4. To understand the effect of the threshold τ , note that, in general, the effect of selecting a higher threshold should be to “cherry pick” those frame elements which are most likely to appear in the complete frame G_u , thereby increasing precision while decreasing recall of the frame elements in S_j^{SUB} in relation to G_u . In the figure, we can see that this is indeed the case. The lines marked “(complete frame)”

²Note that no utterances in our *training* set were annotated.

Explicit subframe (with frame element probabilities)	Predicted complete frame	Annotated subframe
Partial ASR result: <i>we will</i> 0.856 <S>.mood declarative 0.824 <S>.sem.agent captain-kirk 0.663 <S>.sem.modal.intention will 0.663 <S>.sem.speechact.type promise 0.776 <S>.sem.type event	<S>.mood declarative <S>.sem.agent captain-kirk <S>.sem.event deliver <S>.sem.modal.intention will <S>.sem.speechact.type promise <S>.sem.theme medical-supplies <S>.sem.type event	<S>.mood declarative <S>.sem.modal.intention will <S>.sem.speechact.type promise
Partial ASR result: <i>we will provide transportation</i> 0.991 <S>.mood declarative 0.990 <S>.sem.agent captain-kirk 0.927 <S>.sem.event move 0.905 <S>.sem.instrument us-army 0.964 <S>.sem.modal.intention will 0.927 <S>.sem.source market 0.964 <S>.sem.speechact.type promise 0.928 <S>.sem.theme clinic 0.989 <S>.sem.type event	<S>.mood declarative <S>.sem.agent captain-kirk <S>.sem.event move <S>.sem.instrument us-army <S>.sem.modal.intention will <S>.sem.source market <S>.sem.speechact.type promise <S>.sem.theme clinic <S>.sem.type event	<S>.mood declarative <S>.sem.agent captain-kirk <S>.sem.event move <S>.sem.instrument us-army <S>.sem.modal.intention will <S>.sem.source market <S>.sem.speechact.type promise <S>.sem.theme clinic <S>.sem.type event

Figure 3: Explicit subframes and predicted complete frames for two partial ASR results in a user utterance of *we will provide transportation at no cost*.

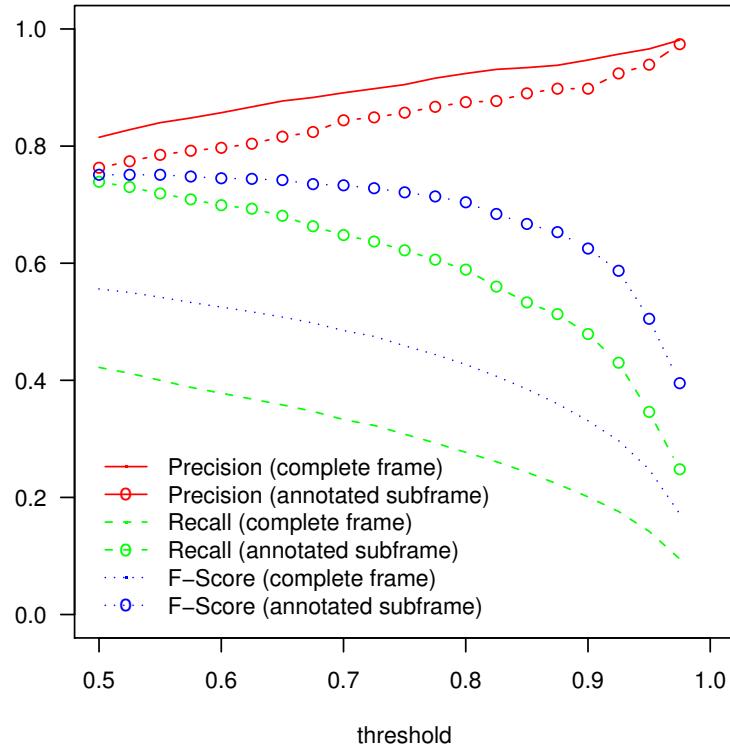

Figure 4: The effect of threshold on precision, recall, and F-Score of explicit subframes. All scores are measured in relation to complete utterance frames and annotated subframes.

in the figure evaluate the returned subframes in relation to the complete frame G_u associated with the user’s *complete* utterance. We see that this method enables us to select subsets of frame elements that are most likely to appear in G_u : by increasing the threshold, it is possible to return subframes which are of increasingly higher precision in relation to the final frame G_u , but that also have lower recall.

We also evaluated the returned subframes in relation to the hand-annotated subframes, to assess its performance at identifying the user’s explicit meaning. For an utterance u that generates partial ASR results $\langle r_1, \dots, r_m \rangle$, we denote the hand-annotated subframe corresponding to partial ASR result r_j by G_j^{SUB} . In the lines marked “(annotated subframe)”, we show the precision, recall, and F-score of the explicit subframe for each ASR result r_j in relation to the annotated subframe G_j^{SUB} .

As a first observation, note that at any threshold level, the explicit subframes do better at recalling the hand-annotated subframe elements than they do at recalling the complete frame elements. This means our new method is better at recalling what has been said already by the user than it is at predicting what will be said, as intended. We have seen two examples of this already, for the partial ASR result *hello* in Figure 2, and for the partial ASR result *we will* in Figure 3.

A second observation in Figure 4 is that precision remains better against the complete utterance frame than against the hand-annotated subframe (at all threshold levels). This indicates that the explicit subframes are often still predicting some aspects of the full frame. An example of this is given in Figure 5, where the user’s partial utterance *we need to* is assigned an explicit subframe that includes frame elements describing an event of moving the clinic, which the user has not said explicitly. This happens because, in the SASO-EN domain, in fact there is nothing else that the interlocutors need to do besides move the clinic. So based on the NLU training data, the data-driven probabilities assigned by Equation (1) describe the additional frame elements as about as probable as the ones capturing the *we need to* part of the semantics (given at the right).

Finally, a third observation is that overall, the precision, recall, and F-score results against the annotated subframes using our method are surprisingly strong. For example, when evaluating the explicit subframes over all partial ASR results, an F-score of 0.75 is attained at thresholds in the range 0.5-0.55. This F-score is substantially better than the F-score of our predictive NLU in relation to the final full frames, which is 0.56 when evaluated over all partial ASR results. This means that our proposed model works better as an explicit incremental NLU than mxNLU works as a predictive incremental NLU. Further, we observe that this F-score of

0.75 against hand-annotated subframes is approximately as good as the F-score of 0.76 that is achieved when mxNLU is used to interpret complete utterances. We therefore conclude that the proposed model is a promising and viable approach to explicit incremental NLU in SASO-EN.

4 Discussion and Related Approaches

In this section, we discuss some of the practical aspects of using the technique presented here, in relation to some alternative approaches.

An important consideration for NLU techniques is the cost, in both time and knowledge, of the annotation that is needed. One attractive aspect of our technique is that the only semantic annotation that is required is the association of complete user utterances with complete NLU output frames. This task can be performed by anyone familiar with the scenario and the semantic frame format, such as a system developer or scenario designer. In fact, the annotation of the SASO-EN data set we use in this paper has been described in (DeVault et al., 2010), which reports that the overall corpus of 4678 token utterances was semantically annotated at an average rate of about 10 seconds per unique utterance.

The model in Equation (2) is what (Heintze et al., 2010) call a *hybrid output* approach, in which larger and larger frames are provided as partial input grows, but in which a detailed alignment between surface text and frames is not provided by the incremental NLU component. They contrast hybrid output systems with techniques that deliver either *whole-frame output* (like the predictive mxNLU) or *aligned output* that connects individual words to their meanings. A data-driven approach to providing aligned outputs would involve preparing a more detailed annotated corpus that aligns individual words and surface expressions to their corresponding frame elements. Given such a word-aligned corpus, one could train several kinds of models to produce the aligned outputs incrementally. One strategy would be to use a sequential tagging model such as a CRF to tag partial utterances with the frame elements that capture their explicit meaning, as in (Heintze et al., 2010).

Using a machine learning approach that models a more detailed alignment between surface text and frames would be one way to more cleanly separate explicit from predictive aspects of meaning. Preparing the training data for such models, however, would create additional annotation costs. As part of creating the annotated subframes for the evaluation presented in Section 3, we measured the time requirement for such annotation of word-meaning alignments at about 30 seconds per unique utterance. Performing full word-meaning alignment therefore takes about three times as much time as the complete utterance annotation needed for our technique. Ad-

Explicit subframe (with frame element probabilities)	Predicted complete frame	Annotated subframe
Partial ASR result: we 0.753 <S>.mood declarative 0.687 <S>.sem.agent captain-kirk 0.692 <S>.sem.type event	<S>.mood declarative <S>.sem.agent captain-kirk <S>.sem.event deliver <S>.sem.modal.possibility can <S>.sem.speechact.type offer <S>.sem.theme medical-supplies <S>.sem.type event	
Partial ASR result: we need to 0.945 <S>.mood declarative 0.928 <S>.sem.agent captain-kirk 0.900 <S>.sem.event move 0.816 <S>.sem.modal.deontic must 0.900 <S>.sem.source market 0.900 <S>.sem.speechact.type statement 0.906 <S>.sem.theme clinic 0.930 <S>.sem.type event	<S>.mood declarative <S>.sem.agent captain-kirk <S>.sem.event move <S>.sem.modal.deontic must <S>.sem.source market <S>.sem.speechact.type statement <S>.sem.theme clinic <S>.sem.type event	<S>.mood declarative <S>.sem.modal.deontic must <S>.sem.speechact.type statement

Figure 5: Explicit subframes and predicted complete frames for two partial ASR results in a user utterance of *we need to move the clinic*.

ditionally, this task requires a greater degree of linguistic knowledge and sophistication, as the annotator must be able to segment the utterance and align specific surface segments with potentially complex aspects of meaning such as modality, polarity, speech act types, and others. An example of the kinds of complexities that arise is illustrated in Figure 3, where the relationship between specific words like “provide” and “transportation” to frame elements like $\langle S \rangle.\text{sem.event move}$ and $\langle S \rangle.\text{sem.theme clinic}$ is not transparent, even if it is straightforward to mark the whole utterance as conveying that meaning in this domain. We have generally found this alignment task challenging for people without advanced linguistics training.

The reason we describe the method in this paper as an *approximation* of explicit NLU is that, partly because it is trained without detailed word-meaning alignments, it can be expected to occasionally include some predictive aspects of user utterance meaning. An example of this is the method’s explicit subframe output for the phrase *we need to* in Figure 5.

Another way to approximate explicit NLU would be using the method (Heintze et al., 2010) call an *ensemble of classifiers*; it involves training an individual classifier for each frame key. Like the method presented here, an ensemble of classifiers can be easily trained to predict those frame elements that will appear in the *final* frame G_u for each utterance. And like our method, prediction with an ensemble of classifiers does not require detailed annotation of word-meaning alignment in the training data. One difference is that, with our method, by selecting an appropriate threshold, it is easy to enforce certain consistency properties on subframe outputs. In an ensemble of classifiers approach, there is no immediate

guarantee that the output frame constructed by the independent classifiers will be internally consistent from the standpoint of downstream system modules (Heintze et al., 2010). For example, in the SASO-EN domain, an NLU frame should not contain frame elements that mix aspects of events and states in the SASO-EN ontology; e.g., the frame element $\langle S \rangle.\text{sem.type event}$ should not co-occur in an NLU output frame with the frame element $\langle S \rangle.\text{sem.object-id market}$ (which would be appropriate for a state frame but not for an event frame). With the method proposed here, if we select a threshold τ that is greater than 0.5, and if none of the complete NLU frames contain incompatible key values (which is relatively easy to enforce as part of the annotation task), then it will be mathematically impossible for two incompatible frame elements to be returned in a subframe.³

Ultimately, a classification method that is trained on word-meaning aligned data and that uses additional techniques to ensure that only valid, grammatical output frames are produced could prove to be an attractive approach. In future work, we will explore such techniques, and compare both their performance as well as their annotation and development costs to the approximation technique presented here.

5 Conclusion

The analysis in this paper has explored a method of approximating explicit incremental NLU using predictive

³Suppose frame element e_i is incompatible with e_j , and that $P(e_i \in G_u | r_j) > 0.5$. By stipulation, no complete frame $S \in \mathcal{S}$ such that $e_i \in S$ will also contain e_j . Since we know that the total probability of all the frames containing e_i must be greater than 0.5 in order for e_i to be selected, we can infer that the total probability of all frames including e_j must be less than 0.5, and thus that e_j will not be selected.

techniques in finite semantic domains. We have shown that an estimate of a user’s explicit utterance meaning can be derived from an existing predictive understanding model in an example domain. We have quantified the performance of this new method in a corpus evaluation, showing that the method returns incremental explicit subframes with performance – as measured by precision, recall, and F-Score against hand-annotated subframes – that is competitive with a current statistical, data-driven approach for understanding complete spoken utterances in the same domain. We have provided examples that illustrate its strengths and weaknesses, and discussed the annotation costs associated with implementing this technique in relation to some alternative approaches. The method requires no additional annotation beyond what is needed for training an NLU module to understand complete spoken utterances. (Hand annotation of word-meaning alignment for a small number of utterances may be performed in order to tune the selected threshold and evaluate explicit understanding performance.) The method provides a free parameter that can be used to target the most advantageous levels of precision and recall for a particular dialogue system application. In future work, we will explore additional machine learning models that leverage richer training data, and investigate further the combination of explicit and predictive techniques.

Paving the Way to a Large-scale Pseudosense-annotated Dataset

Mohammad Taher Pilehvar and Roberto Navigli

Abstract

In this paper we propose a new approach to the generation of pseudowords, i.e., artificial words which model real polysemous words. Our approach simultaneously addresses the two important issues that hamper the generation of large pseudosense-annotated datasets: semantic awareness and coverage. We evaluate these pseudowords from three different perspectives showing that they can be used as reliable substitutes for their real counterparts.

1 Introduction

A fundamental problem in computational linguistics is the paucity of manually annotated data, such as part-of-speech tagged sentences, treebanks, and logical forms, which exist only for few languages (Ide et al., 2010). A case in point is the lack of abundant sense annotated data, which hampers the performance and coverage of lexical semantic tasks such as Word Sense Disambiguation (Navigli, 2009; Navigli, 2012, WSD) and semantic role labeling (Gildea and Jurafsky, 2002). A possible way to break this bottleneck is to use pseudowords, i.e., artificial words constructed by conflating a set of unambiguous words, with the aim of modeling polysemy in real ambiguous words. The idea of pseudowords was originally proposed by Gale et al. (1992) and Schütze (1992) for WSD evaluation, but later found application in other tasks such as selectional preferences (Erk, 2007; Bergsma et al., 2008; Chambers and Jurafsky, 2010), Word Sense Induction (Bordag, 2006; Di Marco and Navigli, 2013) or studies

concerning the effects of the amount of data on machine learning for natural language disambiguation (Banko and Brill, 2001). Being made up of monosemous words, pseudowords can potentially be used to create large amounts of pseudosense-annotated data at virtually no cost, hence enabling large-scale studies in lexical semantics. Unfortunately, though, the extent of their usability for such a purpose is hampered by two main issues: semantic awareness and wide coverage.

Semantic awareness corresponds to the constraint that pseudowords, in order to be realistic, are expected to have senses which are in a semantic relationship (thus modeling systematic polysemy). Recent work has focused on this issue and, by exploiting either specific lexical hierarchies (Nakov and Hearst, 2003; Lu et al., 2006), or the WordNet structure (Otrusina and Smrz, 2010), have succeeded in generating pseudowords which are comparable to real words in terms of disambiguation difficulty. The second challenge is coverage, which corresponds to the number of distinct pseudowords an algorithm can generate. When coupled with the semantic awareness issue, wide coverage is hampered by the difficulty in generating thousands of pseudowords which mimic existing polysemous words.

Unfortunately, none of the existing approaches to the generation of pseudowords can meet both these challenges simultaneously, and this has hindered the generation of a large pseudosense-annotated dataset. For instance, approaches which exploit the monosemous neighbors of a target sense in WordNet (Otrusina and Smrz, 2010) can be used to generate pseudowords with good semantic awareness, but

they have low coverage of ambiguous nouns when many pseudosense-tagged sentences are needed (cf. Section 2.1.1).

In this paper we propose a new approach, based on Personalized PageRank, which simultaneously addresses the two above-mentioned issues concerning the generation of pseudowords (i.e., semantic awareness and coverage), and hence enables the generation of large-scale pseudosense-annotated datasets. We perform three different experiments to show that our pseudowords are good at modeling existing ambiguous words in terms of disambiguation difficulty, representativeness of real senses and distinguishability of the artificial senses. As a byproduct of this work, we generate a large dataset that provides 1000 tagged sentences for each of the 15,935 pseudowords modeled after real ambiguous nouns in WordNet 3.0.

2 Pseudowords

A pseudoword $p = w_1 * w_2 * \dots * w_n$ is an artificially-generated ambiguous word of polysemy degree n which is usually created by conflating n unique unambiguous words w_i called pseudosenses. For instance, *airplane*river* is a pseudoword with two meanings explicitly identified by its pseudosenses: *airplane* and *river*. Pseudowords are particularly interesting as they can be used to introduce controlled artificial ambiguity into a corpus. Given a pseudoword p and an untagged corpus C , this artificial tagging is achieved by substituting all occurrences of w_i in C with p for each pseudosense $i \in \{1, \dots, n\}$. As a result, each occurrence of the pseudoword p is tagged with the underlying sense w_i . As an example, consider the following two sentences:

- a1. The Wright brothers invented the *airplane*.
- a2. The Nile is the longest *river* in the world.

If we replace the individual occurrences of *airplane* and *river* with the pseudoword *airplane*river* while noting the replaced term as the corresponding sense, we obtain the following pseudosense-tagged sentences:

- b1. The Wright brothers invented the *airplane*river*.
- b2. The Nile is the longest *airplane*river* in the world.

As a result of this procedure, we obtain a corpus of sentences containing the occurrences of an artificially ambiguous word p , for each of which we know its correct sense annotation w_i . Virtually any number of pseudowords can be created, resulting in a large pseudosense-annotated corpus. An obvious restriction on the choice of pseudosenses is that they need to be unambiguous, so as to avoid the introduction of uncontrolled ambiguity. Another constraint is that the constituent w_i must satisfy a minimum occurrence frequency in the corpus C . This minimum frequency corresponds to the number of annotated sentences that are requested for the task of interest which will exploit the resulting annotated corpus.

An immediate way of generating a pseudoword would be to randomly select its constituents from the set of all monosemous words given by a lexicon (e.g., WordNet). However, constructing a pseudoword by merely combining a random set of unambiguous words selected on the basis of their falling in the same range of occurrence frequency (Schütze, 1992), or leveraging homophones and OCR ambiguities (Yarowsky, 1993), does not provide a suitable model of a real polysemous word (Gaustad, 2001; Nakov and Hearst, 2003). This is because in the real world different senses, unless they are homonymous, share some semantic or pragmatic relation. Therefore, random pseudowords will typically model only homonymous distinctions (such as the *centimeter* vs. *curium* senses of *cm*), while they will fall short of modeling systematic polysemy (such as the *lack* vs. *insufficiency* senses of *deficiency*).

2.1 Semantically-aware Pseudowords

In order to cope with the above-mentioned limits of random pseudowords, an artificial word has to model an existing word by providing a one-to-one correspondence between each pseudosense and a corresponding sense of the modeled word. For instance, the pseudoword *lack*shortfall* is a good model of the real word *deficiency* in that its pseudosenses preserve the meanings of their corresponding real word's senses. We call this kind of artificial words semantically-aware pseudowords.

In the next two subsections, we will describe two techniques (the second of which is presented for the first time in this paper) for the generation of

Minimum Frequency	Polysemy												Overall
	2	3	4	5	6	7	8	9	10	11	12	>12	
0	87	82	74	71	67	70	60	64	45	46	44	28	83
500	41	31	24	15	12	13	10	7	7	0	0	0	35
1000	31	20	16	7	4	6	4	3	0	0	0	0	25

Table 1: Ambiguous noun coverage percentage of vicinity-based pseudowords by degree of polysemy for different values of minimum pseudosense occurrence frequency in Gigaword.

semantically-aware pseudowords. In what follows we focus on nominal pseudowords, and leave the extension to other parts of speech to future work.

2.1.1 Vicinity-based Pseudowords

A computational lexicon such as WordNet (Fellbaum, 1998) can be used as the basis for the automatic generation of semantically-aware pseudowords, an idea which was first proposed by Otrusina and Smrz (2010). WordNet can be viewed as a graph in which synsets act as nodes and the lexical and semantic relationships among them as edges. Given a sense, the approach looks into its surrounding synsets in the WordNet graph in order to find a related monosemous term that can represent that sense. As search space, the approach considers: the other literals in the same synset, the genus phrase from its textual definition, direct siblings, and direct hyponyms. If no monosemous candidate can be found, this space is further extended to hypernyms and meronyms. Hereafter, we term this approach as vicinity-based.

For example, consider the generation process of the vicinity-based pseudoword corresponding to the term *coke*, which has three senses in WordNet 3.0. There exist multiple monosemous candidates for each sense: dozens of candidates (such as *biomass* and *butane*) in the direct siblings' vicinity of the first sense, *coca_cola*, *pepsi*, and *pepsi_cola* for the second sense, and *nose_candy* and *coca_cola* for the third sense. Among these candidates Otrusina and Smrz (2010) select those whose occurrence frequency ratio in a given text corpus is most similar to that of the senses of the corresponding real word as given by a sense-annotated corpus. Clearly, a sufficiently large sense-tagged corpus is required for calculating the occurrence frequency of the individual senses of a word. This is a limitation of the vicinity-based approach.

In addition, as we mentioned earlier, we need pseudowords that can enable the generation of large-scale pseudosense-tagged corpora. For this to be achieved, each pseudosense is required to occur with a relatively high frequency in a given text corpus. The vicinity-based approach can, however, identify at best only a few representatives for each pseudosense, thus undermining its ability to cover many ambiguous nouns. Table 1 shows the percentage of ambiguous nouns in WordNet that can be modeled using the vicinity-based approach when different minimum numbers of annotated sentences are requested, i.e. each pseudosense is required to occur in at least 0 (i.e., no minimum frequency restriction), 500, or 1000 unique sentences in the reference corpus (we use Gigaword (Graff and Cieri, 2003) in our experiments). In the Table, beside the overall coverage percentage, we present the coverage by degree of polysemy and for three different values of minimum pseudosense occurrence frequency. Even though the overall coverage is over 80% when no restriction on minimum frequency is considered (first row in the Table), this high coverage drops rapidly when we request some hundred sentences per sense. For instance, only 25% of the ambiguous nouns in WordNet can be modeled using this approach when a minimum frequency of 1000 noun occurrences is required (last row of Table 1), with most of the covered words having low polysemy (in fact about 93% of them are either 2- or 3-sense nouns). This severe limitation of the vicinity-based approach hinders a wide-coverage modeling of ambiguous nouns in WordNet, thus preventing it from being an option for the generation of a large-scale pseudosense-annotated dataset.

With a view to addressing the above-mentioned issues and to enable wide coverage, in the next subsection we propose a flexible approach for the generation of semantically-aware pseudowords.

2.1.2 Similarity-based Pseudowords

The vicinity-based pseudoword generation approach works on local subgraphs of WordNet, considering mostly all those candidates which are in a direct relationship with a real sense s_i , and treating them as potentially good representatives of s_i . We propose an extension to this approach which exploits the WordNet semantic network in its entirety, hence enabling us to determine a graded degree of similarity between s_i and all the senses of all other words in WordNet.

We chose a graph-based similarity measure for two reasons: firstly, it comes as a natural extension of the vicinity-based method, and, secondly, alternative context-based methods such as Lin’s measure (Lin, 1998) have been shown to require a wide-coverage sense-tagged dataset in order to calculate similarities on a sense-by-sense basis for all words in the lexicon (Otrusina and Smrz, 2010). As our similarity measure we selected the Personalized PageRank (Haveliwala, 2002, PPR) algorithm. PPR basically computes the probability according to which a random walker at a specific node in a graph would visit an arbitrary node in the same graph. The algorithm estimates, for a specific node in a graph, a probability distribution (called PPR vector) which determines the importance of any given node in the graph for that specific node. When applied to a semantic graph, this importance can be interpreted as semantic similarity. PPR has previously been used as a core component for semantic similarity¹ (Hughes and Ramage, 2007; Agirre et al., 2009) and Word Sense Disambiguation (Agirre and Soroa, 2009).

Algorithm 1 shows the procedure for the generation of our similarity-based pseudowords. The algorithm takes an ambiguous word w as input, and outputs its corresponding similarity-based pseudoword P_w whose i^{th} pseudosense models the i^{th} sense of w , together with a confidence score which we detail below.

Given w , the algorithm iterates over the synsets corresponding to its individual senses (lines 4-13) and finds the most suitable pseudosenses for P_w . For

¹Top-ranking synsets will contain words which are most likely similar to the target sense, whereas we move to a graded notion of relatedness as far as lower-ranking ones are concerned (Agirre et al., 2009).

Algorithm 1 Generate a similarity-based pseudoword

Input: an ambiguous word w in WordNet
Output: a “similarity-based” pseudoword P_w
 a confidence score $averageRank$

```

1:  $P_w \leftarrow \emptyset$ 
2:  $totalRank \leftarrow 0$ 
3:  $i \leftarrow 1$ 
4: for each  $s \in Synsets(w)$ 
5:    $similarSynsets \leftarrow PersonalizedPageRank(s)$ 
6:   sort  $similarSynsets$  in descending order
7:   for each  $s' \in similarSynsets$ 
8:      $totalRank \leftarrow totalRank + 1$ 
9:     for each  $w' \in SynsetLiterals(s')$ 
10:    if  $|Synsets(w')|=1 \& Freq(w') > minFreq$  then
11:       $P_w \leftarrow P_w \cup \{(i, w')\}$ 
12:      break
13:     $i \leftarrow i + 1$ 
14:   $averageRank \leftarrow totalRank / |Synsets(w)|$ 
15: return  $(P_w, averageRank)$ 
```

each synset s of w , we start the PPR algorithm from s (line 5) and collect the probability distribution vector output by PPR ($similarSynsets$ in the algorithm), which determines the probability of reaching each synset in WordNet starting from s . We then sort this vector (line 6) and check if each of its nominal synsets (s') contains a monosemous word (line 10). This search continues until a suitable candidate is found that satisfies a certain minimum occurrence frequency $minFreq$. When this occurs, the selected monosemous candidate w' is saved as the corresponding pseudosense for the i^{th} sense of P_w (line 11). We iterate these steps for all synsets of w .

In line 14 we calculate the $averageRank$, a value given by the average of synset positions in the $similarSynsets$ lists from which the pseudosenses of P_w are picked out. We later use this value as a confidence score while evaluating our pseudowords. Finally, the algorithm returns the corresponding pseudoword P_w along with its $averageRank$ score (line 15). We show in Table 2 some examples of ambiguous words together with their similarity-based pseudowords.

Thanks to the large search space of our similarity-based approach, we are always able to select a monosemous candidate for each pseudosense, thus resolving the coverage issue regarding vicinity-based pseudowords. A question that arises here is that of how often our algorithm needs to resort to lower-ranking items in the $similarSynsets$ list. To

Table 2: Similarity-based pseudowords generated for six different nouns in WordNet 3.0 (with minimum frequency of 1000 occurrences in Gigaword). Pseudosenses which could not be modeled using the vicinity-based approach are shown in bold.

verify this, we analyzed the *averageRank* values output by Algorithm 1. Table 3 shows for each polysemy degree and for three different values of *minFreq*, the mean and mode statistics of the *averageRank* scores of the generated similarity-based pseudowords for all the 15,935 polysemous nouns in WordNet 3.0. As expected, the higher the number of required sentences per pseudosense (*minFreq*), the further the algorithm descends through the list *similarSynsets* to select a pseudosense. However, as can be seen from the mode statistics in the Table, even when *minFreq* is set to a large value, most of the pseudosenses are picked from the highest-ranking positions in the *similarSynsets* list.

3 Evaluation

Our novel similarity-based algorithm for the generation of pseudowords inherently tackles the coverage issue. To test whether our generated pseudowords also cope with the issue of semantic awareness we carried out three separate evaluations so as to assess their strength in modeling semantic properties of their corresponding real senses from different perspectives. These will be described in the next three subsections. Since our aim was to leverage pseudowords for the creation of a large-scale pseudosense-annotated dataset, we performed evaluations on pseudowords generated with *minFreq* per pseudosense set to 1000 (i.e., we can generate at least 1000 annotated sentences for each pseudosense).

<i>minFreq</i>	0		500		1000		
	poly.	mean	mode	mean	mode	mean	mode
2	2.0	1.0	14.8	2.0	25.4	4.0	
3	2.3	1.7	13.4	2.7	21.0	5.5	
4	2.3	1.8	12.3	5.8	19.8	6.8	
5	2.3	1.8	12.9	5.6	20.0	10.0	
6	2.4	2.0	13.7	4.5	18.7	8.8	
7	2.3	2.1	11.5	6.3	16.0	6.1	
8	2.2	1.8	11.3	9.6	17.2	10.8	
9	2.4	2.0	10.7	10.9	15.6	15.1	
10	2.2	2.0	10.1	7.0	14.3	12.1	
11	2.4	2.1	10.2	7.1	14.2	17.3	
12	2.5	2.4	11.0	4.4	14.4	14.4	
>12	2.6	1.0	9.3	2.0	13.7	4.0	
overall	2.1	1.0	14.1	2.0	23.4	4.0	

Table 3: Statistics of *averageRank* scores for the full set of 15,935 similarity-based pseudowords modeled after ambiguous nouns in WordNet 3.0: we show mean and mode statistics for three different values of minimum occurrence frequency (0, 500, and 1000). We show the average value in the case of multiple modes.

3.1 Disambiguation Difficulty of Pseudowords

Our first experiment is an extrinsic evaluation of pseudowords. Ideally, pseudowords are expected to show a similar degree of difficulty to real ambiguous words in a disambiguation task (Otrusina and Smrz, 2010; Lu et al., 2006). We thus experimentally tested this assumption on similarity-based and random pseudowords. Given its low coverage, we excluded the vicinity-based approach from this experiment.

Starting from a sense-tagged lexical sample dataset for a set of ambiguous nouns, for each such noun and for each kind of pseudoword, we automatically generated a pseudosense-annotated dataset by enforcing the same sense distribution as the corresponding real ambiguous noun. This constraint was particularly important for random pseudowords since they do not model the corresponding real ambiguous words (see Section 2). An analysis was then performed to compare the disambiguation performance of a supervised WSD system on a given ambiguous word against its corresponding pseudoword.

Specifically, for our manually sense-tagged corpus we used the Senseval-3 English lexical sample dataset (Mihalcea et al., 2004), which contains 3593 and 1807 sense-tagged sentences for 20 ambiguous nouns (with an average polysemy degree of 5.8) in its training and test sets, respectively. We generated,

with $\minFreq = 1000$, the similarity-based pseudowords corresponding to these 20 nouns, as well as a set of 20 random pseudowords with the same polysemy degrees. We note that, in this setting, the vicinity-based approach could only generate pseudowords corresponding to 5 of the 20 nouns.

In order to create the datasets for our experiments, for each of our similarity-based and random pseudowords, we sampled unique sentences from the English Gigaword corpus (Graff and Cieri, 2003) according to the same sense distributions given by the Senseval-3 training and test datasets for the corresponding real word. Next, we performed WSD on our three datasets, namely: the Senseval-3 dataset of real words, and the two artificially sense-tagged datasets for the similarity-based and random pseudowords. As our WSD system for this experiment, we used It Makes Sense (IMS), a state-of-the-art supervised WSD system (Zhong and Ng, 2010).

WSD recall² performance values on the above-mentioned datasets are shown in Table 4. For the random setting, in order to ensure stability, the results are averaged on a set of 25 different pseudowords modeling a given ambiguous noun. We can see from the Table that the overall system performance with the similarity-based pseudowords (75.14%) is much closer to the real setting (73.26%) than it is with random pseudowords (78.80%). For random pseudowords, the overall recall over 25 runs ranges from 75.40% to 80.80%.

Moreover, the similarity-based approach exhibits a closer WSD recall performance to that of real data ($|RE-SB|$ column in the table) for 15 of the 20 nouns (shown in bold in the Table). Accordingly, the overall sum of the differences (distance) between the recall values is 129.3 for similarity-based pseudowords, which is considerably lower than the 196.4 for random pseudowords (averaged over 25 runs whose distances range from 158.3 to 262.0).

To further corroborate our findings, we calculated the Pearson’s r correlation between recall values on real words with those obtained on the corresponding pseudowords. Similarity-based pseudowords obtain the high correlation of 0.74, whereas this value drops to 0.54 for random pseudowords. Even worse, we

²Since in our experiments the WSD system always provides an answer for each item in the test set, the values of precision, recall and $F1$ will be equal.

observed a high variation of correlation (in the range of [0.18, 0.67]) over the 25 sets of random pseudowords (0.54 being the average).

3.2 Representative Power of Pseudosenses

The ideal case for pseudosenses would be that of being in a synonymous relationship with the corresponding real sense, i.e., selected from the same WordNet synset. But given that many of the WordNet synsets do not contain monosemous terms, the similarity-based approach often needs to look further into other related synsets to find a suitable pseudosense. To get a clear idea of the exact statistics, we went through all our similarity-based pseudowords and, for each pseudosense w_i , checked the relationship in WordNet between the synset containing w_i and the corresponding real sense. Table 5 shows for three values of \minFreq the distribution of pseudosenses across different types of WordNet relationships, also including indirect ones. As can be seen in the Table, when \minFreq is set to 0, a large portion of pseudosenses (around 75%) are selected from synonyms or generalization/specialization relations

	<i>minFreq</i>	0	500	1000
Relation type				
Synonyms		33.0	7.6	5.4
Hypernyms		33.4	16.1	13.0
Hyponyms		9.1	6.1	4.9
Meronyms		0.2	0.2	0.2
Siblings		8.2	17.2	16.6
Indirect relations		16.1	52.8	59.9

Table 5: Percentage of similarity-based pseudosenses obtained from different types of WordNet relations.

(hypernym and hyponyms). However, this percentage drops to about 23% when $minFreq = 1000$. This suggests that many of our pseudosenses are modeled from indirect relations when higher values of $minFreq$ are used. This can potentially increase the risk of an undesirable modeling in which meanings are not properly preserved. For this reason, we carried out another experiment to assess the representative power of similarity-based pseudosenses. To this end, we randomly sampled 110 pseudowords (from the entire set of 15,935 pseudowords generated with minimum frequency of 1000), 10 for each degree of polysemy, from 2 to 12, totaling 770 pseudosenses. Then we presented each of these pseudowords³ to two annotators who were asked to judge the degree of representativeness of its pseudosenses based on the following scores: 1: completely unrelated, 2: somewhat related, 3: good substitute, or 4: perfect substitute.

As an example, the scores assigned by the two annotators to different pseudosenses of the pseudoword generated for the noun *representative* are shown in Table 6. The overall representativeness score for each pseudoword is calculated by averaging the scores assigned to its individual pseudosenses. For instance, the overall scores calculated for the pseudoword *representative* are 3.75 and 3.50 (as given by the two annotators). The first row in Table 7 shows the average representativeness scores for each degree of polysemy on the full set of 770 pseudosenses. It can be seen that the score remains around 3.0 for all polysemy degrees from 2 to 12. Despite the fact that only one fifth of pseudosenses are taken from synonyms, hypernyms and hyponyms (when $minFreq$ is 1000, cf. Table 5), the overall

³For each pseudoword, we provided annotators with the corresponding real word, as well as its synsets and glosses as given by WordNet.

<i>Sense Definition (in short)</i>	<i>Score 1</i>	<i>Score 2</i>
{Synset}		
> Corresponding Pseudosense		
<i>a person who represents others</i>	3	3
{representative}		
> negotiator		
<i>an advocate who represents someone else's policy</i>	4	4
{spokesperson, interpreter, representative, voice}		
> spokesperson		
<i>a member of the U.S. House of Representatives</i>	4	4
{congressman, congresswoman, representative}		
> congressman		
<i>an item of information that is typical of a group</i>	4	3
{example, illustration, instance, representative}		
> case_in_point		
average score	3.75	3.50

Table 6: Examples of representativeness scores assigned by the annotators to pseudosenses of the term *representative*.

representativeness score of 3.12 shows that most of these pseudosenses can be considered as good substitutes for their corresponding real senses. Therefore we conclude that not only does our similarity-based pseudoword generation approach extend the coverage of the vicinity-based method from 25% to 100% (when $minFreq = 1000$), but also that the pseudosenses coming from more distant synsets as ranked by PPR are still good representatives on average.

3.3 Distinguishability of Pseudosenses

In addition to assessing the representativeness of pseudosenses, their degree of distinguishability has to be determined. In other words, we have to determine how easily each pseudosense can be distinguished from the others in a pseudoword. Our reason for having such an experiment is readily illustrated by way of an example: consider the similarity-based pseudoword *philanthropist*benefactor*⁴ corresponding to the noun *donor*⁵. Even though both pseudosenses are good representatives for their corresponding senses, the distinguishability of the two

⁴From WordNet: “Philanthropist: someone who makes charitable donations intended to increase human well-being”; “Benefactor: a person who helps people or institutions (especially with financial help)”.

⁵*donor* has 2 senses according to WordNet 3.0: (1) “person who makes a gift of property”; (2) “(medicine) someone who gives blood or tissue or an organ to be used in another person”.

Polysemy	2	3	4	5	6	7	8	9	10	11	12	Overall
Representativeness score	3.3	3.4	3.1	3.1	2.9	3.1	2.9	2.8	3.3	3.1	3.3	3.12
Distinguishability score	0.90	0.83	0.83	0.82	0.81	0.77	0.75	0.73	0.80	0.71	0.70	0.79

Table 7: Average representativeness and distinguishability scores for pseudosenses of different polysemy classes (scores range from 1 to 4 for representativeness and from 0 to 1 for distinguishability evaluation).

real senses is not preserved in the pseudoword. For instance, *benefactor* is a suitable pseudosense for both senses of *donor*, whereas *philanthropist* cannot be used in the blood donation sense.

Therefore we carried out another manual evaluation to test the efficacy of pseudowords in preserving the distinguishability of senses of real words. To this end, for each pseudoword P_w (from the same set of 110 sampled pseudowords used in Section 3.2) we presented its corresponding pseudosenses in random order to two annotators and asked them to associate each pseudosense with the most appropriate WordNet sense of the real word w . Then we calculated a distinguishability score for each polysemy degree by dividing the number of correct mappings by the total number of senses.

For instance, for the similarity-based pseudoword corresponding to the word *representative* (shown in Table 6), we provided the shuffled list of pseudosenses [*spokesperson*, *case_in_point*, *negotiator*, *congressman*] to each annotator and asked them to sort the list according to the WordNet sense inventory of *representative* (i.e., map each pseudosense to its most suitable real sense). Both annotators correctly mapped all pseudosenses of this pseudoword; hence, the distinguishability score given by each annotator for this pseudoword was $4/4 = 1$.

The average distinguishability scores for each degree of polysemy, as well as the overall score, is shown in Table 7 (second row). Each value is an average of the scores obtained from the two annotators. It can be seen that the distinguishability score decreases for higher degrees of polysemy. The score, however, remains above 0.70 with highly-polysemous pseudowords. The overall score of 0.79 shows that similarity-based pseudowords effectively preserve the distinguishability of senses of their real counterparts. In other words, they do not tend to have over-generalized pseudosenses which cover more than one sense.

4 Related Work

The idea of pseudowords dates back to 1992, when it was first proposed as a means of generating large amounts of artificially annotated evaluation data for WSD algorithms (Gale et al., 1992; Schütze, 1992). However, as mentioned earlier in Section 2, constructing a pseudoword by combining a random set of unambiguous words, as was done in these early works, can not model systematic polysemy (Gaus-tad, 2001; Nakov and Hearst, 2003), since different senses of a real ambiguous word, unless it is homonymous, share some semantic or pragmatic relation.

Several researchers addressed the issue of producing semantically-aware pseudowords that can model semantic relationships between senses. Nakov and Hearst (2003) used lexical category membership from a medical term hierarchy (extracted from MeSH⁶ (Medical Subject Headings)) to create “more plausibly-motivated” pseudowords. By considering the frequency distributions from lexical category co-occurrence, they produced a set of pseudowords which were closer to real ambiguous words in terms of disambiguation difficulty than random pseudowords. However, this approach requires a specific hierarchical lexicon and falls short of creating many pseudowords with high polysemy (the authors report generating pseudowords with two senses only).

More recent work has focused on the identification of monosemous representatives in the surrounding of a sense, i.e., selected among concepts directly related to the given sense. Lu et al. (2006) modeled senses of a real ambiguous word by picking out the most similar monosemous morpheme from a Chinese hierarchical lexicon. Pseudowords are then constructed by conflating these morphemes accordingly. However, this method leverages a specific Chinese hierarchical lexicon, in which different lev-

⁶<http://www.nlm.nih.gov/mesh>

els of the hierarchy correspond to different levels of sense granularity. A more flexible technique is proposed by Otrusina and Smrz (2010) who model ambiguous words in WordNet. Their vicinity-based approach searches the surroundings of each particular sense in the WordNet graph in order to find an unambiguous representative for that sense. However, as we described in Section 2.1.1, while the approach addresses the semantic awareness issue, it falls short of providing a high coverage, an issue which we tackle in our novel similarity-based approach.

5 Conclusion and Future Work

In this paper we proposed a new technique for the generation of pseudowords which, in contrast to existing work, can simultaneously tackle the two major issues associated with pseudowords, i.e., semantic awareness and coverage. Our approach can be used to model any given ambiguous noun in WordNet, hence enabling the generation of large-scale pseudosense-annotated datasets for thousands of pseudowords. We performed three experiments to evaluate the reliability of our pseudowords. We showed that the similarity-based pseudowords are highly correlated with their real counterparts in terms of disambiguation difficulty. Further evaluations demonstrated that this approach is able to provide a good semantic modeling of individual senses of real words while preserving their distinguishability.

We are releasing to the research community the entire set of 15,935 pseudowords, i.e., for all WordNet polysemous nouns (<http://lcl.uniroma1.it/pseudowords/>). This set of pseudowords (together with the English Gigaword corpus) can be used to generate a large pseudosense-tagged dataset containing ≥ 1000 annotated sentences for every sense of all the pseudowords modeled after real ambiguous nouns in WordNet. The resulting dataset could be a good complement for MASC (Ide et al., 2010) which, being human-created, can provide 1000 sense-annotated sentences for just a few words.

We hope that the availability of this resource will enable large-scale experiments in tasks such as semantic role labeling, semantic parsing, and Word Sense Disambiguation. Specifically, as future work,

we plan to utilize the generated pseudosense-tagged dataset to perform an in-depth study of different WSD paradigms. We also plan to extend our work to other part-of-speech tags.

Abstract

In this paper we consider the problem of labeling the languages of words in mixed-language documents. This problem is approached in a weakly supervised fashion, as a sequence labeling problem with monolingual text samples for training data. Among the approaches evaluated, a conditional random field model trained with generalized expectation criteria was the most accurate and performed consistently as the amount of training data was varied.

1 Introduction

Language identification is a well-studied problem (Hughes et al., 2006), but it is typically only studied in its canonical text-classification formulation, identifying a document’s language given sample texts from a few different languages. But there are several other interesting and useful formulations of the problem that have received relatively little attention. Here, we focus on the problem of labeling the languages of individual words within a multilingual document. To our knowledge, this is the first paper to specifically address this problem.

Our own motivation for studying this problem stems from issues encountered while attempting to build language resources for minority languages. In trying to extend parts of Kevin Scannell’s Crúbadán project (Scannell, 2007), which automatically builds minority language corpora from the Web, we found that the majority of webpages that contain text in a minority language also contain text in other languages. Since Scannell’s method builds these cor-

pora by bootstrapping from the pages that were retrieved, the corpus-building process can go disastrously wrong without accounting for this problem. And any resources, such as a lexicon, created from the corpus will also be incorrect.

In this paper, we explore techniques for performing language identification at the word level in mixed language documents. Our results show that one can do better than independent word language classification, as there are clues in a word’s context: words of one language are frequently surrounded by words in the same language, and many documents have patterns that may be marked by the presence of certain words or punctuation. The methods in this paper also outperform sentence-level language identification, which is too coarse to capture most of the shifts between language.

To evaluate our methods, we collected and manually annotated a corpus of over 250,000 words of bilingual (though mostly non-parallel) text from the web. After running several different weakly-supervised learning methods, we found that a conditional random field model trained with generalized expectation criteria is the most accurate and performs quite consistently as the amount of training data is varied.

In section 2, we review the related work. In section 3, we define the task and describe the data and its annotation. Because the task of language identification for individual words has not been explicitly studied in the literature, and because of its importance to the overall task, we examine the features and methods that work best for independent word language identification in section 4. We begin to ex-

amine the larger problem of labeling the language of words in context in section 5 by describing our methods. In section 6, we describe the evaluation and present the results. We present our error analysis in section 7 and conclude in section 8.

2 Related Work

Language identification is one of the older NLP problems (Beesley, 1988), especially in regards to spoken language (House and Neuburg, 1977), and has received a fair share of attention through the years (Hughes et al., 2006). In its standard formulation, language identification assumes monolingual documents and attempts to classify each document according to its language from some closed set of known languages.

Many approaches have been proposed, such as Markov models (Dunning, 1994), Monte Carlo methods (Poutsma, 2002), and more recently support vector machines with string kernels, but nearly all approaches use the n -gram features first suggested by (Cavnar and Trenkle, 1994). Performance of language identification is generally very high with large documents, usually in excess of 99% accuracy, but Xia et al. (2009) mention that current methods still can perform quite poorly when the class of potential languages is very large or the texts to be classified are very short.

This paper attempts to address three of the ongoing issues specifically mentioned by Hughes et al. (2006) in their survey of textual language identification: supporting minority languages, sparse or impoverished training data, and multilingual documents.

A number of methods have been proposed in recent years to apply to the problems of unsupervised and weakly-supervised learning. Excluding self- and co-training methods, these methods can be categorized into two broad classes: those which bootstrap from a small number of tokens (sometimes called prototypes) (Collins and Singer, 1999; Haghighi and Klein, 2006), and those which impose constraints on the underlying unsupervised learning problem (Chang et al., 2007; Bellare et al., 2009; Druck et al., 2008; Ganchev et al., 2010).

Constraint-based weakly supervised learning has been applied to some sequence labeling problems,

through such methods as contrastive estimation (Smith and Eisner, 2005), generalized expectation criteria (Mann and McCallum, 2008), alternating projections (Singh et al., 2010), and posterior regularization (Ganchev et al., 2010).

Perhaps the work that is most similar to this work is the study of *code-switching* within NLP literature. Most of the work done has been on automatically identifying code-switch points (Joshi, 1982; Solorio and Liu, 2008). The problem of identifying language in the presence of code-switching has seen the most attention in the realm of speech processing (Chu et al., 2007; Lyu and Lyu, 2008), among many others. Though code-switching has been well-studied linguistically, it is only one possible reason to explain why a document contains multiple languages, and is actually one of the less common causes observed in our corpus. For that reason, we approach this problem more generally, assuming no specific generative process behind multilingual text.

3 Task Definition

The task we describe in this paper is a sequence labeling problem, labeling a word in running text according to the language to which it belongs. In the interest of being able to produce reliable human annotations, we limit ourselves to texts with exactly two languages represented, though the techniques developed in this paper would certainly be applicable to documents with more than two languages. The two languages represented in the paper are known *a priori* by the labeler and the only training data available to the labeler is a small amount of sample text in each of the two languages represented.

In most NLP sequence labeling problems, the researchers can safely assume that each sequence (but not each item in the sequence) is independent and identically distributed (*iid*) according to some underlying distribution common to all the documents. For example, it is safe to assume that a sentence drawn from WSJ section 23 can be labeled by a model trained on the other sections. With the task of this paper we cannot assume that sequences from different documents are *iid*, (e.g. One document may have 90% of its words in Basque, while another only has 20%), but we do make the simplifying as-

sumption that sequences within the same document are *iid*.

Because of this difference, the labeler is presented each document separately and must label its words independently of any other document. And the training data for this task is not in the form of labeled sequences. Rather, the models in this task are given two monolingual example texts which are used only to learn a model for individual instances. Any sequential dependencies between words must be bootstrapped from the document. It is this aspect of the problem that makes it well-suited for weakly-supervised learning.

It is worth considering whether this problem is best approached at the word level, or if perhaps sentence- or paragraph-level language identification would suffice for this task. In those cases, we could easily segment the text at the sentence or paragraph level and feed those segments to an existing language identifier. To answer this question we segmented our corpus into sentences by splitting at every period, exclamation point, or question mark (an overly aggressive approximation of sentence segmentation). Even if every sentence was given the correct majority label under this sentence segmentation, the maximum possible word-level accuracy that a sentence-level classifier could achieve is 85.8%, and even though this number reflects quite optimistic conditions, it is still much lower than the methods of this paper are able to achieve.

3.1 Evaluation Data

To build a corpus of mixed language documents, we used the BootCat tool (Baroni and Bernardini, 2004) seeded with words from a minority language. BootCat is designed to automatically collect webpages on a specific topic by repeatedly searching for keywords from a topic-specific set of seed words. We found that this method works equally well for languages as for topics, when seeded with words from a specific language. Once BootCat returned a collection of documents, we manually identified documents from the set that contained text in both the target language and in English, but did not contain text in any other languages. Since the problem becomes trivial when the languages do not share a character set, we limited ourselves to languages with a Latin orthography.

Table 1: Languages present in the corpus and their number of words before separating out English text.

We found that there was an important balance to be struck concerning the popularity of a language. If a language is not spoken widely enough, then there is little chance of finding any text in that language on the Web. Conversely if a language is too widely spoken, then it is difficult to find mixed-language pages for it. The list of languages present in the corpus and the number of words in each language reflects this balance as seen in Table 1.

For researchers who wish to make use of this data, the set of annotations used in this paper is available from the first author’s website¹.

3.2 Annotation

Before the human annotators were presented with the mixed-language documents fetched by BootCat, the documents were first stripped of all HTML markup, converted to Unicode, and had HTML escape sequences replaced with the proper Unicode characters. Documents that had any encoding errors (*e.g.* original page used a mixture of encodings) were excluded from the corpus.

Table 2: An example of text from an annotated English-Sotho web page.

Since there are many different reasons that the language in a document may change (*e.g.* code-switching, change of authors, borrowing) and many variations thereof, we attempted to create a broad set of annotation rules that would cover many cases, rather than writing a large number of very specific rules. In cases when the language use was ambiguous, the annotators were instructed simply to make their best guess. Table 2 shows an example of an annotated document.

Generally, only well-digested English loanwords and borrowings were to be marked as belonging to the foreign language. If a word appeared in the context of both languages, it was permissible for that word to receive different labels at different times, depending on its context.

Ordinary proper names (like “John Williams” or “Chicago”) were to be marked as belonging to the language of the context in which they appear. This rule also applied to abbreviations (like “FIFA” or “BBC”). The exception to this rule was proper names composed of common nouns (like “Stairway to Heaven” or “American Red Cross”) and to abbreviations that spelled out English words, which were to be marked as belonging to the language of the words they were composed of.

The annotators were instructed not to assign labels to numbers or punctuation, but they were allowed to use numbers as punctuation as clues for assigning other labels.

3.3 Human Agreement

To verify that the annotation rules were reasonable and led to a problem that could potentially be solved by a computer, we had each of the annotators mark

up a small shared set of a few hundred words from each of eight documents, in order to measure the inter-annotator agreement.

The average actual agreement was 0.988, with 0.5 agreement expected by chance for a kappa of 0.975.

3.4 Training Data

Following Scannell (2007), we collected small monolingual samples of 643 languages from four sources: the Universal Declaration of Human Rights², non-English Wikipedias³, the Jehovah’s Witnesses website⁴, and the Rosetta project (Landsbergen, 1989).

Only 30 of these languages ended up being used in experiments. Table 3 shows the sizes of the monolingual samples of the languages used in this paper.

²The Universal Declaration of Human Rights is a document created by the United Nations and translated into many languages. As of February 2011 there were 365 versions available from <http://www.unicode.org/udhr/>

³As of February 2011, there were 113 Wikipedias in different languages. Current versions of Wikipedia can be accessed from http://meta.wikimedia.org/wiki/List_of_Wikipedias

⁴As of February 2011, there were 310 versions of the site available at <http://www.watchtower.org>

They range from 92 for Chippewa to 16469 for English. Most of the languages have between 1300 and 1600 words in their example text. To attempt to mitigate variation caused by the sizes of these language samples, we sample an equal number of words with replacement from each of English and a second language to create the training data.

4 Word-level Language Classification

We shift our attention momentarily to a subproblem of the overall task: independent word-level language classification. While the task of language identification has been studied extensively at the document, sentence, and query level, little or no work has been done at the level of an individual word. For this reason, we feel it is prudent to formally evaluate the features and classifiers which perform most effectively at the task of word language classification (ignoring any sequential dependencies at this point).

4.1 Features

We used a logistic regression classifier to experiment with combinations of the following features: character unigrams, bigrams, trigrams, 4-grams, 5-grams, and the full word. For these experiments, the training data consisted of 1000 words sampled uniformly with replacement from the sample text in the appropriate languages. Table 4 shows the accuracies that the classifier achieved when using different sets of features averaged over 10 independent runs.

Features	Accuracy
Unigrams	0.8056
Bigrams	0.8783
Trigrams	0.8491
4-grams	0.7846
5-grams	0.6977
{1,2,3,4,5}-grams	0.8817
{1,2,3,4,5}-grams, word	0.8819

Table 4: Logistic regression accuracy when trained using varying features.

The use of all available features seems to be the best option, and we use the full set of features in all proceeding experiments. This result also concurs with the findings of (Cavnar and Trenkle, 1994), who

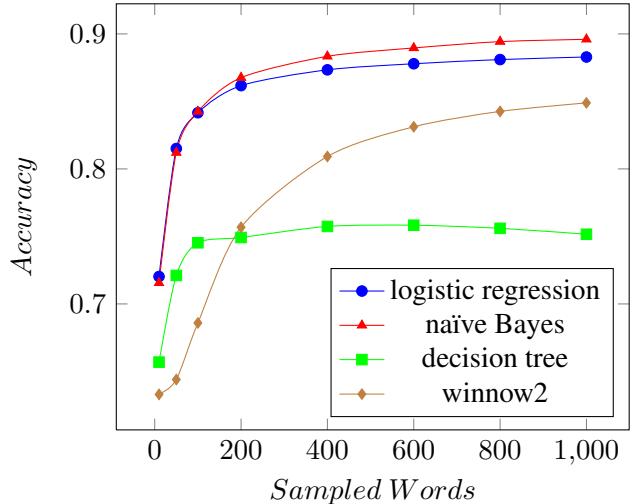

Figure 1: Learning curves for logistic regression, naïve Bayes, decision tree, and Winnow2 on the independent word classification problem as the number of sampled words in each training example changes from 10 to 1000.

found 1-5-grams to be most effective for document language classification.

4.2 Classifiers

Using all available features, we compare four Mallet (McCallum, 2002) classifiers: logistic regression, naïve Bayes, decision tree, and Winnow2. Figure 1 shows the learning curves for each classifier as the number of sampled words comprising each training example is varied from 10 to 1000.

Since a naïve Bayes classifier gave the best performance in most experiments, we use naïve Bayes as a representative word classifier for the rest of the paper.

5 Methods

Moving onto the main task of this paper, labeling *sequences* of words in documents according to their languages, we use this section to describe our methods.

Since training data for this task is limited and is of a different type than the evaluation data (labeled instances from monolingual example texts *vs.* labeled sequences from the multilingual document), we approach the problem with weakly- and semi-supervised methods.

The sequence labeling methods are presented with a few new sequence-relevant features, which are not applicable to independent word classification (since these features do not appear in the training data):

- a feature for the presence of each possible non-word character (punctuation or digit) between the previous and the current words
- a feature for the presence of each possible non-word character between the current and next words

In addition to independent word classification, which was covered in section 4, we also implement a conditional random field model trained with generalized expectation criteria, a hidden Markov model (HMM) trained with expectation maximization (EM), and a logistic regression model trained with generalized expectation criteria.

We had also considered that a semi-Markov CRF (Sarawagi and Cohen, 2004) could be useful if we could model segment lengths (a non-Markovian feature), but we found that gold-standard segment lengths did not seem to be distributed according to any canonical distribution, and we did not have a reliable way to estimate these segment lengths.

5.1 Conditional Random Field Model trained with Generalized Expectation

Generalized expectation (GE) criteria (Druck et al., 2008) are terms added to the objective function of a learning algorithm which specify preferences for the learned model. When the model is a linear chain conditional random field (CRF) model, we can straightforwardly express these criteria in the objective function with a KL-divergence term between the expected values of the current model \tilde{p} and the preferred model \hat{p} (Mann and McCallum, 2008).

$$\mathcal{O}(\theta; D, U) = \sum_d \log p_\theta(y^{(d)}|x^{(d)}) - \frac{\sum_k \theta_k}{2\sigma^2} - \lambda D(\hat{p}||\tilde{p}_\theta)$$

Practically, to compute these expectations, we produce the smoothed MLE on the output label distribution for every feature observed in the training

data. For example, the trigram “ter” may occur 27 times in the English sample text and 34 times in the other sample text, leading to an MLE of $\hat{p}(\text{eng}|ter) \approx 0.44$.

Because we do not expect the true marginal label distribution to be uniform (*i.e.* the document may not have equal numbers of words in each language), we first estimate the expected marginal label distribution by classifying each word in the document independently using naïve Bayes and taking the resulting counts of labels produced by the classifier as an MLE estimate for it: $\hat{p}(\text{eng})$ and $\hat{p}(\text{non})$.

We use these terms to bias the expected label distributions over each feature. Let \mathcal{F}_{eng} and \mathcal{F}_{non} respectively be the collections of all training data features with the two labels. For every label $l \in \mathcal{L} = \{\text{eng}, \text{non}\}$ and every feature $f \in \mathcal{F}_{\text{eng}} \cup \mathcal{F}_{\text{non}}$, we calculate

$$p(l|f) = \frac{\text{count}(f, \mathcal{F}_l) + \delta}{\text{count}(f, \bigcup_i \mathcal{F}_i) + \delta |\mathcal{L}|} \times \frac{\hat{p}(l)}{p_{\text{uniform}}(l)},$$

the biased maximum likelihood expected output label distribution. To avoid having $p(l|f) = 0$, which can cause the KL-divergence to be undefined, we perform additive smoothing with $\delta = 0.5$ on the counts before multiplying with the biasing term.

We use the implementation of CRF with GE criteria from MALLET (McCallum, 2002), which uses a gradient descent algorithm to optimize the objective function. (Mann and McCallum, 2008; Druck, 2011)

5.2 Hidden Markov Model trained with Expectation Maximization

A second method we used was a hidden Markov model (HMM) trained iteratively using the Expectation Maximization algorithm (Dempster et al., 1977). Here an HMM is preferable to a CRF because it is a generative model and therefore uses parameters with simple interpretations. In the case of an HMM, it is easy to estimate emission and transition probabilities using an external method and then set these directly.

To initialize the HMM, we use a uniform distribution for transition probabilities, and produce the emission probabilities by using a naïve Bayes classifier trained over the two small language samples.

In the expectation step, we simply pass the document through the HMM and record the labels it produces for each word in the document.

In the maximization step, we produce maximum-likelihood estimates for transition probabilities from the transitions between the labels produced. To estimate emission probabilities, we retrain a naïve Bayes classifier on the small language samples along the set of words from the document that were labeled as being in the respective language. We iterated this process until convergence, which usually took fewer than 10 iterations.

We additionally experimented with a naïve Bayes classifier trained by EM in the same fashion, except that it had no transition probabilities to update. This classifier’s performance was almost identical to that of the GE-trained MaxEnt method mentioned in the following section, so we omit it from the results and analysis for that reason.

5.3 Logistic Regression trained with Generalized Expectation

GE criteria can also be straightforwardly applied to the weakly supervised training of logistic regression models. The special case where the constraints specified are over marginal label distributions, is called *label regularization*.

As with the CRF constraint creation, here we first use an ordinary supervised naïve Bayes classifier in order to estimate the marginal label distributions for the document, which can be used to create more accurate output label expectations that are biased to the marginal label distributions over all words in the document.

We use the MALLET implementation of a GE-trained logistic regression classifier, which optimizes the objective function using a gradient descent algorithm.

5.4 Word-level Classification

Our fourth method served as a baseline and did not involve any sequence labeling, only independent classification of words. Since naïve Bayes was the best performer among word classification methods, we use that the representative of independent word classification methods. The implementation of the naïve Bayes classifier is from MALLET.

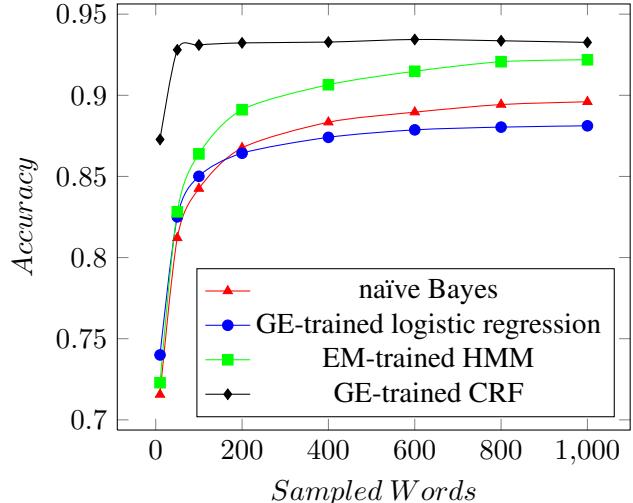

Figure 2: Learning curves for naïve Bayes, logistic regression trained with GE, HMM trained with EM, and CRF trained with GE as the number of sampled words in each training example changes from 10 to 1000.

We also implemented a self-trained CRF, initially trained on the output of this naïve Bayes classifier, and trained on its own output in subsequent iterations. This method was not able to consistently outperform the naïve Bayes classifier after any number of iterations.

6 Evaluation and Results

We evaluated each method using simple token-level accuracy, *i.e.* whether the correct label was assigned to a word in the document. Word boundaries were defined by punctuation or whitespace, and no tokens containing a digit were included. Figure 2 displays the accuracy for each method as the number of sampled words from each language example is varied from 10 to 1000.

In all the cases we tested, CRF trained with GE is clearly the most accurate option among the methods examined, though the EM-trained HMM seemed to be approaching a similar accuracy with large amounts of training data. With a slight edge in efficiency also in its favor, we think the GE+CRF approach, rather than EM+HMM, is the best approach for this problem because of its consistent performance across a wide range of training data sizes. In its favor, the EM+HMM approach has a slightly

lower variance in its performance across different files, though not at a statistically significant level.

Contrary to most of the results in (Mann and McCallum, 2010), a logistic regression classifier trained with GE did not outperform a standard supervised naïve Bayes classifier. We suspect that this is due to the different nature of this problem as compared to most other sequence labeling problems, with the classifier bootstrapping over a single document only. In the problems studied by Mann and McCallum, the GE-trained classifier was able to train over the entire training set, which was on average about 50,000 instances, far more than the number of words in the average document in this set (2,500).

7 Error Analysis

In order to analyze the types of mistakes that the models made we performed an error analysis on ten randomly selected files, looking at each mislabeled word and classifying the error according to its type. The results of this analysis are in Table 5. The three classes of errors are (1) named entity errors, when a named entity is given a label that does not match the label it was given in the original annotation, (2) shared word errors, when a word that could belong to either language is classified incorrectly, and (3) other, a case that covers all other types of errors.

Method	NE	SW	Other
GE+CRF	41%	10%	49%
EM+HMM	50%	14%	35%
GE+MaxEnt	37%	12%	51%
Naïve Bayes	42%	17%	40%

Table 5: Types of errors and their proportions among the different methods. NE stands for Named Entity, SW stands for Shared Word, and Other covers all other types of errors.

Our annotation rules for named entities specified that named entities should be given a label matching their context, but this was rather arbitrary, and not explicitly followed by any of the methods, which treat a named entity as if it was any other token. This was the one of most frequent types of error made by each of the methods and in our conclusion in section 8, we discuss ways to improve it.

In a regression analysis to determine which factors had the greatest correlations with the GE-trained CRF performance, the estimated proportion of named entities in the document had by far the greatest correlation with CRF accuracy of anything we measured. Following that in decreasing order of correlation strength were the cosine similarity between English and the document’s second language, the number of words in the monolingual example text (even though we sampled from it), and the average length of gold-standard monolingual sequences in the document.

The learning curve for GE-trained CRF in Figure 2 is somewhat atypical as far as most machine learning methods are concerned: performance is typically non-decreasing as more training data is made available.

We believe that the model is becoming over-constrained as more words are used to create the constraints. The GE method does not have a way to specify that some of the soft constraints (for the labels observed most frequently in the sample text) should be more important than other constraints (those observed less frequently). When we measure the KL-divergence between the label distributions predicted by the constraints and the true label distribution, we find that this divergence seems to reach its minimum value between 600 and 800 words, which is where the GE+CRF also seems to reach its maximum performance.

The step with a naïve Bayes classifier estimating the marginal label distribution ended up being quite important overall. Without it, the accuracy dropped by more than a full percentage point absolute. But the problem of inaccurate constraint estimation is one that needs further consideration. Some possible ways to address it may be to prune the constraints according to their frequency or perhaps according to a metric like entropy, or to vary the GE-criteria coefficient in the objective function in order to penalize the model less for varying from the expected model.

8 Conclusion

This paper addresses three of the ongoing issues specifically mentioned by Hughes et al. (2006) in their survey of textual language identification. Our approach is able to *support minority languages*; in

fact, almost all of the languages we tested on would be considered minority languages. We also address the issue of *sparse or impoverished training data*. Because we use weakly-supervised methods, we are able to successfully learn to recognize a language with as few as 10 words of training data⁵. The last and most obvious point we address is that of *multilingual documents*, which is the focus of the paper.

We present a weakly-supervised system for identifying the languages of individual words in mixed-language documents. We found that across a broad range of training data sizes, a CRF model trained with GE criteria is an accurate sequence classifier and is preferable to other methods for several reasons.

One major issue to be improved upon in future work is how named entities are handled. A straightforward way to approach this may be to create another label for named entities, which (for the purposes of evaluation) would be considered not to belong to any of the languages in the document. We could simply choose not to evaluate a system on the named entity tokens in a document. Alternatively, the problem of language-independent named entity recognition has received some attention in the past (Tjong Kim Sang and De Meulder, 2003), and it may be beneficial to incorporate such a system in a robust word-level language identification system.

Going forward, an issue that needs to be addressed with this method is its dependence on knowing the set of possible languages *a priori*. Because we don't see an easy way to adapt this method to accurately label words in documents from a possible set of thousands of languages when the document itself may only contain two or three languages, we would propose the following future work.

We propose a two-step approach to general word-level language identification. The first step would be to examine a multilingual document, and with high accuracy, list the languages that are present in the document. The second step would be identical to the approach described in this paper (but with the two-language restriction lifted), and would be responsible for labeling the languages of individual words, using the set of languages provided by the first step.

⁵With only 10 words of each language as training data, the CRF approach correctly labels 88% of words

Abstract

Non-expert annotation services like Amazon’s Mechanical Turk (AMT) are cheap and fast ways to evaluate systems and provide categorical annotations for training data. Unfortunately, some annotators choose bad labels in order to maximize their pay. Manual identification is tedious, so we experiment with an item-response model. It learns in an unsupervised fashion to a) identify which annotators are trustworthy and b) predict the correct underlying labels. We match performance of more complex state-of-the-art systems and perform well even under adversarial conditions. We show considerable improvements over standard baselines, both for predicted label accuracy and trustworthiness estimates. The latter can be further improved by introducing a prior on model parameters and using Variational Bayes inference. Additionally, we can achieve even higher accuracy by focusing on the instances our model is most confident in (trading in some recall), and by incorporating annotated control instances. Our system, MACE (Multi-Annotator Competence Estimation), is available for download¹.

1 Introduction

Amazon’s MechanicalTurk (AMT) is frequently used to evaluate experiments and annotate data in NLP (Callison-Burch et al., 2010; Callison-Burch and Dredze, 2010; Jha et al., 2010; Zaidan and Callison-Burch, 2011). However, some turkers try to maximize their pay by supplying quick answers that have nothing to do with the correct label. We refer to

this type of annotator as a *spammer*. In order to mitigate the effect of spammers, researchers typically collect multiple annotations of the same instance so that they can, later, use de-noising methods to infer the best label. The simplest approach is majority voting, which weights all answers equally. Unfortunately, it is easy for majority voting to go wrong. A common and simple spammer strategy for categorical labeling tasks is to always choose the same (often the first) label. When multiple spammers follow this strategy, the majority can be incorrect. While this specific scenario might seem simple to correct for (remove annotators that always produce the same label), the situation grows more tricky when spammers do not annotate consistently, but instead choose labels at random. A more sophisticated approach than simple majority voting is required.

If we knew whom to trust, *and when*, we could reconstruct the correct labels. Yet, the only way to be sure we know whom to trust is if we knew the correct labels ahead of time. To address this circular problem, we build a generative model of the annotation process that treats the correct labels as latent variables. We then use unsupervised learning to estimate parameters directly from redundant annotations. This is a common approach in the class of unsupervised models called *item-response* models (Dawid and Skene, 1979; Whitehill et al., 2009; Carpenter, 2008; Raykar and Yu, 2012). While such models have been implemented in other fields (e.g., vision), we are not aware of their availability for NLP tasks (see also Section 6).

Our model includes a binary latent variable that explicitly encodes if and *when* each annotator is spamming, as well as parameters that model the annotator’s specific spamming “strategy”. Impor-

¹Available under <http://www.isi.edu/publications/licensed-sw/mace/index.html>

tantly, the model assumes that labels produced by an annotator when spamming are independent of the true label (though, a spammer can still produce the correct label by chance).

In experiments, our model effectively differentiates dutiful annotators from spammers (Section 4), and is able to reconstruct the correct label with high accuracy (Section 5), even under extremely adversarial conditions (Section 5.2). It does not require any annotated instances, but is capable of including varying levels of supervision via token constraints (Section 5.2). We consistently outperform majority voting, and achieve performance equal to that of more complex state-of-the-art models. Additionally, we find that thresholding based on the posterior label entropy can be used to trade off coverage for accuracy in label reconstruction, giving considerable gains (Section 5.1). In tasks where correct answers are more important than answering every instance, e.g., when constructing a new annotated corpus, this feature is extremely valuable. Our contributions are:

- We demonstrate the effectiveness of our model on real world AMT datasets, matching the accuracy of more complex state-of-the-art systems
- We show how posterior entropy can be used to trade some coverage for considerable gains in accuracy
- We study how various factors affect performance, including number of annotators, annotator strategy, and available supervision
- We provide MACE (Multi-Annotator Competence Estimation), a Java-based implementation of a simple and scalable unsupervised model that identifies malicious annotators and predicts labels with high accuracy

2 Model

We keep our model as simple as possible so that it can be effectively trained from data where annotator quality is unknown. If the model has too many parameters, unsupervised learning can easily pick up on and exploit coincidental correlations in the data. Thus, we make a modeling assumption that keeps our parameterization simple. We assume that an annotator always produces the correct label when

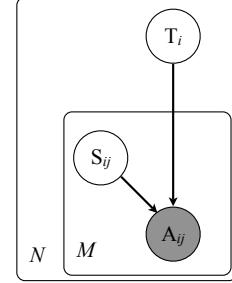

Figure 1: **Graphical model**: Annotator j produces label A_{ij} on instance i . Label choice depends on instance’s true label T_i , and whether j is spamming on i , modeled by binary variable S_{ij} . $N = |instances|$, $M = |annotators|$.

```

for i = 1 ... N :
  Ti ~ Uniform
for j = 1 ... M :
  Sij ~ Bernoulli(1 - θj)
  if Sij = 0 :
    Aij = Ti
  else :
    Aij ~ Multinomial(ξj)
  
```

Figure 2: **Generative process**: see text for description.

he tries to. While this assumption does not reflect the reality of AMT, it allows us to focus the model’s power where it’s important: explaining away labels that are not correlated with the correct label.

Our model generates the observed annotations as follows: First, for each instance i , we sample the true label T_i from a uniform prior. Then, for each annotator j we draw a binary variable S_{ij} from a Bernoulli distribution with parameter $1 - \theta_j$. S_{ij} represents whether or not annotator j is spamming on instance i . We assume that when an annotator is not spamming on an instance, i.e. $S_{ij} = 0$, he just copies the true label to produce annotation A_{ij} . If $S_{ij} = 1$, we say that the annotator is spamming on the current instance, and A_{ij} is sampled from a multinomial with parameter vector ξ_j . Note that in this case the annotation A_{ij} *does not* depend on the true label T_i . The annotations A_{ij} are observed,

while the true labels T_i and the spamming indicators S_{ij} are unobserved. The graphical model is shown in Figure 1 and the generative process is described in Figure 2.

The model parameters are θ_j and ξ_j . θ_j specifies the probability of trustworthiness for annotator j (i.e. the probability that he is not spamming on any given instance). The learned value of θ_j will prove useful later when we try to identify reliable annotators (see Section 4). The vector ξ_j determines how annotator j behaves when he is spamming. An annotator can produce the correct answer even while spamming, but this can happen only by chance since the annotator must use the same multinomial parameters ξ_j across all instances. This means that we only learn annotator biases *that are not correlated with the correct label*, e.g., the strategy of the spammer who always chooses a certain label. This contrasts with previous work where additional parameters are used to model the biases that even dutiful annotators exhibit. Note that an annotator can also choose not to answer, which we can naturally accommodate because the model is generative. We enhance our generative model by adding Beta and Dirichlet priors on θ_j and ξ_j respectively which allows us to incorporate prior beliefs about our annotators (section 2.1).

2.1 Learning

We would like to set our model parameters to maximize the probability of the observed data, i.e., the marginal data likelihood:

$$P(A; \theta, \xi) = \sum_{T,S} \left[\prod_{i=1}^N P(T_i) \cdot \prod_{j=1}^M P(S_{ij}; \theta_j) \cdot P(A_{ij}|S_{ij}, T_i; \xi_j) \right]$$

where A is the matrix of annotations, S is the matrix of competence indicators, and T is the vector of true labels.

We maximize the marginal data likelihood using Expectation Maximization (EM) (Dempster et al., 1977), which has successfully been applied to similar problems (Dawid and Skene, 1979). We initialize EM randomly and run for 50 iterations. We perform 100 random restarts, and keep the model with the best marginal data likelihood. We smooth the M-step by adding a fixed value δ to the fractional counts before normalizing (Eisner, 2002). We find that smoothing improves accuracy, but, overall, learning is robust to varying δ , and set $\delta = \frac{0.1}{\text{num labels}}$.

We observe, however, that the average annotator proficiency is usually high, i.e., most annotators answer correctly. The distribution learned by EM, however, is fairly linear. To improve the correlation between model estimates and true annotator proficiency, we would like to add priors about the annotator behavior into the model. A straightforward approach is to employ Bayesian inference with Beta priors on the proficiency parameters, θ_j . We thus also implement Variational-Bayes (VB) training with symmetric Beta priors on θ_j and symmetric Dirichlet priors on the strategy parameters, ξ_j . Setting the shape parameters of the Beta distribution to 0.5 favors the extremes of the distribution, i.e., either an annotator tried to get the right answer, or simply did not care, but (almost) nobody tried “a little”. With VB training, we observe improved correlations over all test sets with no loss in accuracy. The hyper-parameters of the Dirichlet distribution on ξ_j were clamped to 10.0 for all our experiments with VB training. Our implementation is similar to Johnson (2007), which the reader can refer to for details.

3 Experiments

We evaluate our method on existing annotated datasets from various AMT tasks. However, we also want to ensure that our model can handle adversarial conditions. Since we have no control over the factors in existing datasets, we create synthetic data for this purpose.

3.1 Natural Data

In order to evaluate our model, we use the datasets from (Snow et al., 2008) that use discrete label values (some tasks used continuous values, which we currently do not model). Since they compared AMT annotations to experts, gold annotations exist for these sets. We can thus evaluate the accuracy of the model as well as the proficiency of each annotator. We show results for word sense disambiguation (WSD: 177 items, 34 annotators), recognizing textual entailment (RTE: 800 items, 164 annotators), and recognizing temporal relation (Temporal: 462 items, 76 annotators).

3.2 Synthetic Data

In addition to the datasets above, we generate synthetic data in order to control for different

factors. This also allows us to create a gold standard to which we can compare. We generate data sets with 100 items, using two or four possible labels.

For each item, we generate answers from 20 different annotators. The “annotators” are functions that return one of the available labels according to some strategy. Better annotators have a smaller chance of guessing at random.

For various reasons, usually not all annotators see or answer all items. We thus remove a randomly selected subset of answers such that each item is only answered by 10 of the annotators. See Figure 3 for an example annotation of three items.

		annotators									
		1	0	0	1	–	0	–	–	0	–
items	1	–	–	0	–	1	0	–	–	0	
	–	–	0	–	0	1	–	0	–	0	

Figure 3: Annotations: 10 annotators on three items, labels {1, 0}, 5 annotations/item. Missing annotations marked ‘–’

3.3 Evaluations

First, we want to know which annotators to trust. We evaluate whether our model’s learned trustworthiness parameters θ_j can be used to identify these individuals (Section 4).

We then compare the label predicted by our model and by majority voting to the correct label. The results are reported as accuracy (Section 5). Since our model computes posterior entropies for each instance, we can use this as an approximation for the model’s confidence in the prediction. If we focus on predictions with high confidence (i.e., low entropy), we hope to see better accuracy, even at the price of leaving some items unanswered. We evaluate this trade-off in Section 5.1. In addition, we investigate the influence of the number of spammers and their strategy on the accuracy of our model (Section 5.2).

4 Identifying Reliable Annotators

One of the distinguishing features of the model is that it uses a parameter for each annotator to estimate whether or not they are spamming. Can we use this parameter to identify trustworthy individuals, to invite them for future tasks, and block untrustworthy ones?

	RTE	Temporal	WSD
raw agreement	0.78	0.73	0.81
Cohen’s κ	0.70	0.80	0.13
G-index	0.76	0.73	0.81
MACE-EM	0.87	0.88	0.44
MACE-VB $(0.5, 0.5)$	0.91	0.90	0.90

Table 1: Correlation with annotator proficiency: Pearson ρ of different methods for various data sets. MACE-VB’s trustworthiness parameter (trained with Variational Bayes with $\alpha = \beta = 0.5$) correlates best with true annotator proficiency.

It is natural to apply some form of weighting. One approach is to assume that reliable annotators agree more with others than random annotators. Inter-annotator agreement is thus a good candidate to weigh the answers. There are various measures for inter-annotator agreement.

Tratz and Hovy (2010) compute the average agreement of each annotator and use it as a weight to identify reliable ones. Raw agreement can be directly computed from the data. It is related to majority voting, since it will produce high scores for all members of the majority class. Raw agreement is thus a very simple measure.

In contrast, Cohen’s κ corrects the agreement between two annotators for chance agreement. It is widely used for inter-annotator agreement in annotation tasks. We also compute the κ values for each pair of annotators, and average them for each annotator (similar to the approach in Tratz and Hovy (2010)). However, whenever one label is more prevalent (a common case in NLP tasks), κ overestimates the effect of chance agreement (Feinstein and Cicchetti, 1990) and penalizes disproportionately. The G-index (Gwet, 2008) corrects for the number of labels rather than chance agreement.

We compare these measures to our learned trustworthiness parameters θ_j in terms of their ability to select reliable annotators. A better measure should lend higher score to annotators who answer correctly more often than others. We thus compare the ratings of each measure to the true proficiency of each annotator. This is the percentage of annotated items the annotator answered correctly. Methods that can identify reliable annotators should highly correlate

to the annotator’s proficiency. Since the methods use different scales, we compute Pearson’s ρ for the correlation coefficient, which is scale-invariant. The correlation results are shown in Table 1.

The model’s θ_j correlates much more strongly with annotator proficiency than either κ or raw agreement. The variant trained with VB performs consistently better than standard EM training, and yields the best results. This shows that our model detects reliable annotators much better than any of the other measures, which are only loosely correlated to annotator proficiency.

The numbers for WSD also illustrate the low κ score resulting when all annotators (correctly) agree on a small number of labels. However, all inter-annotator agreement measures suffer from an even more fundamental problem: removing/ignoring annotators with low agreement will always improve the overall score, irrespective of the quality of their annotations. Worse, there is no natural stopping point: deleting the most egregious outlier always improves agreement, until we have only one annotator with perfect agreement left (Hovy, 2010). In contrast, MACE does not discard any annotators, but weighs their contributions differently. We are thus not losing information. This works well even under adversarial conditions (see Section 5.2).

5 Recovering the Correct Answer

	RTE	Temporal	WSD
majority	0.90	0.93	0.99
Raykar/Yu 2012	0.93	0.94	—
Carpenter 2008	0.93	—	—
MACE-EM/VB	0.93	0.94	0.99
MACE-EM@90	0.95	0.97	0.99
MACE-EM@75	0.95	0.97	1.0
MACE-VB@90	0.96	0.97	1.0
MACE-VB@75	0.98	0.98	1.0

Table 2: Accuracy of different methods on data sets from (Snow et al., 2008). MACE-VB uses Variational Bayes training. Results @ n use the $n\%$ items the model is most confident in (Section 5.1). Results below double line trade coverage for accuracy and are thus not comparable to upper half.

The previous sections showed that our model reliably identifies trustworthy annotators. However, we

also want to find the most likely correct answer. Using majority voting often fails to find the correct label. This problem worsens when there are more than two labels. We need to take relative majorities into account or break ties when two or more labels receive the same number of votes. This is deeply unsatisfying.

Figure 2 shows the accuracy of our model on various data sets from Snow et al. (2008). The model outperforms majority voting on both RTE and Temporal recognition sets. It performs as well as majority voting for the WSD task. This last set is somewhat of an exception, though, since almost all annotators are correct all the time, so majority voting is trivially correct. Still, we need to ensure that the model does not perform worse under such conditions. The results for RTE and Temporal data also rival those reported in Raykar and Yu (2012) and Carpenter (2008), yet were achieved with a much simpler model.

Carpenter (2008) models instance difficulty as a parameter. While it seems intuitively useful to model which items are harder than other, it increases the parameter space more than our trustworthiness variable. We achieve comparable performance without modeling difficulty, which greatly simplifies inference. The model of Raykar and Yu (2012) is more similar to our approach, in that it does not model item difficulty. However, it adds an extra step that learns priors from the estimated parameters. In our model, this is part of the training process. For more details on both models, see Section 6.

5.1 Trading Coverage for Accuracy

Sometimes, we want to produce an answer for every item (e.g., when evaluating a data set), and sometimes, we value good answers more than answering all items (e.g., when developing an annotated corpus). Jha et al. (2010) have demonstrated how to achieve better coverage (i.e., answer more items) by relaxing the majority voting constraints. Similarly, we can improve accuracy if we only select high quality annotations, even if this incurs lower coverage.

We provide a parameter in MACE that allows users to set a threshold for this trade-off: the model only returns a label for an instance if it is sufficiently confident in its answer. We approximate the model’s confidence by the posterior entropy of

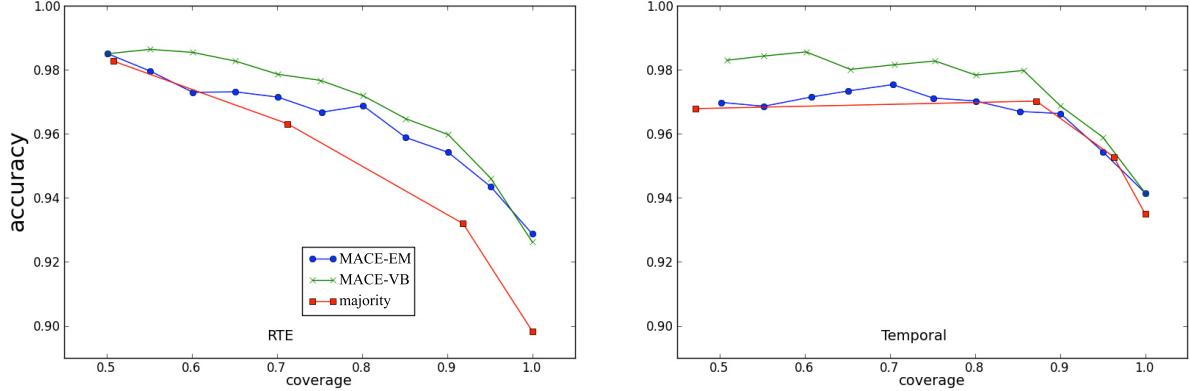

Figure 4: Tradeoff between coverage and accuracy for RTE (left) and temporal (right). Lower thresholds lead to less coverage, but result in higher accuracy.

each instance. However, entropy depends strongly on the specific makeup of the dataset (number of annotators and labels, etc.), so it is hard for the user to set a specific threshold.

Instead of requiring an exact entropy value, we provide a simple thresholding between 0.0 and 1.0 (setting the threshold to 1.0 will include all items). After training, MACE orders the posterior entropies for all instances and selects the value that covers the selected fraction of the instances. The threshold thus roughly corresponds to coverage. It then only returns answers for instances whose entropy is below the threshold. This procedure is similar to precision/recall curves.

Jha et al. (2010) showed the effect of varying the relative majority required, i.e., requiring that at least n out of 10 annotators have to agree to count an item. We use that method as baseline comparison, evaluating the effect on coverage and accuracy when we vary n from 5 to 10.

Figure 4 shows the tradeoff between coverage and accuracy for two data sets. Lower thresholds produce more accurate answers, but result in lower coverage, as some items are left blank. If we produce answers for all items, we achieve accuracies of 0.93 for RTE and 0.94 for Temporal, but by excluding just the 10% of items in which the model is least confident, we achieve accuracies as high as 0.95 for RTE and 0.97 for Temporal. We omit the results for WSD here, since there is little headroom and they are thus not very informative. Using Variational Bayes inference consistently achieves higher

results for the same coverage than the standard implementation. Increasing the required majority also improves accuracy, although not as much, and the loss in coverage is larger and cannot be controlled. In contrast, our method allows us to achieve better accuracy at a smaller, controlled loss in coverage.

5.2 Influence of Strategy, Number of Annotators, and Supervision

Adverse Strategy We showed that our model recovers the correct answer with high accuracy. However, to test whether this is just a function of the annotator pool, we experiment with varying the trustworthiness of the pool. If most annotators answer correctly, majority voting is trivially correct, as is our model. What happens, however, if more and more annotators are unreliable? While some agreement can arise from randomness, majority voting is bound to become worse—can our model overcome this problem? We set up a second set of experiments to test this, using synthetic data. We choose 20 annotators and vary the amount of good annotators among them from 0 to 10 (after which the trivial case sets in). We define a *good* annotator as one who answers correctly 95% of the time.² Adverse annotators select their answers randomly or always choose a certain value (minimal annotators). These are two frequent strategies of spammers.

For different numbers of labels and varying percentage of spammers, we measure the accuracy

²The best annotators on the Snow data sets actually found the correct answer 100% of the time.

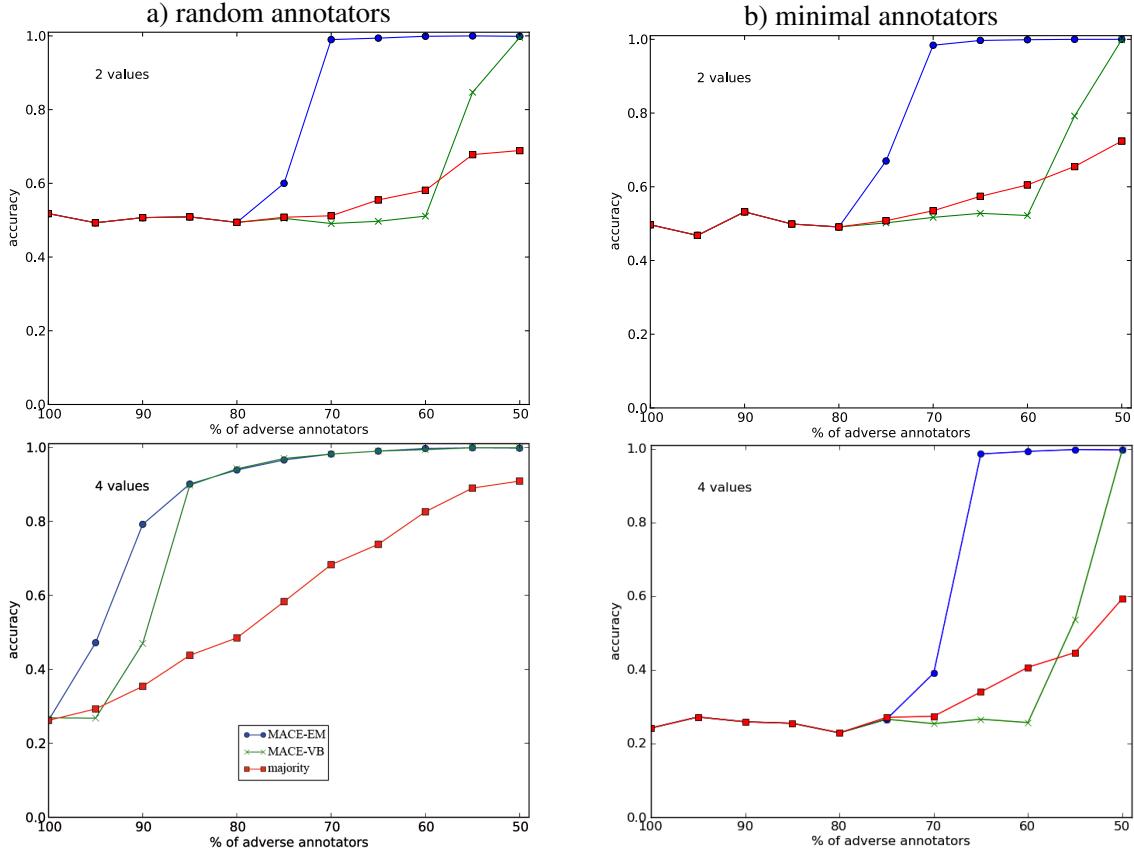

Figure 5: Influence of adverse annotator strategy on label accuracy (y -axis). Number of possible labels varied between 2 (top row) and 4 (bottom row). Adverse annotators either choose at random (a) or always select the first label (b). MACE needs fewer good annotators to recover the correct answer.

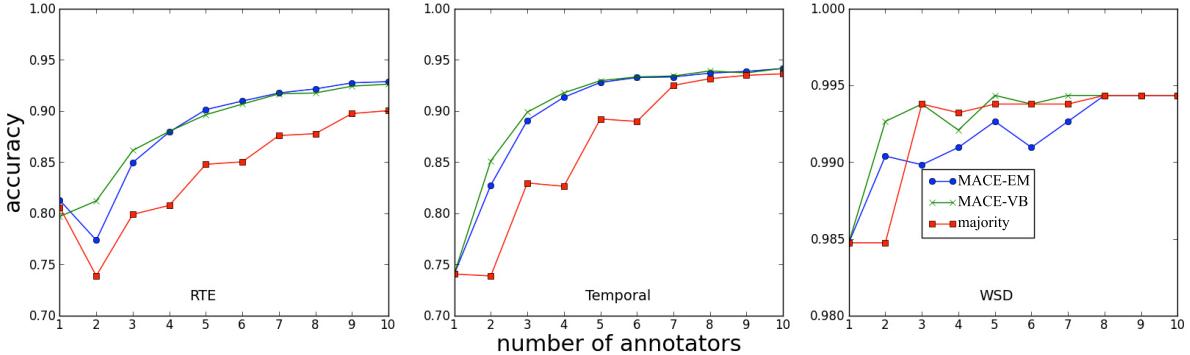

Figure 6: Varying number of annotators: effect on prediction accuracy. Each point averaged over 10 runs. Note different scale for WSD.

of our model and majority voting on 100 items, averaged over 10 runs for each condition. Figure 5 shows the effect of annotator proficiency on both majority voting and our method for both kinds of spammers. Annotator pool strategy affects majority

voting more than our model. Even with few good annotators, our model learns to dismiss the spammers as noise. There is a noticeable point on each graph where MACE diverges from the majority voting line. It thus reaches good accuracy much

faster than majority voting, i.e., with fewer good annotators. This divergence point happens earlier with more label values when adverse annotators label randomly. In general, random annotators are easier to deal with than the ones always choosing the first label. Note that in cases where we have a majority of adversarial annotators, VB performs worse than EM, since this condition violates the implicit assumptions we encoded with the priors in VB. Under these conditions, setting different priors to reflect the annotator pool should improve performance.

Obviously, both of these pools are extremes: it is unlikely to have so few good or so many malicious annotators. Most pools will be somewhere in between. It does show, however, that our model can pick up on reliable annotators even under very unfavorable conditions. The result has a practical upshot: AMT allows us to require a minimum rating for annotators to work on a task. Higher ratings improve annotation quality, but delay completion, since there are fewer annotators with high ratings. The results in this section suggest that we can find the correct answer even in annotator pools with low overall proficiency. We can thus waive the rating requirement and allow more annotators to work on the task. This considerably speeds up completion.

Number of Annotators Figure 6 shows the effect different numbers of annotators have on accuracy. As we increase the number of annotators, MACE and majority voting achieve better accuracy results. We note that majority voting results level off even drop when going from an odd to an even number. In these cases, the new annotator does not improve accuracy if it goes with the previous majority (i.e., going from 3:2 to 4:2), but can force an error when going against the previous majority (i.e., from 3:2 to 3:3), by creating a tie. MACE-EM and MACE-VB dominate majority voting for RTE and Temporal. For WSD, the picture is less clear, where majority voting dominates when there are fewer annotators. Note that the differences are minute, though (within 1 percentage point). For very small pool sizes (< 3), MACE-VB outperforms both other methods.

Amount of Supervision So far, we have treated the task as completely unsupervised. MACE does not require any expert annotations in order to achieve high accuracy. However, we often have

annotations for some of the items. These annotated data points are usually used as control items (by removing annotators that answer them incorrectly). If such annotated data is available, we would like to make use of it. We include an option that lets users supply annotations for some of the items, and use this information as token constraints in the E-step of training. In those cases, the model does not need to estimate the correct value, but only has to adjust the trust parameter. This leads to improved performance.³

We explore for RTE and Temporal how performance changes when we vary the amount of supervision in increments of 5%.⁴ We average over 10 runs for each value of n , each time supplying annotations for a random set of n items. The baseline uses the annotated label whenever supplied, otherwise the majority vote, with ties split at random.

Figure 7 shows that, unsurprisingly, all methods improve with additional supervision, ultimately reaching perfect accuracy. However, MACE uses the information more effectively, resulting in higher accuracy for a given amount of supervision. This gain is more pronounced when only little supervision is available.

6 Related Research

Snow et al. (2008) and Sorokin and Forsyth (2008) showed that Amazon’s MechanicalTurk use in providing non-expert annotations for NLP tasks. Various models have been proposed for predicting correct annotations from noisy non-expert annotations and for estimating annotator trustworthiness. These models divide naturally into two categories: those that use expert annotations for supervised learning (Snow et al., 2008; Bian et al., 2009), and completely unsupervised ones. Our method falls into the latter category because it learns from the redundant non-expert annotations themselves, and makes no use of expertly annotated data.

Most previous work on unsupervised models belongs to a class called “Item-response models”, used in psychometrics. The approaches differ with respect to which aspect of the annotation process

³If we had annotations for all items, accuracy would be perfect and require no training.

⁴Given the high accuracy for the WSD data set even in the fully unsupervised case, we omit the results here.

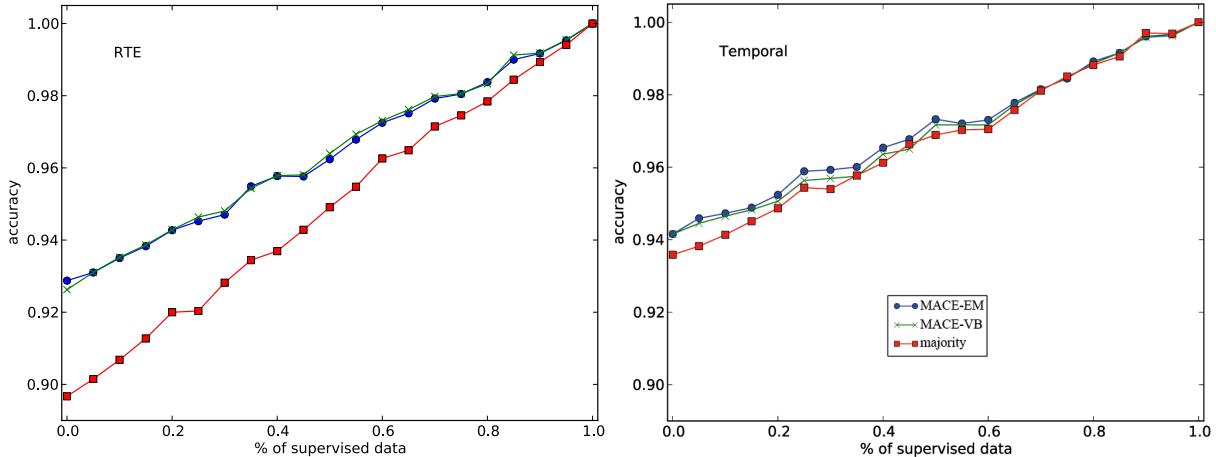

Figure 7: Varying the amount of supervision: effect on prediction accuracy. Each point averaged over 10 runs. MACE uses supervision more efficiently.

they choose to focus on, and the type of annotation task they model. For example, many methods explicitly model annotator bias in addition to annotator competence (Dawid and Skene, 1979; Smyth et al., 1995). Our work models annotator bias, but only when the annotator is suspected to be spamming.

Other methods focus modeling power on instance difficulty to learn not only which annotators are good, but which instances are hard (Carpenter, 2008; Whitehill et al., 2009). In machine vision, several models have taken this further by parameterizing difficulty in terms of complex features defined on each pairing of annotator and annotation instance (Welinder et al., 2010; Yan et al., 2010). While such features prove very useful in vision, they are more difficult to define for the categorical problems common to NLP. In addition, several methods are specifically tailored to annotation tasks that involve ranking (Steyvers et al., 2009; Lee et al., 2011), which limits their applicability in NLP.

The method of Raykar and Yu (2012) is most similar to ours. Their goal is to identify and filter out annotators whose annotations are not correlated with the gold label. They define a function of the learned parameters that is useful for identifying these spammers, and then use this function to build a prior. In contrast, we use simple priors, but incorporate a model parameter that explicitly represents the probability that an annotator is spamming. Our simple model achieves the same accuracy on gold

label predictions as theirs.

7 Conclusion

We provide a Java-based implementation, MACE, that recovers correct labels with high accuracy, and reliably identifies trustworthy annotators. In addition, it provides a threshold to control the accuracy/coverage trade-off and can be trained with standard EM or Variational Bayes EM. MACE works fully unsupervised, but can incorporate token constraints via annotated control items. We show that even small amounts help improve accuracy.

Our model focuses most of its modeling power on learning trustworthiness parameters, which are highly correlated with true annotator reliability (Pearson ρ 0.9). We show on real-world and synthetic data sets that our method is more accurate than majority voting, even under adversarial conditions, and as accurate as more complex state-of-the-art systems. Focusing on high-confidence instances improves accuracy considerably. MACE is freely available for download under <http://www.isi.edu/publications/licensed-sw/mace/index.html>.

Abstract

We propose a supervised lexical substitution system that does not use separate classifiers per word and is therefore applicable to any word in the vocabulary. Instead of learning word-specific substitution patterns, a global model for lexical substitution is trained on delexicalized (i.e., non lexical) features, which allows to exploit the power of supervised methods while being able to generalize beyond target words in the training set. This way, our approach remains technically straightforward, provides better performance and similar coverage in comparison to unsupervised approaches. Using features from lexical resources, as well as a variety of features computed from large corpora (n-gram counts, distributional similarity) and a ranking method based on the posterior probabilities obtained from a Maximum Entropy classifier, we improve over the state of the art in the LexSub Best-Precision metric and the Generalized Average Precision measure. Robustness of our approach is demonstrated by evaluating it successfully on two different datasets.

1 Introduction

In recent years, the task of automatically providing lexical substitutions in context (McCarthy andNavigli, 2007) received much attention. The premise to be able to replace words in a sentence without changing its meaning gave rise to applications like linguistic steganography (Topkara et al., 2006; Chang and Clark, 2010), semantic text similarity (Agirre et al., 2012), and plagiarism detection (Gipp et al., 2011).

Lexical substitution, a special form of contextual paraphrasing where only a single word is replaced, is closely related to word sense disambiguation (WSD): polysemous words have possible substitutions reflecting several senses, and the correct sense has to be picked to avoid spurious system behavior. However, no explicit word sense inventory is required for lexical substitution (Dagan et al., 2006).

The prominent tasks in a lexical substitution system are *generation* and *ranking*, i.e. to generate a set of possible substitutions for the target word and then to rank this set of possible substitutions according to their contextual fitness. The task to generate a high quality set of possible substitutions is challenging in itself, for two reasons. First, the available lexical resources are seldom complete in listing synonyms. Second, manually annotated substitutions show that not all synonyms of a word are appropriate in a given context, and many good substitutions have other lexical relation than synonymy to the original word.

In this work, we present a supervised lexical substitution system that, unlike the usual *lexical sample* supervised approaches, can produce substitutions for targets that are not contained in the training material. We reach this by using non-lexical features from heterogeneous evidence, including lexical-semantic resources and distributional similarity, n-gram and shallow syntactic features based on large, unannotated background corpora. In light of the existence of lexical resources such as WordNet (Fellbaum, 1998) or machine readable dictionaries that can serve as the source for lexical information, and with the ever-increasing availability of large unannotated corpora for many languages and

domains, our proposal enables us to leverage the quality gain of supervised machine learning while generalizing over a large vocabulary through the avoidance of lexicalized features. Using a single classifier for all substitution targets in this way results in an all-words substitution system. As our results demonstrate, our model improves over the state of the art in lexical substitution with practically no open parameters that have to be optimized and selected carefully according to the dataset at hand.

2 Related Work

Previous works in lexical substitution either address both the *generation* and the *ranking* tasks, and are therefore applicable to any word without pre-labeled data (c.f. the Semeval 2007 task (McCarthy and Navigli, 2007) and related work) or focus on the more challenging ranking step only (c.f. Erk and Padó (2008) and related work). The latter approaches take the list of possible substitutions directly from the testing data as a workaround to generating the possible substitutions, and merely evaluate the ranking capabilities of these methods.

The most accurate lexical substitution systems use supervised machine learning to train (and test) a separate classifier per target word, using lexical and shallow syntactic features. These systems rely on the existence of a large number of annotated examples (i.e. sentences together with the contextually valid substitutions) for each word. Biemann (2012) describes a supervised lexical substitution system for frequent nouns. Exploiting a large amount of sense tagged examples and (sense-specific) data annotated with substitutions, an accurate coarse-grained WSD model is trained and then the most frequent substitutions of the predicted sense are assigned to the new occurrences of the target words. The results demonstrate that lexical substitution of noun targets can be attained with very high precision (over 90%) if sufficient training material is available. However, due to high annotation costs, methods that do not require labeled training data per target scale better to a large vocabulary.

Knowledge-based systems like e.g. by Hassan et al. (2007), who use a number of knowledge-based and unsupervised methods and combine these clues using a voting scheme, do not need training data per

target. The combination of different signals, however, has to be done manually. Unsupervised systems that rely on distributional similarity (Thater et al., 2011) or topic models (Li et al., 2010) are single signals in this sense, and their development is guided by the performance and observations on standard datasets. Such signals, however, can also be kept simple avoiding any task-specific optimization and can be integrated in a single model for all words using a limited amount of training data and delexicalized features, as in Senselearner (Mihalcea and Csomai, 2005) for weakly supervised all-words disambiguation. This way, task specific development can be replaced by a machine learning component and the resulting model applies also to unseen words, similar to the knowledge-based approaches.

2.1 Full Lexical Substitution Systems

Related works that address the lexical substitution problem according to the settings established by the *English Lexical Substitution Task* (McCarthy and Navigli, 2007) at Semeval 2007 (LexSub) typically employ a simple ranking strategy based on local n-gram frequencies and focus on finding an optimal source of possible substitutions, as the selection of lexical resources has largest impact on the overall system performance: Sinha and Mihalcea (2009) systematically explored the benefits of multiple lexical resources and found that a supervised combination of several resources lead to statistically significant improvements in accuracy (about 3.5% points over the best single resource, WordNet). They tested LSA (Deerwester et al., 1990), ESA (Gabrilovich and Markovitch, 2007) and n-gram frequencies for contextualization and found n-gram frequencies to be more effective than dimensionality reduction techniques by a large margin. Their improvements were obtained by supervised learning on the *combination* of several lexical resources. Our work, on the other hand, is concerned with using more advanced features and we obtain significant improvements based on a diverse set of features and a different learning setup: we train a *model for contextualization*, rather than to combine substitutions from several different resources.

A recent work by Sinha and Mihalcea (2011) used an approach based on graph centrality to rank the candidates and achieved comparable performance

to n-gram-frequency-based ranking. To summarize, the use of n-gram frequencies for ranking and WordNet as the (most appropriate single) source of synonyms is competitive to more complex solutions and provides a simple and strong lexical substitution system. This motivated the follow-up work by Chang and Clark (2010) to use WordNet and n-grams in a linguistic steganography application and this motivates us to use this method as our baseline.

2.2 Ranking Word Meaning in Context

Another prominent line of related work focused solely on the accurate ranking of a pre-given set of possible synonyms, according to their plausibility as a substitution in a given context. Typically, lexical substitution data is used for evaluation purposes, taking the candidate substitutions directly from the test data. This choice is motivated by the assumption that better semantic models should rank near-synonyms more accurately according to how they fit in the original word’s context.

Erk and Padó (2008) proposed the use of multiple vector representations of words, where the basic representation corresponds to a standard co-occurrence vector, while further vectors are used to characterize words according to their inverse selectional preference statistics for typical dependency relations. The representation of a word in its context is computed via combining the basic representation of a word with the inverse selectional preference vectors of its related words from the context. Ranking is done by comparing vectors of possible substitutions with the substitution target. Thater et al. (2010) took a similar approach but used second order co-occurrence vectors and report improved performance.

An exemplar-based approach is presented by Erk and Padó (2010) and Reisinger and Mooney (2010b) to model word meaning with respect to its context: instead of representing the word and the context as separate vectors and combining them, a set of word occurrences in similar contexts is picked first, and then only these exemplars are used to represent the word in context. While this approach provides good results with relatively simple and transparent models, each occurrence of a word has a unique representation (that can only be computed at testing time), and it is computationally expensive to scale these models to a large number of examples.

Dinu and Lapata (2010) used a bag of words latent variable model to characterize the meaning of a word as a distribution over a set of latent variables (that is, probabilistic senses). Contextualized representation of word meaning is then attained by conditioning the model on the context words in which the target word occurs. A similar approach has been evaluated for word similarity (Reisinger and Mooney, 2010a) and word sense disambiguation (Li et al., 2010).

Although our main goal here is to develop a full-fledged lexical substitution system, we mainly focus on the construction of better ranking models based on supervised machine learning and delexicalized features that scale well for unseen words. This approach has similar properties (applicability to all words without word-specific training data) to the knowledge-based and unsupervised models described above, so we will also refer to these systems for comparison.

3 Datasets

In our work, we use two major freely available datasets that contain human-annotated substitutions for single words in their full-sentence context.

3.1 LexSub dataset

This dataset was introduced in the Lexical Substitution task at Semeval 2007¹. It consists of 2002 sentences for a total of 201 words (10 sentences per word, but 8 sentences does not have gold standard labels). Each sentence was assigned to 5 native speaker annotators, who entered as many paraphrases or substitutions as they found appropriate for the word in context. Paraphrases are assigned a weight (or frequency) that denotes how many annotators suggested that particular word as a substitute.

3.2 TWSI

A similar, but larger dataset is the Turk Bootstrap Word Sense Inventory (TWSI², (Biemann, 2012)). The data was collected through a three-step crowdsourcing process and comprises 24,647 sentences

¹download at <http://nlp.cs.swarthmore.edu/semeval/tasks/task10/data.shtml>

²<http://www.ukp.tu-darmstadt.de/data/lexical-resources/twsi-lexical-substitutions/>

for a total of 1,012 target nouns, where crowdworkers have provided substitutions for a target word in context. We did not use the roughly 150,000 sense-labeled contexts and the sense inventory of this resource, i.e. this dataset – as used in this study – is transparent to the LexSub data. For the majority of the data, responses from 3 annotators were collected per context, and there are on average 24 sentences per target word in the dataset. Due to this, the average weight of good substitutions is somewhat lower than in the LexSub dataset (1.27 vs. 1.58 in LexSub), but the average number of unique substitutions per target word is slightly higher in TWSI (average of 22 words / target vs. 17 in LexSub).

3.3 Source of Possible Substitutions

In our lexical substitution system, we used WordNet as the source for candidate synonyms. For each substitution target, we took all synonyms from all of the word’s WordNet synsets as candidates, together with the words from synsets in *similar to*, *entailment* and *also see* relation to these synsets³. In order to evaluate and compare our ranking methodology in a transparent way with those studies that focused just on the candidate ranking task, we also performed experiments where we pooled the set of candidates from the gold standard dataset. This setting ensures that each set contains a positive candidate, and that all human-suggested paraphrases are available as positive examples for a given sentence.

The main characteristics of the datasets (with both WordNet or the gold standard as the source of candidate substitutions) are summarized in Table 1. The rows in the table indicate the source of possible substitutions, number of target words, instances with at least one non-multiword possible substitution, average size of candidate sets, and number of instances with no good candidate and frequency of different labels. The labels denote how many annotators proposed a particular word as substitution in the given context and can be interpreted as a measure of goodness: the higher the value, the better the candidate fits in the context. Similarly, the label 0 denotes the total number of negative examples in our datasets, i.e. bad substitutions – words that belong to the can-

source	LexSub		TWSI	
	WN	Gold St.	WN	Gold St.
# words	201	201	908	1007
#inst	2002	2002	22543	24643

didate set for a particular target word, but are not listed as good substitutions in the given context in the dataset.

4 Methodology

4.1 Experimental Setup and Evaluation

We follow previous works in lexical substitution and evaluate our models using the Generalized Average Precision (GAP) (Kishida, 2005) measure which assesses the quality of the entire ranked list. In addition, we also provide the precision of our system at the first rank (P@1), i.e. the percentage of correct paraphrases at rank 1. This is a realistic evaluation criterion for many applications, such as paraphrasing for linguistic steganography: it is the highest-ranked candidate that can be used to replace the original word (the manipulated text should preserve the original meaning) and there is no straightforward way to exploit multiple correct answers. In addition, we also provide the Semeval 2007 *best precision*⁴ metric (McCarthy and Navigli, 2007) for the LexSub dataset for comparison to Semeval 2007 participants. This metric also evaluates the first guess of a system (per context), but gives less credit to easier contexts, where several good options exist. This fact motivates us to use P@1 rather than the *best precision* metric in all other experiments.

³This candidate set was found best for WordNet by Martinez et al. (2007).

⁴Since our system always provides an answer, the Semeval 2007 *best recall* equals *best precision*.

4.2 Machine Learning on Delexicalized Features

After the list of potential substitutions is obtained, lexical substitution is cast as a ranking task where the goal is to prefer contextually plausible substitutions over implausible ones. The goal of this study is to learn a ranking model that is applicable to any word, for which a list of synonyms is available. A supervised model can generalize over the example target words in the datasets, if aggregate features can be defined that have the same semantics regardless of the actual context, target word or candidate substitution they are computed from. Having such a representation, one can expect to learn patterns that generalize over the words/context seen in the training dataset, and thus the setup constitutes a supervised all-word system.

To simulate an all-word scenario, we perform a 10-fold cross validation in our experiments, splitting the dataset into equal-sized folds randomly on the *target word* level. That is, all sentences for a particular target word fall into the same fold and thus either the training or the test set (but never both). This way we always train and test the model on disjoint sets of words and as such, the learnt models cannot exploit word-specific properties. This makes our results realistic estimates of an open vocabulary paraphrasing system, where we would apply the models (mostly) to words that were not in the training material.

4.2.1 Machine Learning Model

In our experiments, we used a Maximum Entropy (MaxEnt) classifier model implemented in the Mallet (McCallum, 2002) package and trained a binary classifier to predict if a given substitution is valid in a particular context or not.

We chose to use Maximum Entropy models for two main reasons: MaxEnt is not sensitive to parameter settings and handles correlated features well, which is crucial in our situation where many features are highly correlated.

Due to the low number of positive examples in the datasets (see Table 1, labels 1-5+) and to emphasize better paraphrases suggested by several annotators, we assigned a weight to positive instances during the training process equal to their score (the number of annotators suggesting that paraphrase; the weight of negative instances was set to 1).

The output of the MaxEnt classifier is a posterior probability distribution for each target/substitution pair, denoting the probabilities of the instance to be a good or a bad substitution, given the feature values that describe both the words and their context. The ranking over a set of candidates can be naturally induced based on their posterior scores for the positive class, i.e. a number that denotes ‘how good the candidate is, given the context’. That is, the best substitution candidate s (characterized by a set of features \mathbf{F}) from a set of candidates \mathbf{S} is obtained as $\text{argmax}_{s \in \mathbf{S}}[P(\text{good}|\mathbf{F})]$, the next best as the argmax of the remaining elements, and so on.

This pointwise approach to subset ranking (Cossock and Zhang, 2008) is arguably simplistic, but several studies (c.f. Li et al. (2007; Busa-Fekete et al. (2011)) found this approach to perform reasonably well given that the model provides accurate probability estimates, which is the case for MaxEnt.

4.3 Delexicalized Features

We use heterogeneous sources of information to describe each target word/candidate substitution pair in its context. The most important features describe the syntagmatic coherence of the substitute in context, measured as local n-gram frequencies obtained from web data, in a sliding window around the target word. In addition we use features to describe the (non-positional, i.e. non-local) distributional similarity of the target and its candidate substitution in terms of sentence level co-occurrence statistics collected from newspaper texts. A further set of features captures the properties of the target and candidate word in a lexical resource (WordNet), such as their number of senses, how frequent senses are synonymous, etc. Lastly, we use part of speech patterns to describe the target word in context. This way, unlike many other methods suggested in previous works (Thater et al., 2011; Erk and Padó, 2008), our model does not require deep syntactic analysis of the test sentences in order to rank the candidates. Even though we make intensive use of WordNet to compute some of our feature functions, this is not a severe restriction for a practical paraphrasing system: one has to have a decent lexical resource in order to mine a reasonable set of candidate synonyms and such a resource can also serve as a source for features in the classifier. The rest of the feature func-

tions exploit only large unannotated corpora and a POS tagger at application time.

For a target word t , and candidate substitution s_i from a set of candidates S , we used the features below. Each numeric feature is used both in the form given below, and set-wise scaled to $[0, 1]$ (we leave it to the classifier to pick the more useful form of information). For the LexSub dataset, each feature is defined once for all instances, and once specific to the four POS categories in the dataset. That is each instance would have the described features defined twice, once the general form (defined for every instance) and once the form according to the *predicted* POS category of the target word. This allows the model to learn general and also POS-specific patterns based on the information described below (i.e. frequency thresholds, distributional properties etc. for nouns or verbs etc. in particular). We denote the left and right contexts around t and all words in the sentence except t with c_l , c_r and c , respectively)

4.3.1 Lexical Resource Features

We used Wordnet 3.0 as the source for substitution candidates and as a source for delexicalized features. We found the measure of ambiguity and the sense number to provide useful information in a more general context: it is informative how many senses a word has, and it is informative from which sense number of the substitution target the substitution candidate came from, since they are ordered by corpus frequency. In addition, we used the synsets IDs of the words' hypernyms as features, which can capture more general semantics (the word to replace is 'animate', 'abstract', etc.). The following features were extracted from WordNet:

- number of senses of t and s_i in WordNet
- the sense numbers of t and s_i which are synonymous (in case they are direct synonyms, c.f. WN sense numbers encode sense frequencies)
- binary features for synset IDs of the hypernyms of the synset containing t and s_i (this feature type did not significantly improve results)

4.3.2 Corpus-based Features

In order to create a Distributional Thesaurus (DT) similar to Lin (1998), we parsed a source corpus

of 120M sentence English newspaper texts from the LCC⁵ (Richter et al., 2006) with the Stanford parser (de Marneffe et al., 2006) and used dependencies to extract features for words: each dependency triple (w_1, r, w_2) denoting a dependency of type r between words w_1 and w_2 results in a feature (r, w_2) characterizing w_1 , and a feature (w_1, r) characterizing w_2 ⁶. After counting the frequency of each feature for each word, we apply a significance measure (log-likelihood test (LL), (Dunning, 1993)), rank features per word according to their significance, and prune the data, keeping only the 1000 most salient features (F_w) per word⁷. The similarity of two words is then given by the number of their common features. Our distributional thesaurus provides a list of the 1000 most salient features and a ranked list of up to 200 similar words (sim_w , based on the number of shared features) for all words above a certain frequency in the source corpus. We compute the following features to characterize a target word / substitution pair:

- To what extent the context c characterizes s_i :

$$\frac{\sum_{c \in F_{s_i}} LL(F_{s_i}(c))}{\sum_{s_j \in S} \sum_{c \in F_{s_j}} LL(F_{s_j}(c))}$$
- percentage of shared words among the top k similar words to t and to s_i :

$$\frac{|sim_t|_k \cap |sim_{s_i}|_k}{max(|sim_t|_k, |sim_{s_i}|_k)}, \text{ for } k = 1, 5, 10, 20, 50, 100, 200^8$$
- percentage of shared salient features among the top k features of t and s_i , globally and restricted to the words from the target sentence:

$$\frac{|F_t|_k \cap |F_{s_i}|_k}{max(|F_t|_k, |F_{s_i}|_k)} \text{ and } \frac{|F_t|_k \cap |F_{s_i}|_k \cap |c|}{|c|}, \text{ for } k = 1, 5, 10, 20, 50, 100, 1000$$
- boolean feature indicating whether $s_i \in sim_t$ or not (in top 100 similar words)

⁵<http://corpora.informatik.uni-leipzig.de/>

⁶open source implementation and data available at
<http://sourceforge.net/p/jobimtext>

⁷The pruning operation greatly reduces runtime at thesaurus collection, rendering memory reduction techniques like (Charikar et al., 2004) as unnecessary.

⁸The various values for k trade off the salience of this feature for coverage: only very few substitutions have overlap in the top 1-5 similar words set, but if this happens, it is a very strong indicator of contextual fitness, whereas overlap within the top 100-200 similar words is present for much more target/substitution pairs, but it is a weaker indicator of fitness.

4.3.3 Local n-gram Features (from Web 1T)

Syntagmatic coherence, measured as the n-gram frequency of the context with the candidate substitution serves as the basis of ranking in the best Semeval 2007 system (Giuliano et al., 2007), which is also our baseline method here. We use the same n-grams as features in our supervised model:

- 1-5-gram frequencies in a sliding window around t : $\text{freq}(c_l s_i c_r) / \text{freq}(c_l t c_r)$, normalized w.r.t t
- 1-5-gram frequencies in a sliding window around t : $\text{freq}(c_l s_i c_r) / \sum \text{freq}(c_l S c_r)$, normalized w.r.t. S
- for each of x in $\{\text{'and'}, \text{'or'}, \text{','}\}$, 3-5-gram frequencies in a sliding window around t : $\text{freq}(c_l t x s_i c_r) / \text{freq}(c_l t c_r)$ (how frequently the target and candidate are part of a list or conjunctive phrase)

4.3.4 Shallow Syntactic Features

We also use part of speech information (from TreeTagger (Schmid, 1994)) as features, in order to enable the model to learn POS-specific patterns. This is especially important for the LexSub dataset, which contains examples from all major parts of speech (the TWSI dataset contains only noun targets). Specifically, we use:

- 1-3-grams of main POS categories in a window around t , e.g. *NVV* for a noun, verb, verb context
- Penn Treebank POS code of t

4.3.5 Example

For clarity, we exemplify our delexicalized features briefly. Using WordNet as a source for the word *bright*, we considered the 11 words *brilliant*, *vivid*, *smart*, *burnished*, *lustrous*, *shining*, *shiny*, *undimmed*, *brilliant*, *hopeful*, *promising* from the synsets of *bright*, and 64 further words from its related synsets (e.g. *intelligent*, *glimmery*, *polished*, *happy*, ...) as potential paraphrases. That is, for the sentence "He was **bright** and independent and proud.", where the human annotators listed *intelligent*, *clever* as suitable paraphrases, our system had 1 correct (*intelligent*) and 74 incorrect substitutions

in the candidate set (that is, *clever* is not found in WordNet in the above described way). The substitution *intelligent* in this context is characterized by a total of 178 active features. Of those, 112 features are based on local n-gram features (Sect. 4.3.3), where the large number stems from different n in n-gram, as well as the different variants of normalization and copies for the particular POS (here: JJ) and for all POS. For instance, "bright" and "intelligent" are frequently occurring in comma-separated enumerations, and "intelligent" fits well in the target context based on n-gram probabilities. The second largest block of features is constituted by 48 active distributional similarity features (Sect. 4.3.2), which are also available per POS and for different normalizations. Here is e.g. captured that the candidate has a high distributional similarity to the target with respect to our background corpus. The 12 shallow syntactic features (Sect 4.3.4) capture various present POS patterns around the target, and the 6 resource-based features (Sect. 4.3.1) e.g. inform about the number of senses of the target (10) and the candidate (4).

4.4 Results

Now, we describe our results in detail. First we compare our system on two datasets with a competitive baseline, which uses the same candidate set as our ML-based model, and the simple and effective ranking function based on Google n-grams described by Giuliano et al. (2007). Later on we analyze how the four major feature groups contribute to the results in a feature ablation experiment, and then we provide a detailed and thorough comparison to earlier works that are similar to the model presented here and used the same dataset (LexSub) for evaluation.

4.4.1 Semeval 2007 Lexical Substitution

In Table 2 we report results on the LexSub dataset. As can be seen, our model outperforms the baseline by a significant margin ($p < 0.01$ for all measures, using a paired t-test for significance). Both the overall rankings and the P@1 scores are of higher quality than the rankings based only on n-grams.

4.4.2 Turk Bootstrap Word Sense Inventory

The results on the TWSI dataset are provided in Table 3. Our model outperforms the baseline in all

	cand. from WN		from Gold St.	
	GAP	P@1	GAP	P@1
Baseline	36.8	31.1	46.9	49.5
Our model	43.8	40.2	52.4	57.7

Table 2: Comparison to the baseline on LexSub 2007.

	cand. from WN		from Gold St.	
	GAP	P@1	GAP	P@1
Baseline	33.8	28.2	44.4	44.5
Our model	36.6	32.4	47.2	49.5

Table 3: Comparison to the baseline on the TWSI dataset.

the comparisons similar to the LexSub dataset. The differences are not so pronounced but still highly significant ($p < 0.01$). This is consistent with the observation by several Semeval 2007 participants and with a per-POS analysis of our results on LexSub: the ranking task seems to be more challenging for nouns than for other parts of speech. When using WordNet, for about half (11165/22543) of the instances, individual scores are 0 (cf. Table 1). For the other half, avg. P@1 score is around 0.7, which results in 0.324 overall. Note that the task of ranking in avg. 7.5 items is considerably easier than ranking in avg. 22 items, which explains the high P@1 scores for cases where good candidates exist – also, a random ranker would score higher in this case.

These results demonstrate that the proposed delexicalized approach is superior to a competitive baseline across two datasets.

4.5 Feature Exploration

We explored the contribution of our various feature types on the LexSub dataset with candidate set from the gold standard. Our MaxEnt model relying only on local n-gram frequency features, i.e. the

	GAP	P@1
w/o n-gram features	47.3	48.9
w/o distr. thesaurus	49.8	55.0
w/o POS features	51.6	56.3
w/o WN features	51.7	57.0
Our model (all)	52.4	57.7

Table 4: Feature ablation experiment (on LexSub dataset, with candidates from Gold Standard).

same information as the baseline model, achieved a GAP score of 48.3 and P@1 of 52.1, respectively. This result is significantly better than the baseline ($p < 0.01$), i.e. the machine learnt ranking model is better than a state-of-the-art handcrafted ranker based on the same data. All single feature groups, when combined with n-grams, lead to significant improvements ($p < 0.01$), which proves the usefulness of each feature group. In order to assess the contribution of each group to the *overall* system performance, we performed a feature ablation experiment. That is, we trained the MaxEnt model with using all feature groups (this equals the model in Table 2) and then with leaving each of the feature groups out once. As can be seen, all feature groups improve the overall results in a noticeable way, i.e. their contribution is complementary.

4.5.1 Comparison to Previous Works

In Table 5 we compare our method with previous works in the field, using the LexSub dataset.

	candidates from WN Best-P	from Gold Standard GAP
Giuliano	12.93	PadóErk10 38.6
Martinez	12.68	DinuLapata 42.9
Sinha	13.60	Thater10 46.0
Baseline	11.75	Thater11 51.7
Our model	15.94	Baseline 46.9
		Our model 52.4

Table 5: Comparison to previous works (LexSub dataset).

In the left column of Table 5, we compare the performance of our system to representative Semeval 2007 participants, namely Martinez et al. (2007) and Giuliano et al. (2007). In order to make a fair comparison, we report scores for the official test data of Semeval 2007, using a 10-fold cross-validation scheme. Martinez et al. (2007) developed their system based on WordNet and we use the same candidate set here that they proposed in their system description. Our reimplementation of (Giuliano et al., 2007) performs below the original scores, due to the more restricted source of substitution candidates (they use more lexical resources), yet uses the same ranking methodology based on Google n-grams that we adopted here as our baseline. We also report the best previous result for this task, which

was achieved via the (supervised) combination of lexical resources to improve the performance (Sinha and Mihalcea, 2009). Our model outperforms this result by a large margin for the best-precision evaluation (mode-P, precision measured on those examples where there is a clear best substitution provided by humans was 26.3%, compared to 21.3% reported by Sinha and Mihalcea (2009)). This is especially promising in light of the fact that we use only a single source (WordNet) for synonyms and achieve our improvements through more advanced delexicalized features in an improved ranking model. Sinha and Mihalcea (2009), on the other hand, used comparably simple features for contextualization, of which n-gram features were deemed most successful. As Sinha and Mihalcea (2009) showed improvements through utilizing several synonym sources, a combination of their approach with ours should allow for further improvements in the future.

In the right column of Table 5, we compare our model to previous works that addressed only the ranking task, and report performance on the whole dataset (i.e. trial and test). As can be seen, the methodology proposed here outperforms previous ranking models, without the need to develop a high-quality ranking model by hand, and without the need to parse the test sentences. Our delexicalized supervised model only requires the development of features, and achieves excellent results without major task-specific tuning or customization: we omitted the optimization of the feature set and the parameters of the learning model. This fact makes us assume that the proposed model can be applied more quickly and easily than previous models that have several important design aspects to choose from.

5 Conclusion and Future Work

In this study, we presented a supervised approach to all-words lexical substitution based on delexicalized features, which enables us to fully exploit the power of supervised models while ensuring applicability to a large, open vocabulary.

Results demonstrate the feasibility of this method: our MaxEnt-based ranking approach improved over the baseline in all settings and yielded – to our knowledge – the best scores for lexical substitution with automatically gathered synonyms on the

Semeval 2007 LexSub dataset. Also, it performed slightly better than the state of the art for candidates pooled from the gold standard without any parameter tuning or empirical design choices.

In this study, we established transparency between Semeval-style and ranking-only studies in lexical substitution – two lines of work that were difficult to compare in the past. Further, we observe similar improvements on two different datasets, showing the robustness of the approach.

While previous works showed the potential of more/improved lexical resources for lexical substitution, we improved over the best Semeval-style performance just by exploiting an improved ranking model over a standard WordNet-based candidate set. These results indicate that improvements from lexical resources and better ranking models are additive, thus we want to add more lexical resources in our system in the future.

Of course there are several other ways to improve further the work described here. First of all, similar to the best ranking approaches (e.g. Thater et al. (2011)), one could use contextualized feature functions to make global information from the distributional thesaurus more accurate. Instead of using globally calculated similarities, information from the distributional thesaurus could be contextualized via constraining the statistics with words from the context.

Other natural ways to improve the model described here are to make heavier use of parser information or to employ pair-wise or list-wise machine learning models (Cao et al., 2007), which are specifically designed for subset ranking. Lastly, while intrinsic evaluation of lexical substitution is important, we would like to show its practicability in tasks such as steganography or information retrieval.

Abstract

In this paper, we present a novel method for the computation of compositionality within a distributional framework. The key idea is that compositionality is modeled as a multi-way interaction between latent factors, which are automatically constructed from corpus data. We use our method to model the composition of *subject verb object* triples. The method consists of two steps. First, we compute a latent factor model for nouns from standard co-occurrence data. Next, the latent factors are used to induce a latent model of three-way *subject verb object* interactions. Our model has been evaluated on a similarity task for transitive phrases, in which it exceeds the state of the art.

1 Introduction

In the course of the last two decades, significant progress has been made with regard to the automatic extraction of lexical semantic knowledge from large-scale text corpora. Most work relies on the distributional hypothesis of meaning (Harris, 1954), which states that words that appear within the same contexts tend to be semantically similar. A large number of researchers have taken this dictum to heart, giving rise to a plethora of algorithms that try to capture the semantics of words by looking at their distribution in text. Up till now, however, most work on the automatic acquisition of semantics only deals with individual words. The modeling of meaning beyond the level of individual words – i.e. the combination of words into larger units – is to a large degree left unexplored.

The principle of compositionality, often attributed to Frege, is the principle that states that the meaning of a complex expression is a function of the meaning of its parts and the way those parts are (syntactically) combined (Frege, 1892). It is the fundamental principle that allows language users to understand the meaning of sentences they have never heard before, by constructing the meaning of the complex expression from the meanings of the individual words. Recently, a number of researchers have tried to reconcile the framework of distributional semantics with the principle of compositionality (Mitchell and Lapata, 2008; Baroni and Zamparelli, 2010; Coecke et al., 2010; Socher et al., 2012). However, the absolute gains of the systems remain a bit unclear, and a simple method of composition – vector multiplication – often seems to produce the best results (Blacoe and Lapata, 2012).

In this paper, we present a novel method for the joint composition of a verb with its subject and direct object. The key idea is that compositionality is modeled as a multi-way interaction between latent factors, which are automatically constructed from corpus data. In order to adequately model the multi-way interaction between a verb and its subject and objects, a significant part of our method relies on tensor algebra. Additionally, our method makes use of a factorization model appropriate for tensors.

The remainder of the paper is structured as follows. In section 2, we give an overview of previous work that is relevant to the task of computing compositionality within a distributional framework. Section 3 presents a detailed description of our method, including an overview of the necessary mathematical

machinery. Section 4 illustrates our method with a number of detailed examples. Section 5 presents a quantitative evaluation, and compares our method to other models of distributional compositionality. Section 6, then, concludes and lays out a number of directions for future work.

2 Previous Work

In recent years, a number of methods have been developed that try to capture compositional phenomena within a distributional framework. One of the first approaches to tackle compositional phenomena in a systematic way is Mitchell and Lapata’s (2008) approach. They explore a number of different models for vector composition, of which vector addition (the sum of each feature) and vector multiplication (the elementwise multiplication of each feature) are the most important. They evaluate their models on a noun-verb phrase similarity task, and find that the multiplicative model yields the best results, along with a weighted combination of the additive and multiplicative model.

Baroni and Zamparelli (2010) present a method for the composition of adjectives and nouns. In their model, an adjective is a linear function of one vector (the noun vector) to another vector (the vector for the adjective-noun pair). The linear transformation for a particular adjective is represented by a matrix, and is learned automatically from a corpus, using partial least-squares regression.

Coecke et al. (2010) present an abstract theoretical framework in which a sentence vector is a function of the Kronecker product of its word vectors, which allows for greater interaction between the different word features. A number of instantiations of the framework are tested experimentally in Grefenstette and Sadrzadeh (2011a) and Grefenstette and Sadrzadeh (2011b). The key idea is that relational words (e.g. adjectives or verbs) have a rich (multi-dimensional) structure that acts as a filter on their arguments. Our model uses an intuition similar to theirs.

Socher et al. (2012) present a model for compositionality based on recursive neural networks. Each node in a parse tree is assigned both a vector and a matrix; the vector captures the actual meaning of the constituent, while the matrix models the way

it changes the meaning of neighbouring words and phrases.

Closely related to the work on compositionality is research on the computation of word meaning in context. Erk and Padó (2008, 2009) make use of selectional preferences to express the meaning of a word in context; the meaning of a word in the presence of an argument is computed by multiplying the word’s vector with a vector that captures the inverse selectional preferences of the argument. Thater et al. (2009, 2010) extend the approach based on selectional preferences by incorporating second-order co-occurrences in their model. And Dinu and Lapata (2010) propose a probabilistic framework that models the meaning of words as a probability distribution over latent factors. This allows them to model contextualized meaning as a change in the original sense distribution. Dinu and Lapata use non-negative matrix factorization (NMF) to induce latent factors. Similar to their work, our model uses NMF – albeit in a slightly different configuration – as a first step towards our final factorization model.

In general, latent models have proven to be useful for the modeling of word meaning. One of the best known latent models of semantics is Latent Semantic Analysis (Landauer and Dumais, 1997), which uses singular value decomposition in order to automatically induce latent factors from term-document matrices. Another well known latent model of meaning, which takes a generative approach, is Latent Dirichlet Allocation (Blei et al., 2003).

Tensor factorization has been used before for the modeling of natural language. Giesbrecht (2010) describes a tensor factorization model for the construction of a distributional model that is sensitive to word order. And Van de Cruys (2010) uses a tensor factorization model in order to construct a three-way selectional preference model of verbs, subjects, and objects. Our underlying tensor factorization – Tucker decomposition – is the same as Giesbrecht’s; and similar to Van de Cruys (2010), we construct a latent model of verb, subject, and object interactions. The way our model is constructed, however, is significantly different. The former research does not use any syntactic information for the construction of the tensor, while the latter makes use of a more restricted tensor factorization model, viz. parallel factor analysis (Harshman and Lundy, 1994).

The idea of modeling compositionality by means of tensor (Kronecker) product has been proposed in the literature before (Clark and Pulman, 2007; Coecke et al., 2010). However, the method presented here is the first that tries to capture compositional phenomena by exploiting the multi-way interactions between latent factors, induced by a suitable tensor factorization model.

3 Methodology

3.1 Mathematical preliminaries

The methodology presented in this paper requires a number of concepts and mathematical operations from tensor algebra, which are briefly reviewed in this section. The interested reader is referred to Kolda and Bader (2009) for a more thorough introduction to tensor algebra (including an overview of various factorization methods).

A *tensor* is a multidimensional array; it is the generalization of a matrix to more than two dimensions, or *modes*. Whereas matrices are only able to capture two-way co-occurrences, tensors are able to capture *multi-way* co-occurrences.¹ Following prevailing convention, tensors are represented by boldface Euler script notation (\mathcal{X}), matrices by boldface capital letters (\mathbf{X}), vectors by boldface lower case letters (\mathbf{x}), and scalars by italic letters (x).

The *n-mode product* of a tensor $\mathcal{X} \in \mathbb{R}^{I_1 \times I_2 \times \dots \times I_N}$ with a matrix $\mathbf{U} \in \mathbb{R}^{J \times I_n}$ is denoted by $\mathcal{X} \times_n \mathbf{U}$, and is defined elementwise as

$$(\mathcal{X} \times_n \mathbf{U})_{i_1 \dots i_{n-1} j_{i_n+1} \dots i_N} = \sum_{i_n=1}^{I_n} x_{i_1 i_2 \dots i_N} u_{j_{i_n}} \quad (1)$$

The *Kronecker product* of matrices $\mathbf{A} \in \mathbb{R}^{I \times J}$ and $\mathbf{B} \in \mathbb{R}^{K \times L}$ is denoted by $\mathbf{A} \otimes \mathbf{B}$. The result is a matrix of size $(IK) \times (JL)$, and is defined by

$$\mathbf{A} \otimes \mathbf{B} = \begin{bmatrix} a_{11}\mathbf{B} & a_{12}\mathbf{B} & \dots & a_{1J}\mathbf{B} \\ a_{21}\mathbf{B} & a_{22}\mathbf{B} & \dots & a_{2J}\mathbf{B} \\ \vdots & \vdots & \ddots & \vdots \\ a_{I1}\mathbf{B} & a_{I2}\mathbf{B} & \dots & a_{IJ}\mathbf{B} \end{bmatrix} \quad (2)$$

¹In this research, we limit ourselves to three-way co-occurrences of verbs, subject, and objects, modelled using a three-mode tensor.

A special case of the Kronecker product is the *outer product* of two vectors $\mathbf{a} \in \mathbb{R}^I$ and $\mathbf{b} \in \mathbb{R}^J$, denoted $\mathbf{a} \circ \mathbf{b}$. The result is a matrix $\mathbf{A} \in \mathbb{R}^{I \times J}$ obtained by multiplying each element of \mathbf{a} with each element of \mathbf{b} .

Finally, the *Hadamard product*, denoted $\mathbf{A} * \mathbf{B}$, is the elementwise multiplication of two matrices $\mathbf{A} \in \mathbb{R}^{I \times J}$ and $\mathbf{B} \in \mathbb{R}^{I \times J}$, which produces a matrix that is equally of size $I \times J$.

3.2 The construction of latent noun factors

The first step of our method consists in the construction of a latent factor model for nouns, based on their context words. For this purpose, we make use of non-negative matrix factorization (Lee and Seung, 2000). Non-negative matrix factorization (NMF) minimizes an objective function – in our case the Kullback-Leibler (KL) divergence – between an original matrix $\mathbf{V}_{I \times J}$ and $\mathbf{W}_{I \times K} \mathbf{H}_{K \times J}$ (the matrix multiplication of matrices \mathbf{W} and \mathbf{H}) subject to the constraint that all values in the three matrices be non-negative. Parameter K is set $\ll I, J$ so that a reduction is obtained over the original data. The factorization model is represented graphically in figure 1.

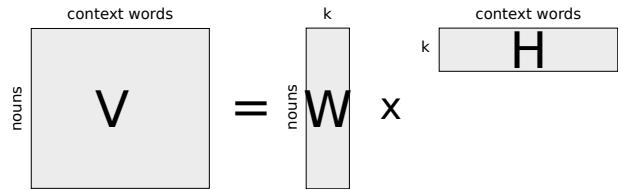

Figure 1: Graphical representation of NMF

NMF can be computed fairly straightforwardly, alternating between the two iterative update rules represented in equations 3 and 4. The update rules are guaranteed to converge to a local minimum in the KL divergence.

$$\mathbf{H}_{a\mu} \leftarrow \mathbf{H}_{a\mu} \frac{\sum_i \mathbf{W}_{ia} \frac{\mathbf{v}_{iu}}{(\mathbf{WH})_{iu}}}{\sum_k \mathbf{W}_{ka}} \quad (3)$$

$$\mathbf{W}_{ia} \leftarrow \mathbf{W}_{ia} \frac{\sum_\mu \mathbf{H}_{a\mu} \frac{\mathbf{v}_{iu}}{(\mathbf{WH})_{iu}}}{\sum_v \mathbf{H}_{av}} \quad (4)$$

3.3 Modeling multi-way interactions

In our second step, we construct a multi-way interaction model for *subject verb object* (*svo*) triples, based

on the latent factors induced in the first step. Our latent interaction model is inspired by a tensor factorization model called Tucker decomposition (Tucker, 1966), although our own model instantiation differs significantly. In order to explain our method, we first revisit Tucker decomposition, and subsequently explain how our model is constructed.

3.3.1 Tucker decomposition

Tucker decomposition is a multilinear generalization of the well-known singular value decomposition, used in Latent Semantic Analysis. It is also known as higher order singular value decomposition (HOSVD, De Lathauwer et al. (2000)). In Tucker decomposition, a tensor is decomposed into a core tensor, multiplied by a matrix along each mode. For a three-mode tensor $\mathcal{X} \in \mathbb{R}^{I \times J \times L}$, the model is defined as

$$\mathcal{X} = \mathcal{G} \times_1 \mathbf{A} \times_2 \mathbf{B} \times_3 \mathbf{C} \quad (5)$$

$$= \sum_{p=1}^P \sum_{q=1}^Q \sum_{r=1}^R g_{pqr} \mathbf{a}_p \circ \mathbf{b}_q \circ \mathbf{c}_r \quad (6)$$

Setting $P, Q, R \ll I, J, L$, the core tensor \mathcal{G} represents a compressed, latent version of the original tensor \mathcal{X} ; matrices $\mathbf{A} \in \mathbb{R}^{I \times P}$, $\mathbf{B} \in \mathbb{R}^{J \times Q}$, and $\mathbf{C} \in \mathbb{R}^{L \times R}$ represent the latent factors for each mode, while $\mathcal{G} \in \mathbb{R}^{P \times Q \times R}$ indicates the level of interaction between the different latent factors. Figure 2 shows a graphical representation of Tucker decomposition.²

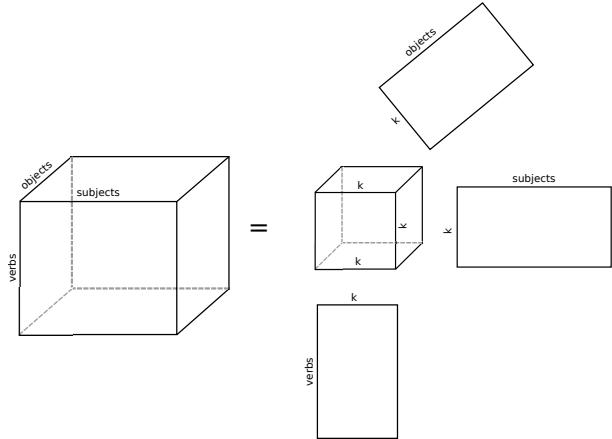

Figure 2: A graphical representation of Tucker decomposition

²where $P = Q = R = K$, i.e. the same number of latent factors K is used for each mode

3.3.2 Reconstructing a Tucker model from two-way factors

Computing the Tucker decomposition of a tensor is rather costly in terms of time and memory requirements. Moreover, the decomposition is not unique: the core tensor \mathcal{G} can be modified without affecting the model's fit by applying the inverse modification to the factor matrices. These two drawbacks led us to consider an alternative method for the construction of the Tucker model. Specifically, we consider the factor matrices as given (as the output from our first step), and proceed to compute the core tensor \mathcal{G} . Additionally, we do not use a latent representation for the first mode, which means that the first mode is represented by its original instances.

Our model can be straightforwardly applied to language data. The core tensor \mathcal{G} models the latent interactions between verbs, subject, and objects. \mathcal{G} is computed by applying the n-mode product to the appropriate mode of the original tensor (equation 7),

$$\mathcal{G} = \mathcal{X} \times_2 \mathbf{W}^T \times_3 \mathbf{W}^T \quad (7)$$

where $\mathcal{X}^{V \times N \times N}$ is our original data tensor, consisting of the weighted co-occurrence frequencies of *svo* triples (extracted from corpus data), and $\mathbf{W}^{N \times K}$ is our latent factor matrix for nouns. Note that we do not use a latent representation for the verb mode. To be able to efficiently compute the similarity of verbs (both within and outside of compositional phrases), only the *subject* and *object* mode are represented by latent factors, while the *verb* mode is represented by its original instances. This means that our core tensor \mathcal{G} will be of size $V \times K \times K$.³ A graphical representation is given in figure 3.

Note that both tensor \mathcal{X} and factor matrices \mathbf{W} are non-negative, which means our core tensor \mathcal{G} will also be non-negative.

3.4 The composition of *svo* triples

In order to compute the composition of a particular subject verb object triple $\langle s, v, o \rangle$, we first extract the appropriate subject vector \mathbf{w}_s and object vector \mathbf{w}_o (both of length K) from our factor matrix \mathbf{W} , and

³It is straightforward to also construct a latent factor model for verbs using NMF, and include it in the construction of our core tensor; we believe such a model might have interesting applications, but we save this as an exploration for future work.

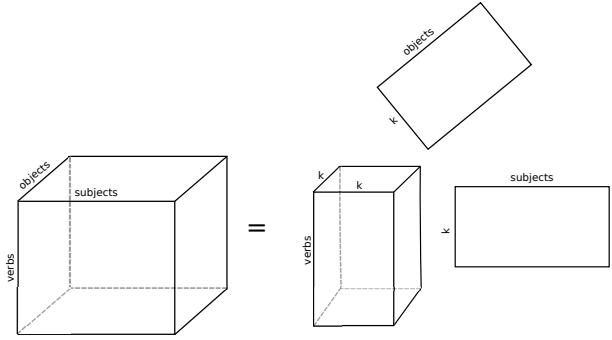

Figure 3: A graphical representation of our model instantiation without the latent verb mode

compute the outer product of both vectors, resulting in a matrix \mathbf{Y} of size $K \times K$.

$$\mathbf{Y} = \mathbf{w}_s \circ \mathbf{w}_o \quad (8)$$

Our second and final step is then to weight the original verb matrix \mathbf{G}_v of latent interactions (the appropriate verb slice of tensor \mathcal{G}) with matrix \mathbf{Y} , containing the latent interactions of the specific subject and object. This is carried out by taking the Hadamard product of \mathbf{G}_v and \mathbf{Y} .

$$\mathbf{Z} = \mathbf{G}_v * \mathbf{Y} \quad (9)$$

4 Example

In this section, we present a number of example computations that clarify how our model is able to capture compositionality. All examples come from actual corpus data, and are computed in a fully automatic and unsupervised way.

Consider the following two sentences:

- (1) The athlete runs a race.
- (2) The user runs a command.

Both sentences contain the verb *run*, but they represent clearly different actions. When we compute the composition of both instances of *run* with their respective subject and object, we want our model to show this difference.

To compute the compositional representation of sentences (1) and (2), we proceed as follows. First, we extract the latent vectors for subject and object ($\mathbf{w}_{\text{athlete}}$ and \mathbf{w}_{race} for the first sentence, \mathbf{w}_{user} and $\mathbf{w}_{\text{command}}$ for the second sentence) from matrix \mathbf{W} .

Next, we compute the outer product of subject and object – $\mathbf{w}_{\text{athlete}} \circ \mathbf{w}_{\text{race}}$ and $\mathbf{w}_{\text{user}} \circ \mathbf{w}_{\text{command}}$ – which yields matrices $\mathbf{Y}_{\langle \text{athlete}, \text{race} \rangle}$ and $\mathbf{Y}_{\langle \text{user}, \text{command} \rangle}$. By virtue of the outer product, the matrices \mathbf{Y} – of size $K \times K$ – represent the level of interaction between the latent factors of the subject and the latent factors of the object. We can inspect these interactions by looking up the factor pairs (i.e. matrix cells) with the highest values in the matrices \mathbf{Y} . Table 1 presents the factor pairs with highest value for matrix $\mathbf{Y}_{\langle \text{athlete}, \text{race} \rangle}$; table 2 represents the factor pairs with highest value for matrix $\mathbf{Y}_{\langle \text{user}, \text{command} \rangle}$. In order to render the factors interpretable, we include the three most salient words for the various factors (i.e. the words with the highest value for a particular factor).

The examples in tables 1 and 2 give an impression of the effect of the outer product: semantic features of the subject combine with semantic features of the object, indicating the extent to which these features interact within the expression. In table 1, we notice that animacy features (28, 195) and a sport feature (25) combine with a ‘sport event’ feature (119). In table 2, we see that similar animacy features (40, 195) and technological features (7, 45) combine with another technological feature (89).

Similarly, we can inspect the latent interactions of the verb *run*, which are represented in the tensor slice \mathbf{G}_{run} . Note that this matrix contains the verb semantics computed over the complete corpus. The most salient factor interactions for \mathbf{G}_{run} are represented in table 3.

Table 3 illustrates that different senses of the verb *run* are represented within the matrix \mathbf{G}_{run} . The first two factor pairs hint at the ‘organize’ sense of the verb (*run a seminar*). The third factor pair represents the ‘transport’ sense of the verb (*the bus runs every hour*).⁴ And the fourth factor pair represents the ‘execute’ or ‘deploy’ sense of *run* (*run Linux*, *run a computer program*). Note that we only show the factor pairs with the highest value; matrix \mathbf{G} contains a value for each pairwise combination of the latent factors, effectively representing a rich latent semantics for the verb in question.

The last step is to take the Hadamard product of matrices \mathbf{Y} with verb matrix \mathbf{G} , which yields our final

⁴Obviously, *hour* is not an object of the verb, but due to parsing errors it is thus represented.

factors	subject	object	value

$\langle 40, 89 \rangle$	<i>anyone (.004), reader (.004), anybody (.003)</i>	<i>filename (.007), null (.006), integer (.006)</i>	.007
$\langle 195, 89 \rangle$	<i>people (.008), child (.008), adolescent (.007)</i>	<i>filename (.007), null (.006), integer (.006)</i>	.006
$\langle 45, 89 \rangle$	<i>website (.004), Click (.003), site (.003)</i>	<i>filename (.007), null (.006), integer (.006)</i>	.006

Table 2: Factor pairs with highest value for matrix $\mathbf{Y}_{\langle \text{user}, \text{command} \rangle}$

matrices, $\mathbf{Z}_{\text{run}, \langle \text{athlete}, \text{race} \rangle}$ and $\mathbf{Z}_{\text{run}, \langle \text{user}, \text{command} \rangle}$. The Hadamard product will act as a bidirectional filter on the semantics of both the verb and its subject and object: interactions of semantic features that are present in both matrix \mathbf{Y} and \mathbf{G} will be highlighted, while the other interactions are played down. The result is a representation of the verb’s semantics tuned to its particular subject-object combination. Note that this final step can be viewed as an instance of function application (Baroni and Zamparelli, 2010). Also note the similarity to Grefenstette and Sadrzadeh’s (2011a, 2011b) approach, who equally make use of the elementwise matrix product in order to weight the semantics of the verb.

We can now go back to our original tensor \mathcal{G} , and compute the most similar verbs (i.e. the most similar tensor slices) for our newly computed matrices \mathbf{Z} .⁵

If we do this for matrix $\mathbf{Z}_{\text{run}, \langle \text{athlete}, \text{race} \rangle}$, our model comes up with verbs *finish* (.29), *attend* (.27), and *win* (.25). If, instead, we compute the most similar verbs for $\mathbf{Z}_{\text{run}, \langle \text{user}, \text{command} \rangle}$, our model yields *execute* (.42), *modify* (.40), *invoke* (.39).

Finally, note that the design of our model naturally takes into account word order. Consider the following two sentences:

- (3) man damages car
- (4) car damages man

⁵Similarity is calculated by measuring the cosine of the vectorized and normalized representation of the verb matrices.

Both sentences contain the exact same words, but the process of damaging described in sentences (3) and (4) is of a rather different nature. Our model is able to take this difference into account: if we compute $\mathbf{Z}_{\text{damage}, \langle \text{man}, \text{car} \rangle}$ following sentence (3), our model yields *crash* (.43), *drive* (.35), *ride* (.35) as most similar verbs. If we do the same for $\mathbf{Z}_{\text{damage}, \langle \text{car}, \text{man} \rangle}$ following sentence (4), our model instead yields *scare* (.26), *kill* (.23), *hurt* (.23).

5 Evaluation

5.1 Methodology

In order to evaluate the performance of our tensor-based factorization model of compositionality, we make use of the sentence similarity task for transitive sentences, defined in Grefenstette and Sadrzadeh (2011a). This is an extension of the similarity task for compositional models developed by Mitchell and Lapata (2008), and constructed according to the same guidelines. The dataset contains 2500 similarity judgements, provided by 25 participants, and is publicly available.⁶

The data consists of transitive verbs, each paired with both a subject and an object noun – thus forming a small transitive sentence. Additionally, a ‘landmark’ verb is provided. The idea is to compose both the target verb and the landmark verb with subject and noun, in order to form two small compositional

⁶<http://www.cs.ox.ac.uk/activities/CompDistMeaning/GS2011data.txt>

factors	subject	object	value
$\langle 128, 181 \rangle$	<i>Mathematics (.004), Science (.004), Economics (.004)</i>	<i>course (.005), tutorial (.005), seminar (.005)</i>	.058
$\langle 293, 181 \rangle$	<i>organization (.007), association (.007), federation (.006)</i>	<i>course (.005), tutorial (.005), seminar (.005)</i>	.053
$\langle 60, 140 \rangle$	<i>rail (.011), bus (.009), ferry (.008)</i>	<i>third (.004), decade (.004), hour (.004)</i>	.038
$\langle 268, 268 \rangle$	<i>API (.008), Apache (.007), Unix (.007)</i>	<i>API (.008), Apache (.007), Unix (.007)</i>	.038

Table 3: Factor combinations for \mathbf{G}_{run}

phrases. The system is then required to come up with a suitable similarity score for these phrases. The correlation of the model’s judgements with human judgements (scored 1–7) is then calculated using Spearman’s ρ . Two examples of the task are provided in table 4.

p	target	subject	object	landmark	sim
19	meet	system	criterion	visit	1
21	write	student	name	spell	6

Table 4: Two example judgements from the phrase similarity task defined by Grefenstette and Sadrzadeh (2011a)

Grefenstette and Sadrzadeh (2011a) seem to calculate the similarity score contextualizing both the target verb and the landmark verb. Another possibility is to contextualize only the target verb, and compute the similarity score with the non-contextualized landmark verb. In our view, the latter option provides a better assessment of the model’s similarity judgements, since contextualizing low-similarity landmarks often yields non-sensical phrases (e.g. *system visits criterion*). We provide scores for both contextualized and non-contextualized landmarks.

We compare our results to a number of different models. The first is Mitchell and Lapata’s (2008) model, which computes the elementwise vector multiplication of verb, subject and object. The second is Grefenstette and Sadrzadeh’s (2011b) best scoring model instantiation of the categorical distributional compositional model (Coecke et al., 2010). This model computes the outer product of the subject and object vector, the outer product of the verb vector with itself, and finally the elementwise product of both results. It yields the best score on the transitive sentence similarity task reported to date.

As a baseline, we compute the non-contextualized

similarity score for target verb and landmark. The upper bound is provided by Grefenstette and Sadrzadeh (2011a), based on interannotator agreement.

5.2 Implementational details

All models have been constructed using the UKWAC corpus (Baroni et al., 2009), a 2 billion word corpus automatically harvested from the web. From this data, we accumulate the input matrix \mathbf{V} for our first NMF step. We use the 10K most frequent nouns, cross-classified by the 2K most frequent context words.⁷ Matrix \mathbf{V} is weighted using pointwise mutual information (PMI, Church and Hanks (1990)).

A parsed version of the corpus is available, which has been parsed with MaltParser (Nivre et al., 2006). We use this version in order to extract our *svo* triples. From these triples, we construct our tensor \mathcal{X} , using 1K verbs \times 10K subjects \times 10K objects. Note once again that the subject and object instances in the second step are exactly the same as the noun instances in the first step. Tensor \mathcal{X} has been weighted using a three-way extension of PMI, following equation 10 (Van de Cruys, 2011).

$$pmi3(x, y, z) = \log \frac{p(x, y, z)}{p(x)p(y)p(z)} \quad (10)$$

We set $K = 300$ as our number of latent factors. The value was chosen as a trade-off between a model that is both rich enough, and does not require an excessive amount of memory (for the modeling of the core tensor). The algorithm runs fairly efficiently. Each NMF step is computed in a matter of seconds, with convergence after 50–100 iterations. The construction of the core tensor is somewhat more

⁷We use a context window of 5 words, both before and after the target word; a stop list was used to filter out grammatical function words.

evolved, but does not exceed a wall time of 30 minutes. Results have been computed on a machine with Intel Xeon 2.93Ghz CPU and 32GB of RAM.

5.3 Results

The results of the various models are presented in table 5; *multiplicative* represents Mitchell and Lapata’s (2008) multiplicative model, *categorical* represents Grefenstette and Sadrzadeh’s (2011b) model, and *latent* represents the model presented in this paper.

model	contextualized	non-contextualized
baseline		.23
multiplicative	.32	.34
categorical	.32	.35
latent	.32	.37
upper bound		.62

Table 5: Results of the different compositionality models on the phrase similarity task

In the contextualized version of the similarity task (in which the landmark is combined with subject and object), all three models obtain the same result (.32). However, in the non-contextualized version (in which only the target verb is combined with subject and object), the models differ in performance. These differences are statistically significant.⁸ As mentioned before, we believe the non-contextualized version of the task gives a better impression of the systems’ ability to capture compositionality. The contextualization of the landmark verb often yields non-sensical combinations, such as *system visits criterion*. We therefore deem it preferable to compute the similarity of the target verb in composition (*system meets criterion*) to the non-contextualized semantics of the landmark verb (*visit*).

Note that the scores presented in this evaluation (including the baseline score) are significantly higher than the scores presented in Grefenstette and Sadrzadeh (2011b). This is not surprising, since the corpus we use – UKWAC – is an order of magnitude larger than the corpus used in their research – the British National Corpus (BNC). Presumably, the scores are also favoured by our weighting measure.

⁸ $p < 0.01$; model differences have been tested using stratified shuffling (Yeh, 2000).

In our experience, PMI performs better than weighting with conditional probabilities.⁹

6 Conclusion

In this paper, we presented a novel method for the computation of compositionality within a distributional framework. The key idea is that compositionality is modeled as a multi-way interaction between latent factors, which are automatically constructed from corpus data. We used our method to model the composition of *subject verb object* combinations. The method consists of two steps. First, we compute a latent factor model for nouns from standard co-occurrence data. Next, the latent factors are used to induce a latent model of three-way *subject verb object* interactions, represented by a core tensor. Our model has been evaluated on a similarity task for transitive phrases, in which it matches and even exceeds the state of the art.

We conclude with a number of future work issues. First of all, we would like to extend our framework in order to incorporate more compositional phenomena. Our current model is designed to deal with the latent modeling of *subject verb object* combinations. We would like to investigate how other compositional phenomena might fit within our latent interaction framework, and how our model is able to tackle the computation of compositionality across a differing number of modes.

Secondly, we would like to further explore the possibilities of our model in which all three modes are represented by latent factors. The instantiation of our model presented in this paper has two latent modes, using the original instances of the verb mode in order to efficiently compute verb similarity. We think a full-blown latent interaction model might prove to have interesting applications in a number of NLP tasks, such as the paraphrasing of compositional expressions.

Finally, we would like to test our method using a number of different evaluation frameworks. We think tasks of similarity judgement have their merits, but in a way are also somewhat limited. In our opinion, research on the modeling of compositional phenomena within a distributional framework would substantially

⁹Contrary to the findings of Mitchell and Lapata (2008), who report a high correlation with human similarity judgements.

benefit from new evaluation frameworks. In particular, we think of a lexical substitution or paraphrasing task along the lines of McCarthy and Navigli (2009), but specifically aimed at the assessment of compositional phenomena.

Abstract

Twitter offers an unprecedented advantage on live reporting of the events happening around the world. However, summarizing the Twitter event has been a challenging task that was not fully explored in the past. In this paper, we propose a participant-based event summarization approach that “zooms-in” the Twitter event streams to the participant level, detects the important sub-events associated with each participant using a novel mixture model that combines the “burstiness” and “cohesiveness” properties of the event tweets, and generates the event summaries progressively. We evaluate the proposed approach on different event types. Results show that the participant-based approach can effectively capture the sub-events that have otherwise been shadowed by the long-tail of other dominant sub-events, yielding summaries with considerably better coverage than the state-of-the-art.

1 Introduction

Twitter has increasingly become a critical source of information. People report the events they are experiencing or publish comments on a wide variety of events happening around the world, ranging from the unexpected natural disasters, regional riots, to many scheduled events, such as sports games, political debates, local festivals, and even academic conferences. The Twitter data streams thus cover a broad range of events and broadcast these information in a live manner. Event summarization in this paper aims to generate a representative and concise textual description of the *scheduled* events

that are being lively reported on Twitter, providing people with an alternative means of observing the world beyond the traditional journalism. Specifically, we investigate scheduled events of different types, including six of the NBA (National Basketball Association) sports games and a representative conference event, namely the Apple CEO’s keynote speech in the Apple Worldwide Developers Conference (WWDC 2012)¹. All these events have excited great discussion among the Twitter community.

Summarizing the Twitter event is a challenging task that has yet been fully explored in the past. Most previous summarization studies focus on the well-formatted news documents, as driven by the annual DUC² and TAC³ evaluations. In contrast, the Twitter messages (a.k.a., tweets) are very short and noisy, containing nonstandard terms such as abbreviations, acronyms, emoticons, etc. (Liu et al., 2011b; Liu et al., 2012; Eisenstein, 2013). The noisy contents also cause great difficulties to the traditional NLP tools such as NER and dependency parser (Ritter et al., 2011; Foster et al., 2011), limiting the possibility of applying finer-grained event analysis tools. In nature, the event tweets are closely associated with the timeline and are drastically different from a static collection of news documents. The tweets converge into text streams that pulse along the timeline and cluster around the important moments or sub-events. These “sub-events” are of crucial importance since they represent a surge of interest from the Twitter audience and the correspond-

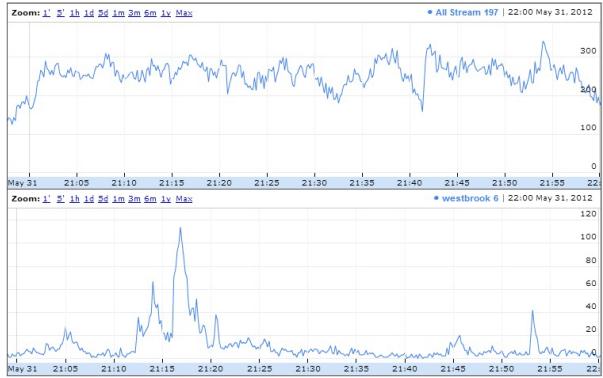

Figure 1: Example Twitter event stream (upper) and participant stream (lower). Event stream contains tweets related to an NBA basketball game (Spurs vs Thunder) scheduled on May 31, 2012; participant stream contains tweets corresponding to the player Russell Westbrook in team Thunder. X-axis denotes the timeline and y-axis represents the number of tweets per 10-second interval.

ing key information must be reflected in the event summary. As such, event summarization research has been focusing on developing accurate sub-event detection systems and generating text descriptions that can best summarize the sub-events in a progressive manner (Chakrabarti and Punera, 2011; Nichols et al., 2012; Zubiaga et al., 2012).

In Figure 1, we show an example Twitter event stream and one of its “participant” streams. The event stream contains all the tweets related to an NBA basketball game Spurs vs Thunder; while the participant stream contains only tweets corresponding to the player Russell Westbrook in this game. Previous research on event summarization focuses on identifying the important moments from the coarse-level event stream. This may yield several side effects: first, the spike patterns are not clearly identifiable from the overall event stream, though they are more clearly seen if we “zoom-in” to the participant level; second, it is arguable whether the important sub-events can be accurately detected based solely on the tweet volume change; third, a popular participant or sub-event can elicit huge volume of tweets which dominate the event discussion and shield less prominent sub-events. For example, in the NBA games, discussions about the key players (e.g., “LeBron James”, “Kobe Bryant”) can heavily shadow other important participants or sub-events, resulting in an event summary with repetitive descriptions about the dominant players.

In this work, we propose a novel participant-based event summarization approach, which dynamically identifies the participants from data streams, then “zooms-in” the event stream to participant level, detects the important sub-events related to each participant using a novel time-content mixture model, and generates the event summary progressively by concatenating the descriptions of the important sub-events. Results show that the mixture model-based sub-event detection approach can efficiently incorporate the “burstiness” and “cohesiveness” of the participant streams, and the participant-based event summarization can effectively capture the sub-events that have otherwise been shadowed by the long-tail of other dominant sub-events, yielding summaries with considerably better coverage than the state-of-the-art approach.

2 Related Work

Mining Twitter for event information has received increasing attention in recent years. Many research studies focus on identifying the trending events from Twitter and providing a concise and dynamic visualization of the information. The identified events are often represented using a set of keywords. (Petrovic et al., 2010) proposed an algorithm based on locality-sensitive hashing for detecting new events from a stream of Twitter posts. (O’Connor et al., 2010; Becker et al., 2011b; Becker et al., 2011a; Weng et al., 2011) proposed demo systems to display the event-related themes and popular tweets, allowing the users to navigate through their topic of interest. (Zhao et al., 2011) described an effort to perform data collection and event recognition despite various limits to the free access of Twitter data. (Diao et al., 2012) integrated both temporal information and users’ personal interests for bursty topic detection from the microblogs. (Ritter et al., 2012) described an open-domain event-extraction and categorization system, which extracts an open-domain calendar of significant events from Twitter.

With the identified events of interest, there is an ever-increasing demand for event summarization, which distills the huge volume of Twitter discussions into a concise and representative textual description of the events. Many studies start with the text summarization approaches that have been shown to perform well on the news documents and

develop adaptations to fit these methods to a collection of event tweets. (Sharifi et al., 2010b) proposed a graph-based phrase reinforcement algorithm to build a one-sentence summary from a collection of topic tweets. (Sharifi et al., 2010a; Inouye and Kalita, 2011) presented a hybrid TF-IDF approach to extract one- or multiple-sentence summary for each topic. (Liu et al., 2011a) proposed to use the concept-based ILP framework for summarizing the Twitter trending topics, using both tweets and the webpages linked from the tweets as input text sources. (Harabagiu and Hickl, 2011) introduced a generative framework that incorporates event structure and user behavior information in summarizing multiple microblog posts related to the same topic.

Regarding summarizing the data streams, (Marcus et al., 2011) introduced a “TwitInfo” system to visually summarize and track the events on Twitter. They proposed an automatic peak detection and labeling algorithm for the social streams. (Takamura et al., 2011) proposed a summarization model based on the facility location problem, which generates summary for a stream of short documents along the timeline. (Chakrabarti and Punera, 2011) proposed an event summarization algorithm based on learning an underlying hidden state representation of the event via hidden Markov models. (Louis and Newman, 2012) presented a method for summarizing a collection of tweets related to a business. The proposed procedure aggregates tweets into subtopic clusters which are then ranked and summarized by a few representative tweets from each cluster. (Nichols et al., 2012; Zubiaga et al., 2012) focused on real-time event summarization, which detects the sub-events by identifying those moments where the tweet volume has increases sharply, then uses various weighting schemes to perform tweet selection and finally generates the event summary.

Our work is different from the above research studies in three folds: first, we propose to “zoom-in” the Twitter event streams to the participant level, which allows us to clearly identify the important sub-events associated with each participant and generate a balanced event summary with comprehensive coverage of all the important sub-events; second, we propose a novel time-content mixture model approach for sub-event detection, which effectively leverages the “burstiness” and “cohesive-

ness” of the event tweets and accurately detects the participant-level sub-events. Third, we evaluate the participant-based event summarization system on different event types and demonstrate that the proposed approach outperforms the state-of-the-art method by a considerable margin.

3 Participant-based Event Summarization

We propose a novel participant-centered event summarization approach that consists of three key components: (1) “Participant Detection” dynamically identifies the event participants and divides the entire event stream into a number of participant streams (Section 3.1); (2) “Sub-event Detection” introduces a novel time-content mixture model approach to identify the important sub-events associated with each participant; these “participant-level sub-events” are then merged along the timeline to form a set of “global sub-events”⁴, which capture all the important moments in the event stream (Section 3.2); (3) “Summary Tweet Extraction” extracts the representative tweets from the global sub-events and forms a comprehensive coverage of the event progress (Section 3.3).

3.1 Participant Detection

We define event participants as the entities that play a significant role in shaping the event progress. “Participant” is a general concept to denote the event participating persons, organizations, product lines, etc., each of which can be captured by a set of correlated proper nouns. For example, the NBA player “LeBron Raymone James” can be represented by $\{LeBron\ James, LeBron, LBJ, King\ James, L. James\}$, where each proper noun represents a unique mention of the participant. In this work, we automatically identify the proper nouns from tweet streams, filter out the infrequent ones using a threshold ψ , and cluster them into individual event participants. This process allows us to dynamically identify the key participating entities and provide a full-coverage for these participants in the event summary.

⁴We use “**participant sub-events**” and “**global sub-events**” respectively to represent the important moments happened on the participant-level and on the entire event-level. A “global sub-event” may consist of one or more “participant sub-events”. For example., the “steal” action in the basketball game typically involves both the defensive and offensive players, and can be generated by merging the two participant-level sub-events.

We formulate the participant detection in a hierarchical agglomerative clustering framework. The CMU TweetNLP tool (Gimpel et al., 2011) was used for proper noun tagging. The proper nouns (a.k.a., mentions) are grouped into clusters in a bottom-up fashion. Two mentions are considered similar if they share (1) lexical resemblance, and (2) contextual similarity. For example, in the following two tweets “*Gotta respect Anthony Davis, still rocking the unibrow*”, “*Anthony gotta do something about that unibrow*”, the two mentions *Anthony Davis* and *Anthony* are referring to the same participant and they share both character overlap (“*anthony*”) and context words (“*unibrow*”, “*gotta*”). We use $\text{sim}(c_i, c_j)$ to represent the similarity between two mentions c_i and c_j , defined as:

$$\text{sim}(c_i, c_j) = \text{lex_sim}(c_i, c_j) \times \text{cont_sim}(c_i, c_j)$$

where the lexical similarity ($\text{lex_sim}(\cdot)$) is defined as a binary function representing whether a mention c_i is an abbreviation, acronym, or part of another mention c_j , or if the character edit distance between the two mentions is less than a threshold θ^5 :

$$\text{lex_sim}(c_i, c_j) = \begin{cases} 1 & c_i(c_j) \text{ is part of } c_j(c_i) \\ 1 & \text{EditDist}(c_i, c_j) < \theta \\ 0 & \text{Otherwise} \end{cases}$$

We define the context similarity ($\text{cont_sim}(\cdot)$) of two mentions as the cosine similarity between their context vectors \vec{v}_i and \vec{v}_j . Note that on the tweet stream, two temporally distant tweets can be very different even though they are lexically similar, e.g., two slam dunk shots performed by the same player at different time points are different. We therefore restrain the context to a segment of the tweet stream $|S_k|$ and then take the weighted average of the segment-based similarity as the final context similarity. To build the context vector, we use term frequency (TF) as the term weight and remove all the stopwords. We use $|D|$ to represent the total tweets in the event stream.

$$\text{cont_sim}_{|S_k|}(c_i, c_j) = \cos(\vec{v}_i, \vec{v}_j)$$

$$\text{cont_sim}(c_i, c_j) = \sum_k \frac{|S_k|}{|D|} \times \text{cont_sim}_{|S_k|}(c_i, c_j)$$

⁵ θ was empirically set as $0.2 \times \min\{|c_i|, |c_j|\}$

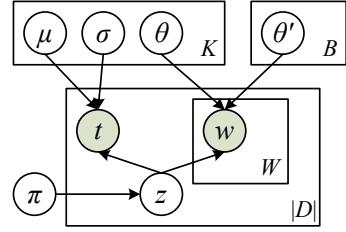

Figure 2: Plate notation of the mixture model.

Similarity between two clusters of mentions are defined as the maximum possible similarity between a pair of mentions, each from one cluster:

$$\text{sim}(C_i, C_j) = \max_{c_i \in C_i, c_j \in C_j} \text{sim}(c_i, c_j)$$

We perform bottom-up agglomerative clustering on the mentions until a stopping threshold δ has been reached for $\text{sim}(C_i, C_j)$. The clustering approach naturally groups the frequent proper nouns into participants. The **participant streams** are then formed by gathering the tweets that contain one or more mentions in the participant cluster.

3.2 Mixture Model-based Sub-event Detection

A sub-event corresponds to a topic that emerges from the data stream, being intensively discussed during a short period, and then gradually fades away. The tweets corresponding to a sub-event thus demand not only “temporal burstiness” but also a certain degree of “lexical cohesiveness”. To incorporate both the time and content aspects of the sub-events, we propose a mixture model approach for sub-event detection. Figure 2 shows the plate notation.

In the proposed model, each tweet d in the data stream D is generated from a topic z , weighted by π_z . Each topic is characterized by both its content and time aspects. The content aspect is captured by a multinomial distribution over the words, parameterized by θ ; while the time aspect is characterized by a Gaussian distribution, parameterized by μ and σ , with μ represents the average time point that the sub-event emerges and σ determines the duration of the sub-event. These distributions bear similarities with the previous work (Hofmann, 1999; Allan, 2002; Haghghi and Vanderwende, 2009). In addition, there are often background or “noise” topics that are being constantly discussed over the entire

event evolution process and do not present the desired “burstiness” property. We use a uniform distribution $U(t_b, t_e)$ to model the time aspect of these “background” topics, with t_b and t_e being the event beginning and end time points. The content aspect of a background topic is modeled by similar multinomial distribution, parameterized by θ' . We use the maximum likelihood parameter estimation. The data likelihood can be represented as:

$$L(D) = \prod_{d \in D} \sum_z \{\pi_z p_z(t_d) \prod_{w \in d} p_z(w)\}$$

where $p_z(t_d)$ models the timestamp of tweet d under the topic z ; $p_z(w)$ corresponds to the word distribution in topic z . They are defined as:

$$p_z(t_d) = \begin{cases} N(t_d; \mu_z, \sigma_z) & \text{if } z \text{ is a sub-event topic} \\ U(t_b, t_e) & \text{if } z \text{ is background topic} \end{cases}$$

$$p_z(w) = \begin{cases} p(w; \theta_z) & \text{if } z \text{ is a sub-event topic} \\ p(w; \theta'_z) & \text{if } z \text{ is background topic} \end{cases}$$

where both $p(w; \theta_z)$ and $p(w; \theta'_z)$ are multinomial distributions over the words. Initially, we assume there are K sub-event topics and B background topics and use the EM algorithm for model fitting. The EM equations are listed below:

E-step:

$$p(z_d = j) \propto \begin{cases} \pi_j N(d; \mu_j, \sigma_j) \prod_{w \in d} p(w; \theta_j) & \text{if } j \leq K \\ \pi_j U(t_b, t_e) \prod_{w \in d} p(w; \theta'_j) & \text{else} \end{cases}$$

M-step:

$$\pi_j \propto \sum_d p(z_d = j)$$

$$p(w; \theta_j) \propto \sum_d p(z_d = j) \times c(w, d)$$

$$p(w; \theta'_j) \propto \sum_d p(z_d = j) \times c(w, d)$$

$$\mu_j = \frac{\sum_d p(z_d = j) \times t_d}{\sum_{j=1}^K \sum_d p(z_d = j)}$$

$$\sigma_j^2 = \frac{\sum_d p(z_d = j) \times (t_d - \mu_j)^2}{\sum_{j=1}^K \sum_d p(z_d = j)}$$

To process the data stream D , we divide the data into 10-second bins and process each bin at a time.

The peak time of a sub-event was determined as the bin that has the most tweets related to this sub-event. During EM initialization, the number of sub-event topics K was empirically decided by scanning through the data stream and examine tweets in every 3-minute stream segment. If there was a spike⁶, we add a new sub-event to the model and use the tweets in this segment to initialize the value of μ , σ , and θ . Initially, we use a fixed number of background topics with $B = 4$. A topic re-adjustment was performed after the EM process. We merge two sub-events in a data stream if they (1) locate closely in the timeline, with peaks times within a 2-minute window; and (2) share similar word distributions: among the top-10 words with highest probability in the word distributions, there are over 5 words overlap. We also convert the sub-event topics to background topics if their σ values are greater than a threshold β ⁷. We then re-run the EM to obtain the updated parameters. The topic re-adjustment process continues until the number of sub-events and background topics do not change further.

We obtain the “**participant sub-events**” by applying this sub-event detection approach to each of the participant streams. The “**global sub-events**” are obtained by merging the participant sub-events along the timeline. We merge two participant sub-events into a global sub-event if (1) their peaks are within a 2-minute window, and (2) the Jaccard similarity (Lee, 1999) between their associated tweets is greater than a threshold (set to 0.1 empirically). The tweets associated with each global sub-event are the ones with $p(z|d)$ greater than a threshold γ , where z is one of the participant sub-events and γ was set to 0.7 empirically. After the sub-event detection process, we obtain a set of global sub-events and their associated event tweets.⁸

3.3 Summary Tweet Extraction

We extract a representative tweet from each of the global sub-events and concatenate them to form an informative event summary. Note that our goal in this work is to identify all the important moments

⁶We use the algorithm described in (Marcus et al., 2011) as a baseline and ad hoc spike detection algorithm.

⁷ β was set to 5 minutes in our experiments.

⁸We empirically set some threshold values in the topic re-adjustment and sub-event merging process. In future, we would like to explore more principled way of parameter selection.

Event		Date	Duration	#Tweets
N	Lakers vs Okc	05/19/2012	3h10m	218,313
	Celtics vs 76ers	05/23/2012	3h30m	245,734
	Celtics vs Heat	05/30/2012	3h30m	345,335
	Spurs vs Okc	05/31/2012	3h	254,670
	Heat vs Okc (1)	06/12/2012	3h30m	331,498
	Heat vs Okc (2)	06/21/2012	3h30m	332,223
Apple's WWDC'12 Conf.		06/11/2012	3h30m	163,775

Table 1: Statistics of the data set, including six NBA basketball games and the WWDC 2012 conference event.

for event summarization, but not on proposing new methods for tweet selection. We thus use the Hybrid TF-IDF approach (Sharifi et al., 2010a; Liu et al., 2011a) to extract the representative sentences from a collection of tweets. In this approach, each tweet was considered as a sentence. The sentences were ranked according to the average TF-IDF score of the consisting words; top weighted sentences were iteratively extracted, while excluding those that have high cosine similarity with the existing summary sentences. (Inouye and Kalita, 2011) showed the Hybrid TF-IDF approach performs constantly better than the phrase reinforcement algorithm and other traditional summarization systems.

4 Data Corpus

We evaluate the proposed event summarization approach on six NBA basketball games and a representative conference event, namely the Apple CEO’s keynote speech in the Apple Worldwide Developers Conference (WWDC 2012)⁹. We use the heterogeneous event types to verify that the proposed approach can robustly and efficiently produce summaries on different event streams. The tweet streams corresponding to these events are collected using the Twitter Streaming API¹⁰ with pre-defined keyword set. For NBA games, we use the team names, first name and last name of the players and head coaches as keywords for retrieving the event tweets; for the WWDC conference, the keyword set contains about 20 terms related to the Apple event, such as “wwdc”, “apple”, “mac”, etc. We crawl the tweets in real-time when these scheduled events are taking place; nevertheless, certain non-event tweets could be mis-included due to the broad coverage of the used keywords. During preprocessing, we filter out

Time	Action (Sub-event)	Score
9:22	Chris Bosh misses 10-foot two point shot	7-2
9:22	Serge Ibaka defensive rebound	7-2
9:11	Kevin Durant makes 15-foot two point shot	9-2
8:55	Serge Ibaka shooting foul (Shane Battier draws the foul)	9-2
8:55	Shane Battier misses free throw 1 of 2	9-2
8:55	Miami offensive team rebound	9-2
8:55	Shane Battier makes free throw 2 of 2	9-3

Table 2: An example clip of the play-by-play live coverage of an NBA game (Heat vs Okc). “Time” corresponds to the minutes left in the current quarter of the game; “Score” shows the score between the two teams.

the tweets containing URLs, non-English tweets, and retweets since they are less likely containing new information regarding the event progress. Table 1 shows statistics of the event tweets after the filtering process. In total, there are over 1.8 million tweets used in the event summarization experiments.

We use the play-by-play live coverage collected from the ESPN¹¹ and MacRumors¹² websites as reference, which provide detailed descriptions of the NBA and WWDC events as they unfold. Table 2 shows an example clip of the play-by-play descriptions of an NBA game. Ideally, each item in the live coverage descriptions may correspond to a sub-event in the tweet streams, but in reality, not all actions would attract enough attention from the Twitter audience. We use a human annotator to manually filter out the actions that did not lead to any spike in the corresponding participant stream. The rest items are projected to the participant and event streams as the goldstandard sub-events. The projection was manually performed since the “game clock” associated with the goldstandard (first column in Table 2) does not align well with the “wall clock” due to the game rules such as timeout and halftime rest. To evaluate the participant detection performance, we ask the annotator to manually group the proper noun mentions into clusters, each cluster corresponds to a participant. The mentions that do not correspond to any participant are discarded. The goldstandard event summaries are generated by manually selecting one representative tweet from each of the groundtruth global sub-events. We choose not to use the play-by-play descriptions as reference summaries since their vocabulary is rather limited and do not overlap with the tweet language.

Table 3: Example participants automatically detected from the NBA game Spurs vs Okc (2012-5-31) and the WWDC’12 conference.

5 Experimental Results

We evaluate the participant-based event summarization in a cascaded fashion and present results for each of the three components, including the participant detection (Section 5.1), sub-event detection (Section 5.2), and quantitative and qualitative evaluation of example event summaries (Section 5.3).

5.1 Participant Detection Results

In Table 3, we show example participants that were automatically detected by the proposed hierarchical agglomerative clustering approach. We note that the clusters include various mentions of the same event participant, e.g., “*gregg popovich*”, “*greg popovich*”, and “*popovich*” are both referring to the head coach of the team Spurs; “*macbooks*”, “*macbook pro*”, “*mbp*” are referring to a line of products from Apple. Quantitatively, we evaluate the participant detection results on both participant- and mention-level. Assume the system-detected and the goldstandard participant clusters are T_s and T_g respectively. We define a **correct participant** as a system detected participant with more than half of its associated mentions are included in a goldstandard participant (referred to as the **hit participant**). As a result, we can define the participant-level precision and recall as below:

$$\text{participant-prec} = \frac{\#\text{correct-participants}}{|T_s|}$$

$$\text{participant-recall} = \frac{\#\text{hit-participants}}{|T_g|}$$

Note that a correct participant may include incorrect mentions, and that more than one correct par-

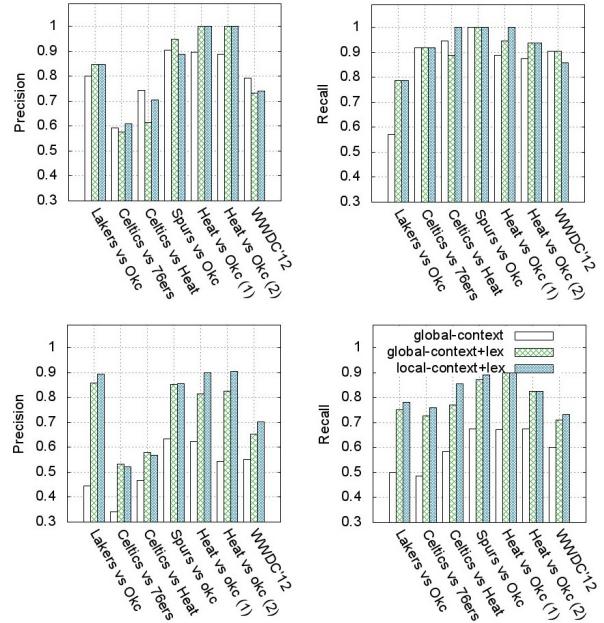

Figure 3: Participant detection performance. The upper figures represent the participant-level precision and recall scores; while the lower figures represent the mention-level precision and recall. X-axis corresponds to the six NBA games and the WWDC conference.

ticipants may correspond to the same hit participant, both of which are undesired. In the latter case, we use **representative participant** to refer to the correct participant which contains the most mentions in the hit participant. In this way, we build a 1-to-1 mapping from the detected participants to the groundtruth participants. Next, we define **correct mentions** as the union of the overlapping mentions between all pairs of representative and hit participants. Then we calculate the mention-level precision and recall as the number of correct mentions divided by the total mentions in the system or goldstandard participant clusters.

Figure 3 shows the participant- and mention-level precision and recall scores. We experimented with different similarity measures for the agglomerative clustering approach¹³. The “global context” means that the context vectors are created from the entire data stream; this may not perform well since different participants can share similar global context. E.g., the terms “shot”, “dunk”, “rebound” can appear in the context of any NBA players and are not

¹³The stopping threshold δ was set to 0.15, local context length is 3 minutes, and frequency threshold ψ was set to 200.

Table 4: Sub-event detection results on both participant and the event streams. “Spike” corresponds to the spike detection algorithm proposed in (Marcus et al., 2011); “MM” represents our proposed time-content mixture model approach. “#P” and “#S” list the number of participants and sub-events in each event stream.

discriminative enough. We found that adding the lexical similarity measure greatly boosted the clustering performance, especially on the mention-level, and that combining the lexical similarity with the local context is even more helpful for some events. We notice that two events (celtics vs 76ers and celtics vs heat) yield relatively low precision on both participant- and mention-level. Taking a close look at the data, we found that these two events accidentally co-occurred with other popular events, namely the TV program “American Idol” finale and the NBA Draft. The keyword based data crawler thus includes many noisy tweets in the event streams, leading to some false participants being detected.

5.2 Sub-event Detection Results

We compare our proposed time-content mixture model (noted as “MM”) against the spike detection algorithm proposed in (Marcus et al., 2011) (noted as “Spike”). The spike algorithm is based on the tweet volume change. It uses 10 seconds as a time unit, calculates the tweet arrival rate in each unit, and identifies the rates that are significantly higher than the mean tweet rate. For these rate spikes, the algorithm finds the local maximum of tweet rate and identify a window surrounding the local maximum. We tune the parameter of the “Spike” approach (set $\tau = 4$) so that it yields similar recall values as the mixture model approach. We then apply the “MM” and “Spike” approaches to both the participant and event streams and evaluate the sub-event detection performance. Results are shown in Table 4. A system detected sub-event is considered to match the goldstandard sub-event if its peak time is within a 2-minute window of the goldstandard.

We first apply the “Spike” and “MM” approach to

the participant streams. The participant streams on which we cannot detect any meaningful sub-events have been excluded, the resulting number of participants are listed in Table 4 and denoted as “#P”. In general, we found the “MM” approach can perform better since it inherently incorporates both the “burstiness” and “lexical cohesiveness” of the event tweets, while the “Spike” approach relies solely on the “burstiness” property. Note that although we divide the entire event stream into participant streams, some key participants still own huge amount of discussion and the spike patterns are not always clearly identifiable. The time-content mixture model gains advantages in these cases.

We apply three settings to detect global sub-events on the data streams. “Spike” directly applies the spike algorithm on the entire event stream; the “Participant + Spike” and “Participant + MM” approaches first perform sub-event detection on the participant streams and then merge the detected sub-events along the timeline to generate global sub-events. Note that there are fewer goldstandard sub-events (“#S”) on the global streams since each global sub-event may correspond to one or multiple participant-level sub-events. Because of the averaging effect, spike patterns on the entire event stream is less obvious than those on the participant streams. As a result, few spikes have been detected on the event stream using the “Spike” algorithm, which leads to low recall as compared to other participant-based approaches. It also indicates that, by dividing the entire event stream into participant streams, we have a better chance of identifying the sub-events that have otherwise been shadowed by the dominant sub-events or participants. The two participant-based methods yield similar recall but “Participant

“+ Spike” yields slightly worse precision, since it is very sensitive to the spikes on the participant-level, leading to the rise of false alarms. The “Participant + MM” approach is much better in precision, which is consistent to our findings on the participant streams.

5.3 Summarization Results

Summarization evaluation has been a longstanding issue in the literature (Nenkova and McKeown, 2011; Liu and Liu, 2010). There are even less studies focusing on evaluating the event summaries generated from data streams. Since the summary annotation takes quite some effort, we sample a 10-minute segment from each of the seven event streams and ask a human annotator to select representative tweets for each segment. We then compare the system summaries against the manual summaries using the ROUGE-1 (Lin, 2004) metric. The quantitative results and qualitative analysis are presented in Table 5 and Table 6 respectively. Note that the ROUGE scores are based solely on the n-gram overlap between the system and reference summaries, which may not be the most appropriate measure for evaluating the Twitter event summaries. However, we do notice that the accurate sub-event detection performance can successfully translate into a gain of the ROUGE scores. Qualitatively, the participant-based event summarization approach focus more on extracting tweets associated with the targeted participants, which could lead to better text coherence.

6 Conclusion and Future Work

In this work, we made an initial attempt to generate event summaries using Twitter data streams. We proposed a participant-based event summarization approach which “zooms-in” the Twitter event streams to the participant level, detects the important sub-events associated with each participant using a novel mixture model that incorporates both the “burstiness” and “cohesiveness” of tweets, and generates the event summaries progressively. Results show that the proposed approach can effectively capture the sub-events that have otherwise been shadowed by the long-tail of other dominant sub-events, yielding summaries with considerably better coverage. Without loss of generality, we report results on the entire event streams, though the proposed approach can well be applied in an online fashion.

Event	Method	R(%)	P(%)	F(%)
NBA Average	Spike	14.73	23.24	16.87
	Participant + Spike	54.60	14.65	22.40
	Participant + MM	54.36	23.06	31.53
WWDC Conf.	Spike	26.58	39.62	31.82
	Participant + Spike	49.37	25.16	33.33
	Participant + MM	42.77	31.73	36.07

Table 5: ROUGE-1 scores of summarization

Method	Summary
Manual	Good drive for <i>durant</i> Pretty shot by <i>Duncan</i> Good 3 point <i>tony parker</i> Nice move <i>westbrook</i> Good shot <i>Westbrook</i>
Spike	Game 3. Spurs vs. OKC Okc and spurs game.

NBA: SA 0 OKC 8, 9:11 1st.#TeamOkc San antonio spurs for 21 consecutive win? #nba Somebody Should Stop <i>Tim Duncan</i> . Pass the damn ball <i>Westbrook</i> Good 3 pointer <i>tony parker</i> !
Participant + MM	<i>Tim Duncan</i> shot is so precise <i>Tim Duncan</i> is gettin started Good 3 pointer <i>tony parker</i> ! Sefalosa guarding <i>tony parker</i> . Good fucking move coach brooks <i>Westbrook</i> = 2 Fast 2 Furious Niggas steady letting <i>Tim Duncan</i> shoot <i>Westbrook</i> mid range shot is automatic

Table 6: Example summaries for an event segment. Participants are marked using *italicized* text.

There are many challenges left in this line of research. Having a standardized evaluation metric for event summaries is one of them. In the current work, we employed ROUGE-1 for summary evaluation, since it has been shown to correlate well with the human judgements on noisy text genres (Liu and Liu, 2010). We would like to explore other evaluation metrics (e.g., ROUGE-2, -SU4, Pyramid (Nenkova et al., 2007)) and the human evaluation in future. We will also explore better ways of integrating the sub-event detection and summarization approaches.

Towards Coherent Multi-Document Summarization

Abstract

This paper presents G-FLOW, a novel system for coherent extractive multi-document summarization (MDS).¹ Where previous work on MDS considered sentence selection and ordering separately, G-FLOW introduces a joint model for selection and ordering that balances coherence and salience. G-FLOW’s core representation is a graph that approximates the discourse relations across sentences based on indicators including discourse cues, deverbal nouns, co-reference, and more. This graph enables G-FLOW to estimate the coherence of a candidate summary.

We evaluate G-FLOW on Mechanical Turk, and find that it generates dramatically better summaries than an extractive summarizer based on a pipeline of state-of-the-art sentence selection and reordering components, underscoring the value of our joint model.

1 Introduction

The goal of multi-document summarization (MDS) is to produce high quality summaries of collections of related documents. Most previous work in extractive MDS has studied the problems of sentence selection (*e.g.*, (Radev, 2004; Haghghi and Vanderwende, 2009)) and sentence ordering (*e.g.*, (Lapata, 2003; Barzilay and Lapata, 2008)) separately, but we believe that a joint model is necessary to produce coherent summaries. The intuition is simple: if the sentences in a summary are first selected—without regard to coherence—then a satisfactory ordering of the selected sentences may not exist.

¹System and data at <http://knowitall.cs.washington.edu/gflow/>

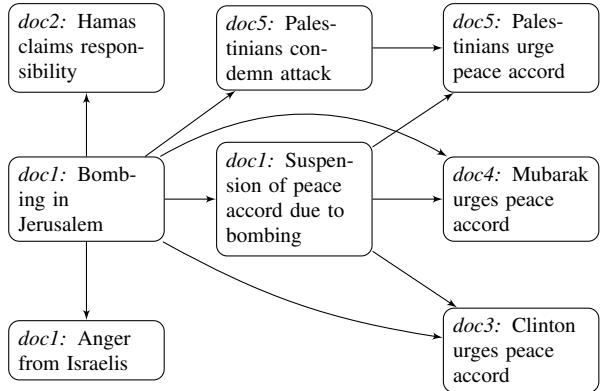

Figure 1: An example of a discourse graph covering a bombing and its aftermath, indicating the source document for each node. A coherent summary should begin with the bombing and then describe the reactions. Sentences are abbreviated for compactness.

An extractive summary is a subset of the sentences in the input documents, ordered in some way.² Of course, most *possible* summaries are incoherent. Now, consider a directed graph where the nodes are sentences in the collection, and each edge represents a pairwise ordering constraint necessary for a coherent summary (see Figure 1 for a sample graph). By definition, any *coherent* summary must obey the constraints in this graph.

Previous work has constructed similar graphs automatically for single document summarization and manually for MDS (see Section 2). Our system, G-FLOW extends this research in two important ways. First, it tackles automatic graph construction for MDS, which requires novel methods for identifying inter-document edges (Section 3). It uses this

²We focus exclusively on extractive summaries, so we drop the word “extractive” henceforth.

State-of-the-art MDS system	G-FLOW
<ul style="list-style-type: none"> The attack took place Tuesday near Cailaco in East Timor, a former Portuguese colony, according to a statement issued by the pro-independence Christian Democratic Union of East Timor. The United Nations does not recognize Indonesian claims to East Timor. Bhichai Rattakul, deputy prime minister and president of the Bangkok Asian Games Organizing Committee, asked the Foreign Ministry to urge the Saudi government to reconsider withdrawing its 105-strong team. The games will be a success. 	<ul style="list-style-type: none"> In a decision welcomed as a landmark by Portugal, European Union leaders Saturday backed calls for a referendum to decide the fate of East Timor, the former Portuguese colony occupied by Indonesia since 1975. Indonesia invaded East Timor in 1975 and annexed it the following year. Thailand won host rights for the quadrennial games in 1995, but setbacks in preparations led officials of the Olympic Council of Asia late last year to threaten to move the games to another country. Thailand showed its nearly complete facilities for the Asian Games to a tough jury Thursday - the heads of the organizing committees from the 43 nations competing in the December event.

Table 1: Pairs of sentences produced by a pipeline of a state-of-the-art sentence extractor (Lin and Bilmes, 2011) and sentence orderer (Li et al., 2011a), and by G-FLOW.

graph to estimate coherence of a candidate summary. Second, G-FLOW introduces a novel methodology for joint sentence selection and ordering (Section 4). It casts MDS as a constraint optimization problem where salience and coherence are soft constraints, and redundancy and summary length are hard constraints. Because this optimization problem is NP-hard, G-FLOW uses local search to approximate it.

We report on a Mechanical Turk evaluation that directly compares G-FLOW to state-of-the-art MDS systems. Using DUC’04 as our test set, we compare G-FLOW against a combination of an extractive summarization system with state-of-the-art ROUGE scores (Lin and Bilmes, 2011) followed by a state-of-the-art sentence reordering scheme (Li et al., 2011a). We also compare G-FLOW to a combination of an extractive system with state-of-the-art coherence scores (Nobata and Sekine, 2004) followed by the reordering system. In both cases participants substantially preferred G-FLOW. Participants chose G-FLOW 54% of the time when compared to Lin, and chose Lin’s system 22% of the time. When compared to Nobata, participants chose G-FLOW 60% of the time, and chose Nobata only 20% of the time. The remainder of the cases were judged equivalent.

A further analysis shows that G-FLOW’s summaries are judged superior along several dimensions suggested in the DUC’04 evaluation (including coherence, repetitive text, and referents). A comparison against manually written, gold standard summaries, reveals that while the gold standard summaries are preferred in direct comparisons, G-FLOW has nearly equivalent scores on almost all dimensions suggested in the DUC’04 evaluation.

The paper makes the following contributions:

- We present G-FLOW, a novel MDS system that

jointly solves the sentence selection and ordering problems to produce coherent summaries.

- G-FLOW automatically constructs a domain-independent graph of ordering constraints over sentences in a document collection, based on syntactic cues and redundancy across documents. This graph is the backbone for estimating the coherence of a summary.
- We perform human evaluation on blind test sets and find that G-FLOW dramatically outperforms state-of-the-art MDS systems.

2 Related Work

Most existing research in multi-document summarization (MDS) focuses on sentence selection for increasing coverage and does not consider coherence of the summary (Section 2.1). Although coherence has been used in ordering of summary sentences (Section 2.2), this work is limited by the quality of summary sentences given as input. In contrast, G-FLOW incorporates coherence in both selection and ordering of summary sentences.

G-FLOW can be seen as an instance of discourse-driven summarization (Section 2.3). There is prior work in this area, but primarily for summarization of single documents. There is some preliminary work on the use of manually-created discourse models in MDS. Our approach is fully automated.

2.1 Subset Selection in MDS

Most extractive summarization research aims to increase the coverage of concepts and entities while reducing redundancy. Approaches include the use of maximum marginal relevance (Carbonell and Goldstein, 1998), centroid-based summarization (Sagiv and Gaizauskas, 2004; Radev et al., 2004), cov-

ering weighted scores of concepts (Takamura and Okumura, 2009; Qazvinian et al., 2010), formulation as minimum dominating set problem (Shen and Li, 2010), and use of submodularity in sentence selection (Lin and Bilmes, 2011). Graph centrality has also been used to estimate the salience of a sentence (Erkan and Radev, 2004). Approaches to content analysis include generative topic models (Haghghi and Vanderwende, 2009; Celikyilmaz and Hakkani-Tur, 2010; Li et al., 2011b), and discriminative models (Aker et al., 2010).

These approaches do not consider coherence as one of the desiderata in sentence selection. Moreover, they do not attempt to organize the selected sentences into an intelligible summary. They are often evaluated by ROUGE (Lin, 2004), which is coherence-insensitive. In practice, these approaches often result in incoherent summaries.

2.2 Sentence Reordering

A parallel thread of research has investigated taking a set of summary sentences as input and reordering them to make the summary fluent. Various algorithms use some combination of topic-relatedness, chronology, precedence, succession, and entity coherence for reordering sentences (Barzilay et al., 2001; Okazaki et al., 2004; Barzilay and Lapata, 2008; Bollegala et al., 2010). Recent work has also used event-based models (Zhang et al., 2010) and context analysis (Li et al., 2011a).

The hypothesis in this research is that a pipelined combination of subset selection and reordering will produce high-quality summaries. Unfortunately, this is not true in practice, because sentences are selected primarily for coverage without regard to coherence. This methodology often leads to an inadvertent selection of a set of disconnected sentences, which cannot be put together in a coherent summary, irrespective of how the succeeding algorithm reorders them. In our evaluation, reordering had limited impact on the quality of the summaries.

2.3 Coherence Models and Summarization

Research on discourse analysis of documents provides a basis for modeling coherence in a document. Several theories have been developed for modeling discourse, *e.g.*, Centering Theory, Rhetorical Structure Theory (RST), Penn Discourse Tree-

Bank (Grosz and Sidner, 1986; Mann and Thompson, 1988; Wolf and Gibson, 2005; Prasad et al., 2008). Numerous discourse-guided summarization algorithms have been developed (Marcu, 1997; Mani, 2001; Taboada and Mann, 2006; Barzilay and Elhadad, 1997; Louis et al., 2010). However, these approaches have been applied to single document summarization and not to MDS.

Discourse models have seen some application to summary generation in MDS, for example, using a detailed semantic representation of the source texts (McKeown and Radev, 1995; Radev and McKeown, 1998). A multi-document extension of RST is Cross-document Structure Theory (CST), which has been applied to MDS (Zhang et al., 2002; Jorge and Pardo, 2010). However, these systems require a stronger input, such as a manual CST-annotation of the set of documents. Our work can be seen as an instance of summarization based on lightweight CST. However, a key difference is that our proposed algorithm is completely automated and does not require any additional human annotation. Additionally, while incorporating coherence into selection, this work does not attempt to order the sentences coherently, while our approach performs joint selection and ordering.

Discourse models have also been used for evaluating summary quality (Barzilay and Lapata, 2008; Louis and Nenkova, 2009; Pitler et al., 2010). Finally, there is work on generating coherent summaries in specific domains, such as scientific articles (Saggion and Lapalme, 2002; Abu-Jbara and Radev, 2011) using domain-specific cues like citations. In contrast, our work generates summaries without any domain-specific knowledge. Other research has focused on identifying coherent threads of *documents* rather than sentences (Shahaf and Guestrin, 2010).

3 Discourse Graph

As described in Section 1, our goal is to identify pairwise ordering constraints over a set of input sentences. These constraints specify a multi-document discourse graph, which is used by G-FLOW to evaluate the coherence of a candidate summary.

In this graph G , each vertex is a sentence and an edge from s_i to s_j indicates that s_j can be placed right after s_i in a coherent summary. In other words, the two share a discourse relationship. In the fol-

lowing three sentences (from possibly different documents) there should be an edge from s_1 to s_2 , but not between s_3 and the other sentences:

s_1 *Militants attacked a market in Jerusalem.*

s_2 *Arafat condemned the bombing.*

s_3 *The Wye River Accord was signed in Oct.*

Discourse theories have proposed a variety of relationships between sentences such as background and interpretation. RST has 17 such relations (Mann and Thompson, 1988) and PDTB has 16 (Prasad et al., 2008). While we seek to identify pairs of sentences that have a relationship, we do not attempt to label the edges with the exact relation.

We use textual cues from the discourse literature in combination with the redundancy inherent in related documents to generate edges. Because this methodology is noisy, the graph used by G-FLOW is an approximation, which we refer to as an approximate discourse graph (ADG). We first describe the construction of this graph, and then discuss the use of the graph for summary generation (Section 4).

3.1 Deverbal Noun Reference

Often, the main description of an event is mentioned in a verbal phrase and subsequent references use deverbal nouns (nominalization of verbs) (e.g., ‘attacked’ and ‘the attack’). In this example, the noun is derivationally related to the verb, but that is not always the case. For example, ‘bombing’ in s_2 above refers to ‘attacked’ in s_1 .

We identify verb-noun pairs with this relationship as follows. First, we locate a set of candidate pairs from WordNet: for each verb v , we determine potential noun references n using a path length of up to two in WordNet (moving from verb to noun is possible via WordNet’s ‘derivationally related’ links).

This set captures verb-noun pairs such as (‘to attack’, ‘bombing’), but also includes generic pairs such as (‘to act’, ‘attack’). To filter such errors we score the candidate references. Our goal is to emphasize common pairs and to deemphasize pairs with common verbs or verbs that map to many nouns. To this end, we score pairs by $(c/p) * (c/q)$, where c is the number of times the pair (v, n) appears in adjacent sentences, p is the number of times the verb appears, and q is the number of times that v appears with a different noun. We generate these statistics over a background corpus of 60,000 arti-

cles from the New York Times and Reuters, and filter out candidate pairs scoring below a threshold identified over a small training set.

We construct edges in the ADG between pairs of sentences containing these verb to noun mappings. To our knowledge, we are the first to use deverbal nouns for summarization.

3.2 Event/Entity Continuation

Our second indicator is related to lexical chains (Barzilay and Lapata, 2008). We add an edge in the ADG from a sentence s_i to s_j if they contain the same event or entity and the timestamp of s_i is less than or equal to the timestamp of s_j (timestamps generated with (Chang and Manning, 2012)).

3.3 Discourse Markers

We use 36 explicit discourse markers (e.g., ‘but’, ‘however’, ‘moreover’) to identify edges between two adjacent sentences of a document (Marcu and Echihabi, 2002). This indicator lets us learn an edge from s_4 to s_5 below:

s_4 *Arafat condemned the bombing.*

s_5 *However, Netanyahu suspended peace talks.*

3.4 Inferred Edges

We exploit the redundancy of information in MDS documents to infer edges to related sentences. An edge (s, s'') can be inferred if there is an existing edge (s, s') and s' and s'' express similar information. As an example, the edge (s_6, s_7) can be inferred based on edge (s_4, s_5) :

s_6 *Arafat condemned the attack.*

s_7 *Netanyahu has suspended the talks.*

To infer edges we need an algorithm to identify sentences expressing similar information. To identify these pairs, we extract Open Information Extraction (Banko et al., 2007) relational tuples for each sentence, and we mark any pair of sentences with an equivalent relational tuple as redundant (see Section 4.3). The inferred edges allow us to propagate within-document discourse information to sentences from other documents.

3.5 Co-referent Mentions

A sentence s_j will not be clearly understood in isolation and may need another sentence s_i in its context, if s_j has a general reference (e.g., ‘the presi-

dent') pointing to a specific entity or event in s_i (e.g., 'President Bill Clinton'). We construct edges based on coreference mentions, as predicted by Stanford's coreference system (Lee et al., 2011). We are able to identify syntactic edge (s_8, s_9) :

s_8 Pres. Clinton expressed sympathy for Israel.

s_9 He said the attack should not derail the deal.

3.6 Edge Weights

We weight each edge in the ADG by adding the number of distinct indicators used to construct that edge – if sentences s and s' have an edge because of a discourse marker and a deverbal reference, the edge weight $w_G(s, s')$ will be two. We also include negative edges in the ADG. $w_G(s, s')$ is negative if s' contains a deverbal noun reference, a discourse marker, or a co-reference mention that is not fulfilled by s . For example, if s' contains a discourse marker, and s is neither the sentence directly preceding s' and there is no inferred discourse link between s and s' , then we will add a negative edge $w_G(s, s')$.

3.7 Preliminary Graph Evaluation

We evaluated the quality of the ADG used by G-FLOW, which is important not only for its use in MDS, but also because the ADG may be used for other applications like topic tracking and decomposing an event into sub-events. One author randomly chose 750 edges and labeled an edge correct if the pair of sentences did have a discourse relationship between them and incorrect otherwise. 62% of the edges accurately reflected a discourse relationship. Our ADG has on average 31 edges per sentence for a dataset in which each document cluster has on average 253 sentences. This evaluation includes only the positive edges.

4 Summary Generation

We denote a candidate summary X to be a sequence of sentences $\langle x_1, x_2, \dots, x_{|X|} \rangle$. G-FLOW's summarization algorithm searches through the space of ordered summaries and scores each candidate summary along the dimensions of coherence (Section 4.1), salience (Section 4.2) and redundancy (Section 4.3). G-FLOW returns the summary that maximizes a joint objective function (Section 4.4).

weight	feature
-0.037	position in document
0.033	from first three sentences
-0.035	number of people mentions
0.111	contains money
0.038	sentence length > 20
0.137	length of sentence
0.109	#sentences verbs appear in (any form)
0.349	#sentences common nouns appear in
0.355	#sentences proper nouns appear in

Table 2: Linear regression features for salience.

4.1 Coherence

G-FLOW estimates coherence of a candidate summary via the ADG. We define coherence as the sum of edge weights between successive summary sentences. For disconnected sentence pairs, the edge weight is zero.

$$Coh(X) = \sum_{i=1 \dots |X|-1} w_{G+}(x_i, x_{i+1}) + \lambda w_{G-}(x_i, x_{i+1})$$

w_{G+} represents positive edges and w_{G-} represents negative edge weights. λ is a tradeoff coefficient for positive and negative weights, which is tuned using the methodology described in Section 4.4.

4.2 Salience

Salience is the inherent value of each sentence to the documents. We compute salience of a summary ($Sal(X)$) as the sum of the saliences of individual sentences ($\sum_i Sal(x_i)$).

To estimate salience of a sentence, G-FLOW uses a linear regression classifier trained on ROUGE scores over the DUC'03 dataset. The classifier uses surface features designed to identify sentences that cover important concepts. The complete list of features and learned weights is in Table 2. The classifier finds a sentence more salient if it mentions nouns or verbs that are present in more sentences across the documents. The highest ranked features are the last three – number of other sentences that mention a noun or a verb in the given sentence. We use the same procedure as in deverbal nouns for detecting verb mentions that appear as nouns in other sentences (Section 3.1).

4.3 Redundancy

We also wish to avoid redundancy. G-FLOW first processes each sentence with a state-of-the-art Open Information extractor OLLIE (Mausam et al., 2012), which converts a sentence into its component relational tuples of the form (arg1, relational phrase,

arg2 .³ For example, it finds (Militants, bombed, a marketplace) as a tuple from sentence s_{12} .

Two sentences will express redundant information if they both contain the same or synonymous component fact(s). Unfortunately, detecting synonymy even at relational tuple level is very hard. G-FLOW approximates this synonymy by considering two relational tuples synonymous if the relation phrases contain verbs that are synonyms of each other, have at least one synonymous argument, and are timestamped within a day of each other. Because the input documents cover related events, these relatively weak rules provide good performance. The same algorithm is used for inferring edges for the ADG (Section 3.4). This algorithm can detect that the following sentences express redundant information:

s_{12} *Militants bombed a marketplace in Jerusalem.*

s_{13} *He alerted Arafat after assailants attacked the busy streets of Mahane Yehuda.*

4.4 Objective Function

The objective function needs to balance coherence, salience and redundancy and also honor the given budget, *i.e.*, maximum summary length B . G-FLOW treats redundancy and budget as hard constraints and coherence and salience as soft. Coherence is necessarily soft as the graph is approximate. While previous MDS systems specifically maximized coverage, in preliminary experiments on a development set, we found that adding a coverage term did not improve G-FLOW’s performance. We optimize:

$$\begin{aligned} \text{maximize: } & F(x) \triangleq \text{Sal}(X) + \alpha \text{Coh}(X) - \beta |X| \\ \text{s.t. } & \sum_{i=1..|X|} \text{len}(x_i) < B \\ & \forall x_i, x_j \in X : \text{redundant}(x_i, x_j) = 0 \end{aligned}$$

Here len refers to the sentence length. We add $|X|$ term (the number of sentences in the summary) to avoid picking many short sentences, which may increase coherence and salience scores at the cost of overall summary quality.

The parameters α , β and λ (see Section 4.1) are tuned automatically using a grid search over a development set as follows. We manually generate *extractive* summaries for each document cluster in our development set (DUC’03) and choose the parameter setting that minimizes $|F(X_{\text{G-FLOW}}) - F(X^*)|$

³ Available from <http://ollie.cs.washington.edu>

summed over all document clusters. F is the objective function, $X_{\text{G-FLOW}}$ is the summary produced by G-FLOW and X^* is the manual summary.

This constraint optimization problem is NP hard, which can be shown by using a reduction of the longest path problem. For this reason, G-FLOW uses local search to reach an approximation of the optimum. G-FLOW employs stochastic hill climbing with random restarts as the base search algorithm. At each step, the search either adds a sentence, removes a sentence, replaces a sentence by another, or reorders a pair of sentences. The initial summary for random restarts is constructed as follows. We first pick the highest salience sentence with no incoming negative edges as the first sentence. The following sentences are probabilistically added one at a time based on the summary score up to that sentence. The initial summary is complete when there are no possible sentences left to fit within the budget. Intuitively, this heuristic chooses a good starting point by selecting a first sentence that does not rely on context and subsequent sentences that build a high scoring summary. As with all local search algorithms, this algorithm is highly scalable and can easily apply to large collections of related documents, but does not guarantee global optima.

5 Experiments

Because summaries are intended for human consumption we focused on human evaluations. We hired workers on Amazon Mechanical Turk (AMT) to evaluate the summaries. Our evaluation addresses the following questions: (1) how do G-FLOW summaries compare against the state-of-the-art in MDS (Section 5.2)? (2) what is G-FLOW’s performance along important summarization dimensions such as coherence and redundancy (Section 5.3)? (3) how does G-FLOW perform on coverage as measured by ROUGE (Section 5.3.1)? (4) how much do the components of G-FLOW’s objective function contribute to performance (Section 5.4)? (5) how do G-FLOW’s summaries compare to human summaries?

5.1 Data and Systems

We evaluated the systems on the Task 2 DUC’04 multi-document summarization dataset. This dataset consists of 50 clusters of related documents, each of which contains 10 documents. Each cluster of doc-

uments also includes four gold standard summaries used for evaluation. As in the DUC’04 competition, we allowed 665 bytes for each summary including spaces and punctuation. We used DUC’03 as our development set, which contains 30 document clusters, again with approximately 10 documents each.

We compared G-FLOW against four systems. The first is a recent MDS extractive summarizer, which we choose for its state-of-the-art ROUGE scores (Lin and Bilmes, 2011).⁴ The second is a pipeline of Lin’s system followed by a reimplementation of a state-of-the-art sentence reordering system (Li et al., 2011a). We refer to these systems as LIN and LIN-LI, respectively. This second baseline allows us to quantify the advantage of using coherence as a factor in both sentence extraction and ordering.

We also compare against the system that had the highest coherence ratings at DUC’04 (Nobata and Sekine, 2004), which we refer to as NOBATA. As this system did not perform sentence ordering on its output, we also compare against a pipeline of Nobata’s system and the sentence reordering system. We refer to this system as NOBATA-LI.

Lastly, to evaluate how well the system performs against human generated summaries, we compare against the gold standard summaries provided by DUC.

5.2 Overall Summary Quality

Following (Haghghi and Vanderwende, 2009) and (Celikyilmaz and Hakkani-Tur, 2010), to compare overall summary quality, we asked AMT workers to compare two candidate system summaries. The workers first read a gold standard summary, followed by the two system summaries, and were then asked to choose the better summary from the pair. The system summaries were shown in a random order to remove any bias.

To ensure that workers provided high quality data we added two quality checks. First, we restricted to workers who have an overall approval rating of over 95% on AMT. Second, we asked the workers to briefly describe the main events of the summary. We manually filtered out work where this description was incorrect.

⁴We thank Lin and Bilmes for providing us with their code. Unfortunately, we were unable to obtain other recent MDS systems from their authors.

Six workers compared each pair of summaries. We recorded the scores for each cluster, and report three numbers: the percentages of clusters where a system is more often preferred over the other and the percentage where the two systems are tied. G-FLOW is preferred almost three times as often as LIN:

G-FLOW	Indifferent	LIN
56%	24%	20%

Next, we compared G-FLOW and LIN-LI. Sentence reordering improves performance, but G-FLOW is still overwhelmingly preferred:

G-FLOW	Indifferent	LIN-LI
54%	24%	22%

These results suggest that incorporating coherence in sentence extraction adds significant value to a summarization system. In these experiments, LIN and LIN-LI are preferred in some cases. We analyzed those summaries more carefully, and found that occasionally, G-FLOW will sacrifice a small amount of coverage for coherence, resulting in lower performance in those cases (see Section 5.3.1).

We also compared LIN and LIN-LI, and found that reordering does not improve performance by much.

LIN-LI	Indifferent	LIN
32%	38%	30%

While the scores presented above represent comparisons between G-FLOW and a summarization system with state-of-the-art ROUGE scores, we also compared against a summarization system with state-of-the-art coherence scores – the system with the highest coherence scores from DUC’04, (Nobata and Sekine, 2004). We found that G-FLOW was again preferred:

G-FLOW	Indifferent	NOBATA
68%	10%	22%

Adding in sentence ordering again improved the scores for the comparison system somewhat:

G-FLOW	Indifferent	NOBATA-LI
60%	20%	20%

While these scores show a significant improvement over previous systems, they do not convey how well G-FLOW compares to the gold standard – manually generated summaries. As a final experiment, we compared G-FLOW and a second, manually generated summary:

G-FLOW	Indifferent	Gold
14%	18%	68%

While we were pleased that in 32% of the cases, Turkers either preferred G-FLOW or were indifferent, there is clearly a lot of room for improvement despite the gains reported over previous systems.

5.3 Comparison along Summary Dimensions

A high quality summary needs to be good along several dimensions. We asked AMT workers to rate summaries using the quality questions enumerated in DUC’04 evaluation scheme.⁵ These questions concern: (1) coherence, (2) useless, confusing, or repetitive text, (3) redundancy, (4) nouns, pronouns, and personal names that are not well-specified (5) entities rementioned in an overly explicit way, (6) ungrammatical sentences, and (7) formatting errors.

We evaluated G-FLOW LIN-LI and NOBATA-LI against the gold standard summaries, using the same AMT scheme as in the previous section. To assess automated performance with respect to the standards set by human summaries, we also evaluated a (different) gold standard summary for each document cluster, using the same Mechanical Turk scheme as in the previous section. The 50 summaries produced by each system were evaluated by four workers. The results are shown in Figure 2.

G-FLOW was rated significantly better than LIN-LI in all categories except ‘Redundancy’ and significant better than NOBATA-LI on ‘Coherence’ and ‘Referents’. The ratings for ‘Coherence’, ‘Referents’, and ‘OverlyExplicit’ are not surprising given G-FLOW’s focus on coherence. The results for ‘UselessText’ may also be due to G-FLOW’s focus on coherence which ideally prevents it from getting off topic. Lastly, G-FLOW may perform better on ‘Grammatical’ and ‘Formatting’ because it tends to choose longer sentences than other systems, which are less likely to be sentence segmentation errors. There may also be some bleeding from one dimension to the other – if a worker likes one summary she may score it highly for many dimensions.

Finally, somewhat surprisingly, we find G-FLOW’s performance to be nearly that of human summaries. G-FLOW is rated statistically significantly lower than the gold summaries on only ‘Re-

System	R	F
NOBATA	30.44	34.36
Best system in DUC-04	38.28	37.94
Takamura and Okumura (2009)	38.50	-
LIN	39.35	38.90
G-FLOW	37.33	37.43
Gold Standard Summaries	40.03	40.03

Table 3: ROUGE-1 recall and F-measure results (%) on DUC-04. Some values are missing because not all systems reported both F-measure and recall.

dundancy’. Given the results from the previous section, G-FLOW is likely performing worse on categories not conveyed in these scores, such as Coverage, which we examine next.

5.3.1 Coverage Evaluation using ROUGE

Most recent research has focused on the ROUGE evaluation, and thus implicitly on coverage of information in a summary. To estimate the coverage of G-FLOW, we compared the systems on ROUGE (Lin, 2004). We calculated ROUGE-1 scores for G-FLOW, LIN, and NOBATA.⁶ As sentence ordering does not matter for ROUGE, we do not include LIN-LI or NOBATA-LI in this evaluation. Because our algorithm does not explicitly maximize coverage while LIN does, we expected G-FLOW to perform slightly worse than LIN.

The ROUGE-1 scores for G-FLOW, LIN, NOBATA and other recent MDS systems are listed in Table 3. We also include the ROUGE-1 scores for the gold summaries (compared to the other gold summaries). G-FLOW has slightly lower scores than LIN and the gold standard summaries, but much higher scores than NOBATA. G-FLOW only scores significantly lower than LIN and the gold standard summaries.

We can conclude that good summaries have both the characteristics listed in the quality dimensions, and good coverage. The gold standard summaries outperform G-FLOW on both ROUGE scores and the quality dimension scores, and therefore, outperform G-FLOW on overall comparison. However, G-FLOW is preferred to LIN-LI in addition to NOBATA-LI indicating that its quality scores outweigh its ROUGE scores in that comparison. An improvement to G-FLOW may focus on increasing

⁵<http://duc.nist.gov/duc2004/quality.questions.txt>

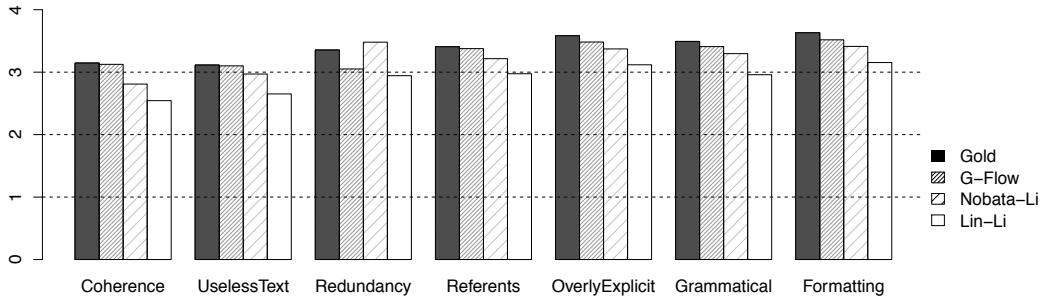

Figure 2: Ratings for the systems. 0 is the lowest possible score and 4 is the highest possible score. G-FLOW is rated significantly higher than LIN-LI on all categories, except for ‘Redundancy’, and significantly higher than NOBATA-LI on ‘Coherence’ and ‘Referents’. G-FLOW is only significantly lower than the gold standard on ‘Redundancy’.

coverage while retaining strengths such as coherence.

5.4 Ablation Experiments

In this ablation study, we evaluated the contribution of the main components of G-FLOW – coherence and salience. The details of the experiments are the same as in the experiment described in Section 5.2.

We first measured the importance of coherence in summary generation. This system G-FLOW-SAL is identical to the full system except that it does not include the coherence term in the objective function (see Section 4.4). The results show that coherence is very important to G-FLOW’s performance:

G-FLOW	Indifferent	G-FLOW-SAL
54%	26%	20%

Similarly, we evaluated the contribution of salience. This system G-FLOW-COH does not include the salience term in the objective function:

G-FLOW	Indifferent	G-FLOW-COH
60%	20%	20%

Without salience, the system produces readable, but highly irrelevant summaries.

5.5 Agreement of Expert & AMT Workers

Because summary evaluation is a relatively complex task, we compared AMT workers’ annotations with expert annotations from DUC’04. We randomly selected ten summaries from each of the seven DUC’04 annotators, and asked four Turk workers to annotate them on the DUC’04 quality questions. For each DUC’04 annotator, we selected all pairs of summaries where one summary was judged more than one point better than the other summary. We

compared whether the workers (voting as in Section 5.2) likewise judged that summary better than the second summary. We found that the annotations agreed in 75% of cases. When we looked only at pairs more than two points different, the agreement was 80%. Thus, given the subjective nature of the task, we feel reasonably confident that the AMT annotations are informative, and that the dramatic preference of G-FLOW over the baseline systems is due to a substantial improvement in its summaries.

6 Conclusion

In this paper, we present G-FLOW, a multi-document summarization system aimed at generating coherent summaries. While previous MDS systems have focused primarily on salience and coverage but not coherence, G-FLOW generates an ordered summary by jointly optimizing coherence and salience. G-FLOW estimates coherence by using an approximate discourse graph, where each node is a sentence from the input documents and each edge represents a discourse relationship between two sentences. Manual evaluations demonstrate that G-FLOW generates substantially better summaries than a pipeline of state-of-the-art sentence selection and reordering components. ROUGE scores, which measure summary coverage, show that G-FLOW sacrifices a small amount of coverage for overall readability and coherence. Comparisons to gold standard summaries show that G-FLOW must improve in coverage to equal the quality of manually written summaries. We believe this research has applications to other areas of summarization such as update summarization and query based summarization, and we are interested in investigating these topics in future work.

Abstract

We introduce a novel algorithm for generating referring expressions, informed by human and computer vision and designed to refer to visible objects. Our method separates absolute properties like color from relative properties like size to stochastically generate a diverse set of outputs. Expressions generated using this method are often overspecified and may be underspecified, akin to expressions produced by people. We call such expressions *identifying descriptions*. The algorithm outperforms the well-known Incremental Algorithm (Dale and Reiter, 1995) and the Graph-Based Algorithm (Krahmer et al., 2003; Viethen et al., 2008) across a variety of images in two domains. We additionally motivate an evaluation method for referring expression generation that takes the proposed algorithm’s non-determinism into account.

1 Introduction

Referring expression generation (REG) is the task of generating an expression that can identify a referent to a listener. These expressions generally take the form of a definite noun phrase such as “the large orange plate” or “the furry running dog”. Research in REG primarily focuses on the subtask of selecting a set of properties that may be used to construct the final surface expression, e.g., $\langle \text{color:orange}, \text{size:large}, \text{type:plate} \rangle$. This property selection task is optimized to meet different goals: for example, to be identical to those a person would generate in the same situation, or to be unique to the intended referent and no other item in the discourse.

We focus on the task of generating referring expressions for visible objects, specifically with the goal of generating descriptive, human-like referring expressions. We are motivated by the desire to connect this algorithm to input from a computer vision system, and discuss how this may work throughout the paper. Computer vision (CV) does not yet reliably provide features for some of the most frequent properties that people use in visual description (in particular, size-based features), and so we use a gold-standard visual input, evaluating purely on REG. The proposed algorithm, which we call the Visible Objects Algorithm, is designed to approximate human variation identifying an object in a group of visible, real world objects.

Our primary contributions are the following. Background for each issue is provided in Section 2:

1. An approach accounting for overspecification, underspecification, and some of the known effects of vision on reference.
2. A function to approximate the stochastic nature of reference. This reflects that people will produce different references to the same object.
3. A separation between absolute properties like color, which may be detected directly by CV, from relative properties like size and location, which require reasoning over visual features to determine an appropriate form (e.g., height/width and distance features between pixels are available from a visual input; saying an object is “tall” requires further reasoning).
4. An evaluation method for non-deterministic REG that aligns generated and observed data and calculates accuracy over alignments.

2 Motivation & Overview

Most implemented algorithms for referring expression generation focus on unique identification of a referent, determining the set of properties that distinguish a particular target object from the other objects in the scene (the *contrast set*) (Dale, 1989; Reiter and Dale, 1992; Dale and Reiter, 1995; Krahmer et al., 2003; Areces et al., 2008). This view of reference was first outlined by Olson (1970), “the specification of an intended referent relative to a set of alternatives”. A substantial body of evidence now shows that contrastive value relative to alternatives is not the only factor motivating speakers’ property choices, specifically in visual domains. The phenomena of *overspecification* and *redundancy*, where speakers select properties that have little or no contrastive value, was observed in early developmental studies in visual domains (Ford and Olson, 1975; Whitehurst, 1976; Sonnenschein, 1985) as well as later studies on adult speakers in visual domains (Pechmann, 1989; Engelhardt et al., 2006; Koolen et al., 2011). The related phenomenon of *underspecification*, where speakers select a set of properties that do not linguistically specify the referent, has also received some attention, particularly in visual domains (Clark et al., 1983; Kelleher et al., 2005).

These findings make sense in light of visual evidence that some properties “pop out” in the scene (Treisman and Gelade, 1980), and speakers may begin referring before scanning the full set of scene objects (Pechmann, 1989), selecting those properties that are salient for them (Horton and Keysar, 1996; Bard et al., 2009) without spending a great amount of cognitive effort considering the perception of a hearer (Keysar and Henly, 2002).

We take this evidence to suggest an approach for a visual reference algorithm that generates natural, human-like reference by generating visual properties that are salient for a speaker.¹ We can understand what is salient visually (what does the visual system first respond to, what guides attention?), linguistically (what do people tend to mention in visual scenes?), and cognitively, which we will not have room to discuss in this paper (what is atypical for

¹We can also add functionality to ensure that a referent is uniquely identified against the contrast set (whether or not that reflects what a person would do), which we will describe.

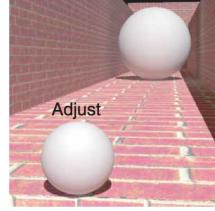

Figure 1: Relative properties, like size and location, are difficult to obtain from a two-dimensional image. We find it easy to perceive the background object as larger than the one in the front; but they are technically the same size in the image (from Murray et al. (2006)).

this object?); as well as in terms of broader notions of salience, e.g., discourse salience (Krahmer and Theune, 2002).

This suggests a paradigm shift in the generation task when referring to visible objects, if the goal is to produce human-like reference. In particular, this suggests moving from selecting properties that *rule out* other scene objects to selecting properties that are salient for the speaker (visually, conversationally, based on previous experiences, etc.). This mirrors related research on the tradeoff between audience design and egocentrism in language production (Clark and Murphy, 1982; Horton and Keysar, 1996; Bard et al., 2009; Gann and Barr, 2013). Under- and overspecification naturally fall out from such an approach, with no need to specifically model either phenomenon.

Perhaps unsurprisingly, the set of properties that are visually salient and the set of properties that are linguistically salient largely overlap. Color is the first property our visual system processes, followed soon after by size (Murray et al., 2006; Fang et al., 2008; Schwarzkopf et al., 2010); and people tend to use color (Pechmann, 1989; Viethen et al., 2012) and size when identifying objects, with size common when there is another object of the same type in the scene (Brown-Schmidt and Tanenhaus, 2006).

Following this, our algorithm gives a privileged position to these properties, processing them first. Using computer vision techniques to determine an object’s color works reasonably well (Berg et al., 2011), and the relevant visual features for this task may be useful in future work to return several possible color labels that capture differences in lexical choice (cf. Reiter and Sripada (2002)).

Detecting size does not work well (Forsyth,

2011); and when it does, it will likely not take the form supposed in recent generation work. Most REG algorithms use a predefined single-featured value, such as “big”; however, given an image-based input, obtaining such a value requires (1) determining how the object is situated in a three-dimensional space, difficult to obtain from a two-dimensional image (see Figure 1); and (2) determining what the value should be: object detectors currently can provide the height and width of the location where an object is likely to exist (its bounding box), as well as the x- and y-axis locations of the pixels within the object detection; but a value from these features like “big”, “tall”, or “long” requires further reasoning. As such, we incorporate the top-performing size algorithm introduced in Mitchell et al. (2011), which takes as input the height and widths of objects in the image and outputs a size value or NONE, indicating that size should not be used to describe the object.

In addition to color and size, location and orientation begin to be processed early on in the visual system (Treisman, 1985; Itti and Koch, 2001), with our first perception of location corresponding to basic cues of where an object is relative to our focus of attention. For an input image, this simple type of location corresponds to surface forms such as, e.g., “on the right of the image” or “at the top of the image”. Along with size, location and orientation make up the three primary relative properties that we aim to generate language for.

After the simple forms for color, size, location, and orientation properties are processed, our visual system feeds forward to two parallel pathways, the so-called “what” and “where” pathways (Ungerleider and Mishkin, 1982), which process properties with growing complexity. The “what” pathway includes absolute properties like shape and material, which computer vision has had some success detecting (Ferrari and Zisserman, 2007; Farhadi et al., 2009) while the “where” pathway corresponds to more complex spatial orientation and location information, such as where objects are relative to one another and which way they are facing.

To begin connecting this process to the generation of human-like descriptions of visible objects, we start with the following simplification: Color and size have a privileged status, the first properties processed. These are followed by the relative properties

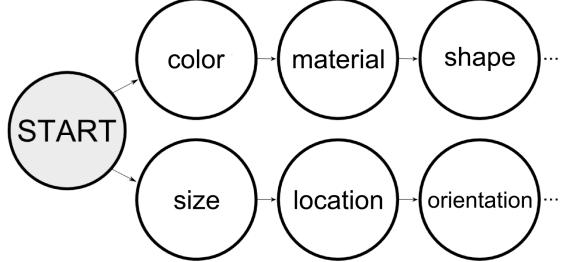

Figure 2: Initial model for generating visual reference.

of location and orientation, which may feed forward to more complex location and orientation properties in one pathway; and absolute properties following color, like material and shape, which may be processed in another pathway.

This gives us the basic model for generating reference to visible objects shown in Figure 2. To generate reference in this model, nodes correspond to general visual *attributes* and may generate forms for visual *properties* (attribute:value pairs). That is, a property such as color:red is generated from the attribute node color and a property such as size:tall is generated from the attribute node size. We are limited by existing REG corpora in which properties we can evaluate; in this paper, we examine the effect of the independent selection of color and size, followed by location and orientation.²

Generating human-like expressions in this setting begins to be possible by adopting recent proposals that REG handle speaker variation (Viethen and Dale, 2010) and the non-deterministic nature of reference (van Gompel et al., 2012; van Deemter et al., 2012b). We can capture such variation simply by estimating α_{att} , the likelihood that an attribute att generates a corresponding visual property. During generation, the algorithm passes through each attribute node, and uses this estimate to stochastically add each property to the output property set.

Such a non-deterministic process means that the algorithm will not return the same output every time, which offers new challenges for evaluation. If we run the algorithm 1,000 times, we have a distribution over several possible output property sets. From this we can obtain the majority set and check if it matches the majority observed set. Similarly, we can

²We have also built an algorithm and corpus with more complex properties in order to tease out further details of visual reference, but must leave these details for follow up work; for now, we focus on the properties common to REG corpora.

run the algorithm for as many instances as we have in our test data, and see how well the property sets it produces aligns to the observed property sets. We discuss evaluation using both methods in Section 6.

3 The State of the Art in REG

3.1 Algorithms

In order to understand how this approach compares to the state of the art in REG, we evaluate against two of the most well-known algorithms, the Incremental Algorithm (Dale and Reiter, 1995) and the Graph-Based Algorithm (Krahmer et. al, 2003, as implemented in Viethen et al., 2008). Details on these algorithms are available in their corresponding papers. As a brief summary, both algorithms formalize the objects in the discourse as a set of properties (attribute:value pairs). For example, one object may be represented as `<type:box, color:red, size:large>`. The task is to find the set of properties that uniquely specify the referent. This is known as a content selection problem, and the set of properties chosen by the algorithm is called a *distinguishing description*.

The Incremental Algorithm (IA) proceeds by iterating through attributes in a predefined order (a preference order), and for each attribute, it checks whether specifying a value would rule out at least one item in the contrast set that has not already been ruled out. If it will, the attribute:value is added to the distinguishing description. This process continues until all contrast items (distractors) are ruled out or all available properties have been checked. We use the implementation of the IA available from the NLTK (Bird et al., 2009).³

In the Graph-Based Algorithm (GB), the objects in the discourse are represented within a labeled directed graph, and content selection is a subgraph construction problem. Each object is represented as a vertex, with properties for an object represented as self-edges on the object vertex, and spatial relations between objects represented as edges between vertices. The algorithm seeks to find the cheapest subgraph, calculated from the edge costs. We use the implementation available from Viethen et al. (2008), which adds a preference order to decide between edges with the same cost during search. This has

³https://github.com/nltk/nltk_contrib/blob/master/nltk_contrib/referring.py retrieved 1.Aug.2012.

been one of the best-performing systems in recent generation challenges (Gatt and Belz, 2008; Gatt et al., 2009).

An important commonality between these algorithms, and much of the work on REG that they have influenced, is the focus on *unique identification* and operating *deterministically*. Both produce one property set (and only one), and stop once a target item has been uniquely identified (or else fail). Their driving goal is to rule out distractor objects.

In the approach introduced here, the algorithm produces a distribution over several possible outputs, and the initial driving mechanism is based on likelihood estimates for each attribute independent of the other objects in the scene, rather than ruling out all distractors. This offers a way to capture some aspects of human-like reference, including under- and overspecification and speaker variation. Due to the fundamentally different objective of this algorithm, we will call the kind of expression it generates an *identifying description*, following Searle (1969). This is a description that the system finds (1) useful to describe the referent and (2) true of the referent.

4 The Algorithm

The Visible Objects Algorithm iterates through lists of visible attributes, stochastically adding properties to the property set it will generate. After this initial search, the algorithm then scans through the objects in the scene, roughly corresponding to how people scan a scene when referring (Pechmann, 1989). The target referent type, corresponding to the head noun in the final generated description, is added to the property set at the end of the algorithm.

We represent the basic components of the algorithm graphically in Figure 3. Full code is available online.⁴ After START, the algorithm proceeds in parallel through a list of absolute attributes and a list of relative attributes. The likelihood of generating a property is a function of the prior likelihood α_{att} and γ , a penalty on the length of the constructed property set up to that point. This ensures that only a few properties are generated for a referent, and the expression will not be too complex. This is also in line with recent research suggesting that there are rarely more than three adjectives in a visual noun phrase

⁴<https://github.com/itallow/VisibleObjectsAlgorithm>.

(Berg et al., 2011). Once the algorithm hits END, it scans through the objects in the scene. If it finds an object that is the same type as the referent object, the algorithm checks through the attributes again in a preference order akin to the IA, comparing the object’s properties against the referent’s and generating properties as a function of the length penalty alone. If the algorithm does not find an object that it is the same type, no further properties are added.

4.1 Requirements

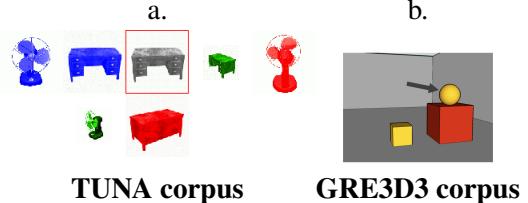

The algorithm requires the following:

1. Prior likelihood estimates on the inclusion of different attributes. Represented as α_{att} .
2. Ordered list of absolute attributes beyond color. Represented as AP.
3. Ordered list of relative attributes beyond size. Represented as RP.
4. Ordered list of all attributes. Represented as P.
5. Ordered list specifying the order in which to scan through other scene objects. The current implementation uses the order in which the objects are listed in the corpora it is run on.

(1) is similar to the cost functions for GB, but attributes are selected non-deterministically using prior likelihoods. (2), (3), and (4) are similar to the IA’s and GB’s preference order. For our evaluation corpora, AP is empty and RP contains location and orientation. (5) is novel to this algorithm, defining an order in which to compare the target object against other objects in the scene. This is inspired by the process of incremental speech production (Pechmann, 1989), where speakers scan objects during naming, incrementally producing properties.

4.2 The Stochastic Process

Generally speaking, we want to penalize longer descriptions and encourage the attributes that we know people are likely to use. We can encourage a likely attribute by using its prior likelihood as an estimate of whether to include it. We can penalize longer descriptions with a penalty proportional to the length of the property set under construction. In other words, given a prior likelihood estimate for including an attribute att , α_{att} , and the property set constructed so far A , we compute whether to add a prop-

TUNA corpus GRE3D3 corpus

Figure 4: Example scenes from corpora.

erty for att to A as a function of α_{att} and the length-based penalty γ :

$$f(A \cup \{x\}) = \gamma \alpha_{att}$$

where

$$\gamma = \begin{cases} \frac{1}{\lambda|A|} & \text{if } |A| > 0 \\ 1 & \text{otherwise} \end{cases}$$

and λ is an empirically determined weight. The algorithm then chooses a random number n , $0 \leq n \leq 1$. If $n < f(A \cup \{x\})$, it adds the property.

4.3 Scanning Through Objects

After the initial pass through the properties, the algorithm compares each object in the scene that is the same type as the target. If the values for an attribute are different, then the corresponding property is added to the property set based on the length penalty alone; when the goal is unique identification, the algorithm can use no penalty. In development, we found that incrementally scanning through objects after initially adding properties resulted in better performance than an algorithm that did not contain this step.

4.4 Worked Example

Suppose the input in Figure 6 (visualized in Figure 4a), with the goal of referring to obj_1 by producing a property set A . First, the algorithm scans through color and size in parallel. For color, it finds the corresponding value grey; with a computer vision input, this would be possible using the object pixels as features. There is no length penalty at this point ($|A|=0$), so it adds the property color:grey to A with likelihood α_{color} . For our evaluation domains, α_{color} is around .90 across folds, and so a color property is usually added.

For size, the algorithm finds an appropriate value using the Size Algorithm from Mitchell et al. (2011). The Size Algorithm uses the average height and

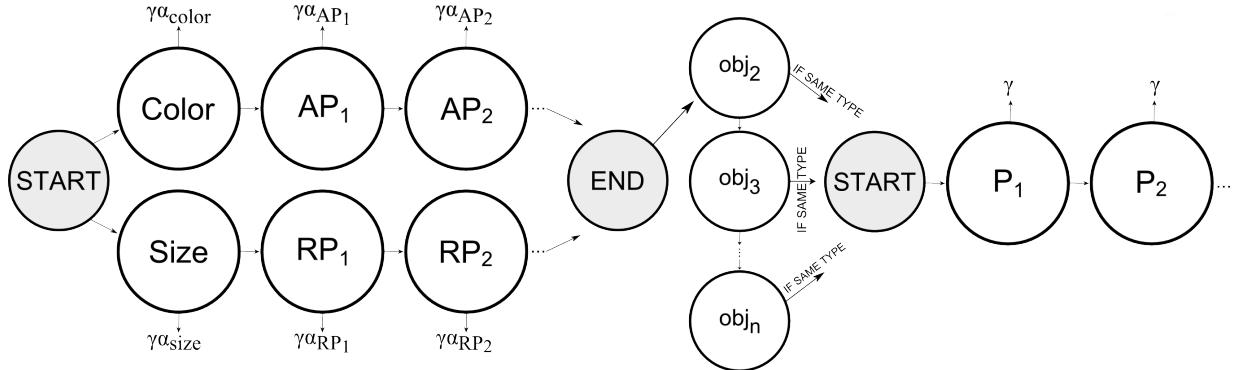

Figure 3: Basic model for generating visual reference.

width of all objects that are the same type as the referent object; in this case, obj_2 , obj_3 , obj_4 . This returns a size value large, and so the property size:large is added to A with likelihood α_{size} (around .40 to .70 across folds, depending on the domain).

The most likely property set at this point is simply $\langle \text{color:grey} \rangle$. The next most likely is $\langle \text{color:grey}, \text{size:large} \rangle$, then $\langle \text{size:large} \rangle$. There are no further absolute properties in this example, but there are values for the relative attributes loc (location) and ori (orientation). Assuming $RP = \langle \text{location}, \text{orientation} \rangle$, the algorithm first analyzes location, then orientation. A location property is added to A with likelihood α_{loc} multiplied by the length penalty $\gamma = \frac{1}{(\lambda \times 1)}$ if $A = \langle \text{color:grey} \rangle$; $\gamma = \frac{1}{(\lambda \times 2)}$ if $A = \langle \text{color:grey}, \text{size:large} \rangle$, etc.; and an orientation property is added to A with likelihood α_{ori} multiplied by the length penalty $\gamma = \frac{1}{(\lambda \times 1)}$ if the property set is $\langle \text{color:grey} \rangle$, etc. At this point, the likelihood of adding further properties quickly diminishes.

Once all properties have been analyzed, the algorithm scans through the objects in the scene. For each object $obj_2 \dots obj_n$, if the object is the same type as the target object obj_1 , then any different property of the target referent is added to A with a likelihood based on the length penalty alone γ . $\langle \text{type:desk} \rangle$ is added at the end.

For this example scene, the algorithm will generate the property sets $\langle \text{color:grey}, \text{type:desk} \rangle$, $\langle \text{color:grey}, \text{size:large}, \text{type:desk} \rangle$, $\langle \text{size:large}, \text{type:desk} \rangle$, $\langle \text{color:grey}, \text{ori:front}, \text{type:desk} \rangle$, $\langle \text{color:grey}, \text{loc:(3,1)}, \text{type:desk} \rangle$, etc., with different frequencies. Due to the length penalty, generated property sets will almost never have more than 3 properties.

tg	color:yellow	size:(63,63)	type:ball	loc:right-hand
lm	color:red	size:(345,345)	type:cube	loc:right-hand
obj3	color:yellow	size:(70,70)	type:cube	loc:left-hand

Figure 5: Example input scene: GRE3D3 corpus. For IA And GB, gold-standard size values are provided rather than measurements (small, large).

obj1	colour:grey	size:(454,454)	type:desk	loc:(3,1)	ori:front
obj2	colour:blue	size:(454,454)	type:desk	loc:(2,1)	ori:front
obj3	colour:red	size:(454,454)	type:desk	loc:(3,2)	ori:back
obj4	colour:green	size:(254,254)	type:desk	loc:(4,1)	ori:left
obj5	colour:blue	size:(454,454)	type:fan	loc:(1,1)	ori:front
obj6	colour:red	size:(454,454)	type:fan	loc:(5,1)	ori:back
obj7	colour:green	size:(254,254)	type:fan	loc:(2,2)	ori:left

Figure 6: Example input scene: TUNA corpus. For IA And GB, gold-standard size values are provided rather than measurements (small, large).

As such, although $\langle \text{color:grey}, \text{type:desk} \rangle$ would sufficiently distinguish the intended referent, we instead produce a variety of sets, overspecifying in some instances (e.g., $\langle \text{color:grey}, \text{ori:front}, \text{type:desk} \rangle$), and with a small chance of underspecifying in others (e.g., $\langle \text{size:large}, \text{type:desk} \rangle$).

5 Evaluation Algorithms & Corpora

5.1 Corpora

We evaluate on two well-known REG corpora, the GRE3D3 corpus (Viethen and Dale, 2008) and the singular furniture section of the TUNA corpus (van Deemter et al., 2006). Both corpora contain expressions elicited to computer-generated objects, and so provide a reasonable starting point for evaluating reference to visible objects. For all algorithms, we evaluate on the selection of referent attributes. Lexical choice and word order are not taken into account. Example images from GRE3D3 and TUNA are shown in Figure 4, and example algorithm input

from these corpora are shown in Figures 5 and 6.

In GRE3D3, we evaluate on the selection of type, color, size, and location, but leave aside properties of relatum objects, which are not currently addressed by this algorithm or the IA. In TUNA, we evaluate on the selection of type, color, size and orientation.⁵

5.2 Algorithms

5.2.1 The Incremental Algorithm

The Incremental Algorithm requires a preference order list (PO) specifying the order to iterate through scene attributes. We determine the preference order from corpus frequencies using cross-validation to hold out a test scene and list attributes from the training scenes in descending order. We find that color precedes size in the preference orders, in line with recent research showing that this allows the algorithm to perform optimally on the TUNA corpus (van Deemter et al., 2012a). In development, we find that IA performs best with type as the last attribute in the PO, and report on numbers with this approach.

5.2.2 The Graph-Based Algorithm

The version of the Graph-Based Algorithm that we use is available from Viethen et al. (2008). This algorithm requires (1) a set of cost functions for each edge, and (2) a PO for deciding between properties in the case of a tie. For (1), we use the method from Theune et al. (2011) to assign two costs (0, 1) to the edges. We first determine the relative frequency with which each property is mentioned for a target object, and then create costs for each property using k -means clustering ($k=2$) in the Weka toolkit (Hall et al., 2009). We refer interested readers to the Theune et al. paper for further details. For (2), we follow the same method as for the Incremental Algorithm.

5.2.3 The Visual Objects Algorithm

The proposed algorithm requires α_{att} , which we estimate as the relative frequency of each attribute att in the training data. The ordered attribute lists for the algorithm (AP, RP and P) are built in the same way as the preference order list for the IA and GB, listing attributes from the training data in order of

⁵We remove location from evaluation in this corpus. Location is not annotated directly, but split such that only x-dimension or y-dimension may be marked for a reference.

descending frequency. For these corpora, there are not absolute properties beyond color, so AP is empty.

6 Evaluation

Previous evaluation of REG algorithms have used measurements such as Uniqueness, Minimality, Dice (Belz and Gatt, 2008), and Accuracy (Gatt et al., 2009; Reiter and Belz, 2009). *Uniqueness* is the proportion of outputs that identify the referent uniquely, and *Minimality* is the proportion of outputs that are both minimal and unique. As our goal is to mimic human reference, these metrics are not as useful for the evaluations as the others.

The *Dice* metric provides a value for the similarity between a generated description and a human-produced description, and therefore serves as a reasonable objective measure for how human-like the produced sets are. Given the generated property set (D_S) and the human-produced property set (D_H), Dice is calculated as:

$$\frac{2 \times |D_S \cap D_H|}{|D_S| + |D_H|}$$

For each input domain, we evaluate over boolean values (included or excluded) for the attributes D (see Table 1). Note that this means the specific values for the attributes are not compared. In this formulation based on boolean values, $|D_S|=|D_H|=|D|$ and Dice reduces to:

$$\frac{|D_S \cap D_H|}{|D|}$$

Calculating Dice over the same number of attributes for both the observed and generated data has the nice mathematical property of making Dice equal to other common metrics for evaluating a model, including Accuracy, Precision, and Recall.⁶

Since the proposed algorithm is stochastic, this introduces a problem in using a metric that compares single expressions. We therefore seek to find the best alignment between the set of expressions produced by the algorithm and the set of expressions produced by people. We formulate this alignment as an assignment problem weighted by Dice. For the corpus of observed property sets H and the corpus of generated property sets S , we find the best align-

⁶A false positive is a false negative, and there are no true negatives, so all four metrics are equivalent.

Example Expression	Corresponding Property Set	Evaluated Property Set
<i>the red ball</i>	$\langle \text{color:red}, \text{type:ball} \rangle$	type:1 color:1 size:0 loc:0

Table 1: Example human expression and corresponding boolean-valued property set for evaluation in GRE3D3, with $D = \{\text{type, color, size, and location}\}$.

ment x out of all possible alignments X between the corpora:

$$\arg \max_{x \in X} \sum_{(S,H) \in x} \text{Dice}(D_S, D_H)$$

This may be solved in polynomial time using the Hungarian method (Kuhn, 1955; Munkres, 1957). Note that because IA and GB are deterministic, finding an optimal alignment is trivial. We call this method **ALIGNED DICE**.

It is an open question whether an alignment-based evaluation is fair: the proposed algorithm has more than one chance to match the human descriptions. In the second evaluation method (**MAJORITY**) we address this issue, comparing how often the *most frequent* generated set compares with the most frequent observed set. We run the proposed algorithm 1,000 times, and the generated property sets are ordered by frequency. The most frequent generated set is compared against the most frequent human-produced set. The majority score is the percentage of folds where these two sets match. For IA and FB, the most frequent generated set is the only generated set. This is a simple way to fairly compare the output of deterministic and non-deterministic algorithms. There are no ties in the generated sets, but in the case of a tie in the observed data, we count a match if any match the most frequent generated set.

6.1 GRE3D3

We randomly select two scenes (7, 9) from Set 1 and their mirrored counterparts in Set 2 (17, 19) for development. We empirically determine $\lambda=5$ for the length-based penalty γ in the proposed algorithm.

We use the eight remaining scenes in each Set for eight-fold cross-validation, estimating parameters for the algorithms on the seven training scenes in each fold, as discussed in Section 5.2.

For **ALIGNED DICE**, we run the proposed algorithm five times in each fold and report the average

Algorithm	ALIGNED DICE		MAJORITY	
	Set 1	Set 2	Set 1	Set 2
Proposed Alg.	88.23	90.06	62.50	50.00
IA	87.71	85.13	62.50	25.00
GB	87.71	88.73	62.50	50.00

Table 2: GRE3D3: Results (in %).

Algorithm	ALIGNED DICE		MAJORITY	
	+LOC	-LOC	+LOC	-LOC
Proposed Alg.	88.75	86.07	40.00	40.00
IA	81.79	81.55	0.00	100.00
GB	75.36	66.04	20.00	20.00

Table 3: TUNA: Results (in %).

score. Results are shown in Table 2.⁷

The proposed Visible Objects Algorithm achieves higher accuracy than either version of the Incremental Algorithm or the Graph-Based Algorithm using **ALIGNED DICE**. In **MAJORITY**, the Graph-Based and the Visible Objects Algorithm both predict the majority property set in this evaluation at least 50% of the time. The algorithm is competitive with the state of the art on this corpus.

6.2 TUNA

TUNA is split into two conditions: subjects discouraged to use location (-LOC) or not (+LOC). We randomly hold out two scenes from both conditions (1 and 2), and find a value of $\lambda=5$ again works well on the development data.

As in the GRE3D3 corpus, we use the TUNA scenes in five-fold cross-validation, estimating parameters on the four training scenes in each fold. For **ALIGNED DICE**, we average over five runs of the algorithm, and for **MAJORITY**, we run the proposed algorithm 1,000 times for each test scene.

Results are shown in Table 3. Again we see that the proposed Visible Objects Algorithm is competitive with the IA and GB for both **ALIGNED DICE** and **MAJORITY**. GB performs poorly here, and this may be due to the data sparsity issue that arises when requiring the algorithm to train on properties.⁸ In

⁷We do not report statistical significance; the proposed algorithm produces several possible outputs for one input, while the IA and GB produce only one.

⁸The original property-based weighting approach (Theune et al., 2011; Koolen et al., 2012, see Section 5.2) trained on object collections that were identical to their test data in all properties except x- and y-dimension, and so this was less of an issue. We hope to explore whether basing weights on attributes alone

MAJORITY, the Visible Objects Algorithm is relatively stable across conditions, generating the majority property set in 40% of the test scenes. It does not outperform the IA in the -LOC condition, but the IA has a large range across the two conditions (0% and 100%).

7 Conclusions and Future Work

We have introduced a new algorithm for generating referring expressions, inspired by human and computer vision and aiming to refer in a human-like way to visible objects. The algorithm successfully generates the most common attributes that people choose for different objects, and offers a varied output to capture speaker variation. In contrast to most algorithms for the generation of referring expressions, which have aimed to produce distinguishing descriptions when these exist (Krahmer and van Deemter, 2012), the core idea behind this algorithm is to generate what is likely for a speaker in a visual domain. Since the driving mechanism behind the algorithm is not to uniquely identify the object, but rather to pipeline the analysis of properties in a way similar to human visual processing, the generated expression may be overspecified or underspecified.

We are limited by available REG corpora to reliably assess methods for generating more complex absolute properties like shape and material, but adding such properties would help advance the generation of human-like reference in visual scenes and offers further points of connection between the generation process and computer vision property detection. Models for generating more complex spatial relations are currently available, and are a natural extension to this framework (e.g., those of Kelleher and Costello (2009)) as object detection becomes more robust.

We may also be able to build more sophisticated graphical models as larger corpora become available. For example, modeling the conditional probability of generating reference for a property v_n given the previously generated context $p(v_n|v_1 \dots v_{n-1})$ may bring us closer to human-like output.

There are several additional issues that do not arise in this evaluation, but we expect must be accounted for when referring to naturalistic objects in

improves performance.

visual domains. These include:

- The interconnected nature of properties, where some properties entail others; for example, a wooden object is likely to be called *wooden*, referring to its material, rather than *tan* or *brown*.
- The role of typicality, where properties are selected because they are atypical for the object.
- Referring to more complex properties, e.g., material, texture, etc., and object parts.
- Better methods for determining the length penalty and attribute likelihoods.

We hope to discuss extensions to this algorithm covering these aspects of reference in future work.

Abstract

We describe a supervised approach to predicting the set of all inflected forms of a lexical item. Our system automatically acquires the orthographic transformation rules of morphological paradigms from labeled examples, and then learns the contexts in which those transformations apply using a discriminative sequence model. Because our approach is completely data-driven and the model is trained on examples extracted from Wiktionary, our method can extend to new languages without change. Our end-to-end system is able to predict complete paradigms with 86.1% accuracy and individual inflected forms with 94.9% accuracy, averaged across three languages and two parts of speech.

1 Introduction

For natural languages with rich morphology, knowledge of how to inflect base forms is critical for both text generation and analysis. Hand-engineered, rule-based methods for predicting inflections can offer extremely high accuracy, but they are laborious to construct and do not exist with full lexical coverage in all languages. By contrast, a large number of example inflections are freely available in a semi-structured format on the Web. The English Wiktionary¹ is a crowd-sourced lexical resource that includes complete inflection tables for many lexical items in many languages. We present a supervised

system that, given only data from Wiktionary, automatically discovers and learns to apply the orthographic transformations governing a language’s inflectional morphology.²

Our data-driven approach is designed to extend to any language for which we have a substantial number of example inflection tables. The design of our model is guided by three structural assumptions:

1. The inflections of many lexical items are governed by a few repeated morphological paradigms.
2. A morphological paradigm can be decomposed into independent orthographic transformation rules (including prefix, suffix, and stem changes), which are triggered by orthographic context.
3. A base form is transformed in consistent, correlated ways to produce its inflected variants.

Learning proceeds in two stages that both utilize the same training set of labeled inflection tables. First, an inventory of interpretable transformation rules is generated by aligning each base form to all of its inflected forms. Second, a semi-Markov conditional random field (CRF) (Sarawagi and Cohen, 2004) is trained to apply these rules correctly to unseen base forms. As we demonstrate experimentally, the CRF is most effective when jointly predicting all inflected forms of a lexical item together, forcing the system to adopt a single consistent analysis of each base form.

*Research conducted during an internship at Google.

²See <http://eecs.berkeley.edu/~gdurrett> for our datasets and code.

Previous work has also described supervised and semi-supervised approaches to predicting inflectional morphology (Yarowsky and Wicentowski, 2000; Wicentowski, 2004; Dreyer and Eisner, 2011). Our approach differs primarily in its use of automatically extracted morphological rules and our discriminative prediction method which jointly models entire inflection tables. These modeling choices are directly inspired by the data setting: Wiktionary contains complete inflection tables for many lexical items in each of a large number of languages, so it is natural to make full use of this information with a joint model of all inflected forms.

We evaluate our predictions on held-out Wiktionary inflection tables for three languages and two parts of speech. Our language-independent method predicts inflections for unseen base forms with accuracies ranging from 88.9% (German nouns) to 99.7% (Spanish verbs). For comparability with previous work, we also evaluate our approach on German verb forms in the CELEX lexical database (Baayen et al., 1995). Our approach outperforms the semi-supervised hierarchical Bayesian model of Dreyer and Eisner (2011), while employing scalable exact inference and interpretable transformation rules.

2 Background: Inflectional Morphology

Among the valid words W and parts of speech P in a language, the base forms $B \subset W \times P$ are the canonical forms of the language’s lexical items. A base form relates to an inflected form via an inflectional relation (b, w, a) , where $b \in B$ is a base form, $w \in W$ is the inflected form, and a is a vector of morphological attributes. An inflection table $T(b)$ is the set of all such relations for a base form b .

Two partial inflection tables are shown in Table 1, for the base forms (infinitives) of the German verbs *machen* and *schleichen*, containing such inflectional relations as (*machen*, *mache*, [1P,PRES,SING]) and (*machen*, *gemacht*, [PAST PART.]). Only a small sample of the valid attribute combinations are shown; a full inflection table for a German verb in our Wiktionary dataset contains 27 relations.

The goal of this paper is to learn how to map b to $T(b)$. We generate candidate inflection tables by applying compact, interpretable orthographic trans-

INFINITIVE	machen	schleichen

2P,PRES,SING	machst	schleichst
3P,PRES,SING	macht	schleicht
PAST PART.	gemacht	geschlichen
...

Table 1: Two partial inflection tables for the German verbs *machen* (to make) and *schleichen* (to crawl).

formation rules that have been extracted from example tables. As an example of our rule application process, to inflect *machen* appropriately in the forms listed in Table 1, one could apply the following rules:

1. Replace a suffix *-en* with *-e* for first person, *-st* for second person, *-t* for third person, and *-t* for the past participle.
2. Add a prefix *ge-* for the past participle.

To inflect *schleichen*, one could apply a larger set of three rules:

1. Replace a suffix *-en* with *-e* for first person, *-st* for second person, *-t* for third person, and *-en* for the past participle.
2. Add a prefix *ge-* for the past participle.
3. Delete the first *e* for the past participle.

The inflection tables of other German verbs can be generated using precisely the same rules above, and different inflection patterns may share rules, such as the repeated rule 2. This example illustrates one of our chief assumptions, that the inflections of many base forms can be modeled with a small number of such rules, applied in various combinations.

3 Learning Transformation Rules

From a training set of inflection tables $\{T(b_1), \dots, T(b_n)\}$, our system learns a set of orthographic transformation rules. A rule is a function $R : s, a \rightarrow s'$ that takes as input a substring s of a base form and an attribute vector a and outputs a replacement substring s' . The suffix transformation from Section 2 for *machen* can be described using a

Algorithm 1 Learning rules from examples.

rule with four entries:

$$\begin{aligned} R(en, [1P, PRES, SING]) &= e \\ R(en, [2P, PRES, SING]) &= st \\ R(en, [3P, PRES, SING]) &= t \\ R(en, [\text{PAST PART.}]) &= t \end{aligned}$$

Our method for learning rules from examples is described in Algorithm 1 and depicted in Figure 1. We extract rules from each observed inflection table $T(b_i)$ independently, and the final set of rules is simply the union of the sets of rules learned from each example. The procedure for a single inflection table has three steps:

Alignment: Align each inflected form to the base form with an iterated edit-distance algorithm.

Span Merging: Extract the set of spans of the base form that changed to produce the inflected form, and take their union across all attribute vectors to identify maximal changed spans.

Rule Extraction: Extract a rule for each maximal changed span.

Alignment. For each setting of attributes a , we find the lowest-cost transformation of the base form b into the corresponding inflected form $T_a(b)$ using single-character insertions, deletions, and substitutions. This minimum edit distance calculation is computed via the following recurrence, where i is an index into the base form b and j is an index into

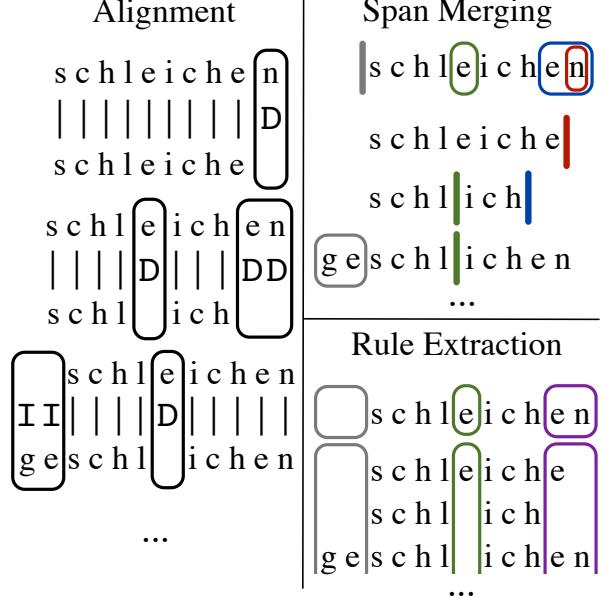

Figure 1: Demonstration of the rule extraction algorithm with the base form *schleichen* and three inflected forms: *schleiche* (first person singular present), *schlich* (first person singular past), and *geschlichen* (past participle). We ideally want to extract appropriate transformation rules like those described in Section 2. In the alignment step, we minimize the edit distance between each inflected form and the base form to identify changed spans. In the span merging step, we project changes onto the base form and take the union of adjacent or overlapping spans. In the rule extraction step, we project these spans back onto the inflected forms to identify transformation rules.

an inflected form $T_a(b)$:

$$\begin{aligned} L(i, j) = \min\{ &L(i, j - 1) + I, \\ &L(i - 1, j) + D, \\ &L(i - 1, j - 1) + S(i, j) \} \end{aligned}$$

I , D , and S are insertion, deletion, and substitution costs, respectively. Tracing the computation of $L(\text{len}(b), \text{len}(T_a(b)))$ yields an optimal sequence of edit operations. The alignments output by this procedure are depicted in the first panel of Figure 1.

The most typical cost scheme sets $I = 1$, $D = 1$, and $S(i, j) = (1 - \mathbb{I}[\text{match}(i, j)])$, i.e. 0 if the i th character of b is the same as the j th character of $T_a(b)$, and 1 otherwise. However, this cost scheme did not yield intuitive alignments for some of our training instances. For example, in the case of the verb *denken* aligning to its past participle *gedacht*,

the initial *d* and *g* will be aligned and the following *e*'s will be aligned, preventing the algorithm from recognizing the addition of the prefix *ge-*. To solve this problem, we use a dynamic edit distance cost scheme in which I , D , and unmatched substitutions all have a cost of 0. Matched substitutions have a negative cost $-c_i$, where i is the index in the base form and c_i is the number of other inflected forms for which i is aligned to a matching character. The inflected forms are iteratively realigned with the base form until the c_i converge (Eisner, 2002; Oncina and Sebban, 2006). This cost scheme encourages a single consistent analysis of the base form as it aligns to all of its inflected forms.

Span Merging. From each aligned pair of words, the PROJECTSPANS procedure identifies sequences of character edit operations with contiguous spans of the base form. We construct a set of changed spans C_a of b as follows: include the span (i, j) if and only if no characters between i and j were aligned to matching characters in $T_a(b)$ and no smaller span captures the same set of changes. Projected spans for the inflected forms of *schleichen* are shown in the “Span Merging” panel of Figure 1.

The UNIONSPANS procedure combines two sets of spans by iteratively merging any two spans that are overlapping or adjacent. Repeating this procedure to accumulate spans for each setting of a yields the set C of maximal changed spans for a base form. Any span in C is bordered either by word boundaries or by characters that are match-aligned in every inflected form, meaning that we have isolated a region characterized by a particular orthographic transformation.

Rule Extraction. The final step of Algorithm 1 extracts one rule for each maximal changed span of the base form. The Rule Extraction panel of Figure 1 depicts how maximal changed spans in the base form correspond to transformation rules. Because UNIONSPANS guarantees that match-aligned characters border each maximal changed span, there is no ambiguity about the segmentation of transformations. The EXTRACTRULE procedure produces one rule $R(s, a)$ corresponding to each changed span.

Table 2 contains examples of the transformation rules we extract from German verbs. The extracted

Attributes	Suffix				Stem	Pre.

3P,PRES,SING	t	t	t	t	e	
3P,PAST,SING	te	te		te		
PAST PART.	t	t	en	t		ge
...
Label	$R_{\text{suf},1}$	$R_{\text{suf},2}$	$R_{\text{suf},3}$	$R_{\text{suf},4}$	$R_{\text{st},1}$	$R_{\text{pre},1}$

Table 2: Each column is an example of a morphological transformation rule extracted by our approach. The first four are suffix changes; these apply to, in order, regular verbs such as *machen*, verbs ending in *-zen* or *-sen* such as *setzen*, verbs such as *schleichen* and *beheben*, and verbs ending in *-ern* or *-eln* such as *sprecken*. The stem change occurs in strong verbs of the first class such as *schleichen*, *greifen*, and *streiten*. Finally, we learn that *ge-* can be added as a prefix to indicate the past participle.

rules are interpretable descriptions of common inflection patterns.

4 Applying Transformation Rules

For a novel base form b , the inventory of learned transformation rules $\mathcal{R} = \{R(s, a)\}$ can typically generate many candidate inflection tables $T(b)$ for us to choose between. A rule can potentially apply to a base form in a number of places; we define an anchored rule $A = (R, i, j, b)$ to be the application of R to a span (i, j) in b . A is only a valid anchoring if the substring of b between i and j matches the input of rule R .

Given a set \mathcal{A} of non-overlapping anchored rules for b , each entry of $T(b)$ can be deterministically produced by rewriting each anchored rule's span (i, j) using the rule R . Therefore, the task of predicting $T(b)$ is equivalent to selecting a coherent subset \mathcal{A} of anchored rules from the set of all possible anchored rules for this base form. By coherent, we mean that the selected rules are anchored to non-overlapping, non-adjacent³ spans of b . Figure 2a shows two coherent anchored rule subsets for *schleichen* (the top one being correct). Underlining indi-

³During rule extraction, any adjacent changed spans are merged into a single rule. Disallowing adjacent spans here therefore prevents us from synthesizing new rules.

cates length-one spans $S = (i, i + 1, b)$ that are not part of any anchored rule in \mathcal{A} . We denote the set of such spans by $\mathcal{S}(\mathcal{A})$; this set is uniquely defined for the given base form by the selected anchored rules.

We use a log-linear model to place a conditional distribution over valid anchored rule subsets \mathcal{A} given the base form b :

$$p_w(\mathcal{A}|b) \propto \exp w^T \left(\sum_{A \in \mathcal{A}} \phi(A) + \sum_{S \in \mathcal{S}(\mathcal{A})} \psi(S) \right)$$

where w is a weight vector, $\phi(A)$ computes a feature vector for anchored rule A , and $\psi(S)$ computes a feature vector for preserved spans S . We train this model to maximize the regularized conditional log-likelihood of the training data, which consists of base forms b_i and gold subsets of anchored rules \mathcal{A}_i^* derived using Algorithm 1 on the gold inflection tables.

$$L(w) = \sum_{i=1}^n \log p(\mathcal{A}_i^*|b_i) + \frac{\gamma}{2} \|w\|^2.$$

We find $w^* = \arg \max_w L(w)$ using L-BFGS (Liu and Nocedal, 1989), which requires computing $\frac{\partial L}{\partial w}$. This gradient takes the standard form of the difference between gold feature counts and expected feature counts under the model:

$$\begin{aligned} \frac{\partial L}{\partial w} = \sum_{i=1}^n & \left[\left(\sum_{A \in \mathcal{A}_i^*} \phi(A) + \sum_{S \in \mathcal{S}(\mathcal{A}_i^*)} \psi(S) \right) - \right. \\ & \left. \left(\sum_{A \in \mathcal{A}(R, b)} \mathbb{E}_{p_w} \phi(A) + \sum_{S \in \mathcal{S}(b)} \mathbb{E}_{p_w} \psi(S) \right) \right] - \gamma w \end{aligned}$$

where, by a slight abuse of notation, $\mathcal{S}(b)$ is the set of all length-one spans of b .

In general, the normalizer of p_w and the expectation over p_w cannot be computed directly, since there may be exponentially many coherent subsets of anchored rules. However, we note that \mathcal{A} and its corresponding $\mathcal{S}(\mathcal{A})$ form a segmentation of the base form b , with features decomposing over individual segments. Our model can therefore be viewed a semi-Markov model over b (Sarawagi and Cohen, 2004); more precisely, a zeroth-order semi-Markov model, since we do not include features on state transitions. At training time, we can use the

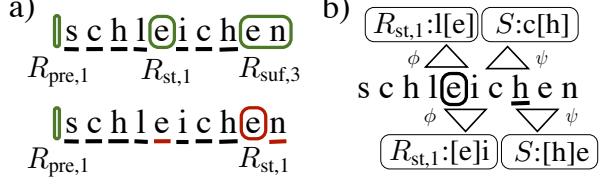

Figure 2: a) Two possible anchored rule sets for *schleichen*. The indicated rules are prefix, stem, and suffix rules as found in Table 2. The top anchoring is correct, while the bottom misplaces the stem change and does not include a suffix change. Underlined letters indicate preserved spans S . b) Bigram context features computed by $\phi(R_{st,1})$, where the stem change is applied to the highlighted *e*, and similar features computed by $\psi(S)$ for the underlined *h*, which is unchanged by the applied rules.

forward-backward algorithm for semi-Markov models to compute the gradient of p_w , and at test time, the Viterbi algorithm can exactly find the best rule subset under the model: $\hat{\mathcal{A}} = \arg \max_{\mathcal{A}} p_w(\mathcal{A}|b)$.

Features. The feature function ϕ captures contextual information in the base form surrounding the site of the anchored rule application. It is well understood that different morphological rules may require examining different amounts of context to apply correctly (Kohonen, 1986; Torkkola, 1993; Shalonova and Golénia, 2010); to this end, we will use local character n -gram features, which have been successfully applied to related problems (Jiampojamarn et al., 2008; Dinu et al., 2012).

A sketch of our feature computation scheme is shown in Figure 2b. Our basic feature template is an indicator on a character n -gram with some offset from the rule application site, conjoined with the identity of the rule R being applied. Our features look at variable amounts of context: we include features on unigrams through 4-grams, starting up to five letters behind the anchored rule span and ending up to five letters past the anchored rule span. These features can model most hand-coded morphological rules, but are in many cases more numerous than necessary. However, we find that regularization is effective at balancing high model capacity with generalization, and reducing the size of the feature set empirically harms overall accuracy.

We also employ factored features that only look at predictions over particular inflected forms; these are

coarser features that are shared between two rules when they predict the same orthographic change for a particular setting of attributes. These features are indicators on R_a (the restriction of R to attributes a), the context n -gram, and its offset from the span.

The feature function ψ is almost identical to ϕ , but instead of indicating a rule appearing in some context, it instead indicates that a particular length-one span is being preserved in its n -gram context. Examples of ψ features are shown in Figure 2b.

Pruning. Thus far, the only requirement on an anchoring A is that the source side of its rule R must match the span it is anchored to in the base form b . We further filter the set of possible A as follows: if every occurrence of R in the training set is preceded by the same character (including a start-of-word character) or followed by the same character (including an end-of-word character), any anchoring A must be preceded or followed accordingly. This stipulation is most useful in restricting prefixing or suffixing insertions, which have an empty source side, to apply only at the beginnings or ends of base forms (rather than at arbitrary points throughout). In doing so, we prune out many erroneous anchored rules and speed up inference substantially without prohibiting correct rule applications.

5 Wiktionary Morphology Data

Our primary source of supervised inflection table data is English Wiktionary. The collective editors of English Wiktionary have created complete, consistent inflection tables for many lexical items in many languages. Previous work has successfully parsed other information from Wiktionary, such as parts of speech, glosses, and etymology (Zesch et al., 2008; Li et al., 2012); however, to our knowledge, inflection tables have not previously been extracted in a format easily amenable to natural language processing applications. These inflection tables are challenging to extract because the layout of tables varies substantially by language (beyond the expected changes due to differing sets of relevant morphological attributes), and some tables contain annotations in addition to word forms.

In order to extract this data, we built a Wiktionary scraper which generates fully structured output by interpreting the templates that generate the rendered

Lang/POS	Base forms	Infl. forms per base
DE-NOUNS	2764	8
DE-VERBS	2027	27
ES-VERBS	4055	57
FI-NOUNS	40589	28
FI-VERBS	7249	53

Table 3: Number of full morphology tables extracted from Wiktionary for each language and part of speech pair that we considered, as well as the number of inflected forms associated with each base form.

inflection tables. Table 3 gives statistics for the number of base forms and inflected forms extracted from Wiktionary. When multiple forms were listed in an inflection table for the same base form and attribute vector, we selected the first in linear order; applying the same principle, we also kept only the first inflection table when more than one was listed for a given base form. Furthermore, base forms and inflected forms separated by spaces, hyphens, or colons were discarded. As a result, we discarded German verb-preposition compounds such as *ablehnen*⁴ and Spanish reflexives such as *lavarse*.

6 Experiments

We evaluate our model under two experimental conditions. First, we use the German verb lexicon in the CELEX lexical database (Baayen et al., 1995) with the same train/test splits as Dreyer and Eisner (2011). Second, we train on our Wiktionary data described in Section 5 and evaluate on held-out forms from this same dataset.

In each case, we evaluate two variants of our model in order to examine the importance of jointly modeling the production of the entire inflection table. Our JOINT model is exactly as defined in Section 4. For our FACTORED model, the dictionary of rules is extracted separately for each setting of the attributes a ; i.e., we run the entire procedure in Section 3 with only one inflected form at a time and forego the UNIONSPANS step. A separate prediction model is trained for each a and so features are not shared across multiple predictions as they are in the JOINT case. Note that this FACTORED approach

⁴This class of verbs was also ignored by Dreyer and Eisner (2011).

	No. of training examples		
	50	100	200
NAÏVE	87.61	87.70	87.70
FACTORED	89.61	91.40	92.64
JOINT	90.47	92.31	93.18
DE11	89.9	91.5	
DE11+CORPUS	90.9	92.2	
ORACLE	95.47	96.09	96.77

Table 4: Accuracies on reconstructing individual inflected forms in CELEX, averaged over the 5415 inflection tables in each of 10 test sets. Three training set sizes are reported. DE11 indicates a reported result from Dreyer and Eisner (2011), with blank results unreported in that work. Our FACTORED model is able to do approximately as well as the DE11 baseline method, and our JOINT model performs better yet, performing comparably to DE11+CORPUS, which uses additional monolingual text. All models substantially outperform the NAÏVE suffixing baseline. The relatively low ORACLE accuracy indicates that some errors arise from failing to apply rules that are not attested in these small training sets.

can produce inflection tables that the JOINT model cannot, due to its ability to “mix and match” orthographic changes in the same inflection table.

We also evaluate a NAÏVE method for applying the joint rules which selects the most common suffix rule available after pruning.⁵ Finally, we report the ORACLE accuracy attainable with the morphological rule dictionary of the JOINT model.

For our conditional likelihood objective, we use $\gamma = 0.0002$; this parameter and the feature set were tuned on a small development set and held fixed for all experiments.

6.1 CELEX Experiments

Dreyer and Eisner (2011) construct ten train/test splits of the 5615 German verb forms in the CELEX lexical database, keeping 200 forms for training in each case, which they further subsample. These random splits serve to control for instability due to the small training set sizes. Each infinitive verb form has 22 corresponding inflected forms capturing variation such as person, number, mood, and tense.

⁵For example, for German verbs ending in *-en*, this applies the most regular *-en* suffix change, that exhibited by *machen* and many other verbs.

Table 4 shows our results compared to those of Dreyer and Eisner (2011). The FACTORED model performs on par with the DE11 baseline model, but the stronger performance of the JOINT model indicates that making joint predictions is important. With 100 training examples, our model is able to equal the performance of DE11+CORPUS, which additionally uses ten million tokens of monolingual German text.

We emphasize that this is not the data condition for which our model was designed. It is unfavorable for two reasons: first, feature-rich models can be learned more stably on larger training sets, and second, the train/test splits are chosen randomly, and therefore the test sets may contain completely irregular verbs using morphological rules that we have never observed. As can be seen from the ORACLE results in Table 4, a substantial fraction of the missed test examples cannot be produced using our extracted rules simply because we have not seen the relevant examples; in many cases, even a human could not generalize correctly from the given examples without exploiting external knowledge of the German language.

6.2 Held-Out Wiktionary Data

Our algorithm was designed with the fundamental assumption that the training set should be a comprehensive description of the morphology of a given language, which is not true for the CELEX data. In order to evaluate on a broader set of languages under these training conditions, we turn to our Wiktionary data. For each language and part of speech, we train on all but 400 inflection tables, holding back 200 examples as a development set and 200 examples as a blind test set.⁶ The forms selected for the development and test data were purposely chosen not to be among the 200 most frequently occurring forms in the language, since these common cases can be easily memorized from Wiktionary.

Results are shown in Table 5. As with the CELEX results, we see that the joint prediction improves accuracy over the factored model, obtaining a 9% error reduction on individual forms and a 35% error reduction on exact match. The more pronounced

⁶For Finnish nouns, because there were so many inflection tables, we trained only on the first 6000 examples. Using more examples did not significantly change performance.

Lang/POS	Exact table match				Individual form accuracy			
	NAÏVE	FACT.	JOINT	ORACLE	NAÏVE	FACT.	JOINT	ORACLE
DE-VERBS	42.0	74.5	85.0	99.5	89.13	94.76	96.19	99.98
DE-NOUNS	12.0	74.0	79.5	98.5	49.06	88.31	88.94	99.25
ES-VERBS	81.5	93.5	95.0	99.5	97.20	99.61	99.67	99.99
FI-VERBS	33.5	82.0	87.5	99.5	75.32	97.23	96.43	99.86
FI-NOUNS	31.0	69.0	83.5	100.0	61.23	92.14	93.41	100.00
AVG	40.0	78.6	86.1	99.4	74.39	94.41	94.93	99.81

Table 5: Accuracies on reconstructing complete inflection tables and individual inflected forms for held-out base forms in our Wiktionary dataset. Results are shown for our fully JOINT model, a FACTORED model that predicts individual inflected forms independently, a NAÏVE baseline that picks the most common applicable suffix rule, and an ORACLE that selects the best inflection table within our model’s capacity. For each language and part of speech, regardless of training set size, evaluation is based on a blind test set of 200 held-out forms.

improvement on exact match is unsurprising, since we expect that the joint predictions should get inflection tables correct in an “all-or-nothing” fashion, whereas factored predictions are more likely to reflect divergent feature weights of the different component models. The NAÏVE baseline performs rather poorly overall, indicating our algorithm is being sophisticated about applying more than just the most common changes. Finally, we note that the ORACLE performance is much higher in this case than on the CELEX data, confirming our intuition that with the appropriate level of supervision our model at least has the capacity to make correct predictions in almost every case.

6.3 Error Analysis

We conducted an error analysis on the output of our JOINT model on German nouns. From 2364 paradigms, we learn 53 different orthographic transformation rules, of which our 200-example development set exhibits 14.⁷

On our development set, 196 inflection tables are within the capacity of our model. Of those 196, 159 are exactly correct. In Table 6, we show the top six rules by frequency in the development set, along

⁷Nineteen of our 53 extracted rules only occur on one example; this suggests a few reasons that fewer rules are applied than are extracted. First, very common base forms with irregular morphology may give rise to completely irregular rules. Second, our edit distance alignment procedure can sometimes merge two adjacent rules if the orthographic context is such that there are multiple minimum-cost analyses. Finally, errors and inconsistencies in Wiktionary can yield nonsense rules that are never applied elsewhere.

Table 6: Breakdown of errors by morphological rule being applied by the JOINT model on the DE-NOUNS development set. We show the rule itself, treating the nominative singular as the base form, an example of a German word using that rule, and then the model’s accuracy at predicting applications of that rule. Errors are spread out over many rules, but it generally appears that common rules are to blame for the errors that are made, due in large part to gender confusion in this case.

with the precision, recall, and F-measure that our model attains for each rule.⁸ These rules are mostly interpretable: for example, the first two columns correspond to common suffix rules for feminine and masculine nouns, respectively. Our model’s performance is consistently high for each of the rules shown, including a stem change (*a* changing to *ä* in plural forms), providing further evidence that our model is useful for modeling rarer morphological

⁸Gold rules are obtained by running our rule extraction procedure over the examples in question.

paradigms as well as more common ones.

As a concrete example of an error our model does make, *Löwe* (lion) is incorrectly predicted to have the first suffix, instead of the correct suffix (not shown) which adds an *-n* for accusative, genitive, and dative singular as well. However, making this prediction correctly is essentially beyond the capacity of a model based purely on orthography. Words ending in *-e* are commonly feminine, and none of our other training examples end in *-we*, so guessing that *Löwe* follows a common feminine inflection pattern is reasonable (though *Löwe* is, in fact, masculine). Disambiguating this case requires either features on observed genders, a more complex model of the German language, or observing the word in a large corpus. Generally, when the model fails, as in this case, it is because of a fundamental linguistic information source that it does not have access to.

7 Related Work

Much of the past work on morphology has focused on concatenative morphology using unsupervised methods (Goldsmith, 2001; Creutz and Lagus, 2007; Monson, 2008; Poon et al., 2009; Goldwater et al., 2009) or weak forms of supervision (Snyder and Barzilay, 2008). These methods can handle aspects of derivational morphology that we cannot, such as compounding, but we can handle a much larger subset of inflectional morphology, including more complex prefix and suffix rules, stem changes, and irregular forms. Some unsupervised work has specifically targeted these sorts of phenomena by, for example, learning spelling rules for mildly nonconcatenative cases (Dasgupta and Ng, 2007; Naradowsky and Goldwater, 2009) or mining lemma-base form pairs from a corpus (Schone and Jurafsky, 2001), but it is extremely difficult to make unsupervised methods perform as well as supervised approaches like ours.

Past supervised work on nonconcatenative inflectional morphology has typically targeted individual pairs of base forms and inflected forms for the purposes of inflection (Clark, 2001) or lemmatization (Yarowsky and Wicentowski, 2000; Wicentowski, 2004; Lindén, 2008; Toutanova and Cherry, 2009). Some of these methods may use analysis (Lindén,

2008) or decoding (Toutanova and Cherry, 2009) steps similar to those of our model, but none attempt to jointly predict a complete inflection table based on automatically extracted rules.

Some previous work has addressed the joint analysis (Zajac, 2001; Monson, 2008) or prediction (Lindén and Tuovila, 2009; Dinu et al., 2012) of whole inflection tables, as we do, but rarely are both aspects addressed simultaneously and most approaches are tuned to one particular language or use language-specific, curated resources. In overall setup, our work most closely resembles that of Dreyer and Eisner (2011), but they focus on incorporating large amounts of raw text data rather than using large training sets effectively.

Broadly similar techniques are also employed in systems to filter candidate rules and aid in human annotation of paradigms (Zajac, 2001; Forsberg et al., 2006; Détrez and Ranta, 2012) for resources such as Grammatical Framework (Ranta, 2011).

8 Conclusion

In this work, we presented a method for inflecting base forms in morphologically rich languages: we first extract orthographic transformation rules from observed inflection tables, then learn to apply these rules to new base forms based on orthographic features. Training examples for our supervised method can be collected from Wiktionary for a large number of languages and parts of speech. The changes we extract are interpretable and can be associated with particular classes of words. Moreover, our model can successfully apply these changes to unseen base forms with high accuracy, allowing us to rapidly generate lexicons for new languages of interest.

Our Wiktionary datasets and an open-source version of our code are available at <http://eecs.berkeley.edu/~gdurrett>

Optimal Data Set Selection: An Application to Grapheme-to-Phoneme Conversion

Young-Bum Kim and Benjamin Snyder

University of Wisconsin-Madison

{ybkim, bsnyder}@cs.wisc.edu

Abstract

In this paper we introduce the task of unlabeled, optimal, data set selection. Given a large pool of unlabeled examples, our goal is to select a small subset to label, which will yield a high performance supervised model over the entire data set. Our first proposed method, based on the rank-revealing QR matrix factorization, selects a subset of words which span the entire word-space effectively. For our second method, we develop the concept of *feature coverage* which we optimize with a greedy algorithm. We apply these methods to the task of grapheme-to-phoneme prediction. Experiments over a data-set of 8 languages show that in all scenarios, our selection methods are effective at yielding a small, but optimal set of labelled examples. When fed into a state-of-the-art supervised model for grapheme-to-phoneme prediction, our methods yield average error reductions of 20% over randomly selected examples.

1 Introduction

Over the last 15 years, supervised statistical learning has become the dominant paradigm for building natural language technologies. While the accuracy of supervised models can be high, expertly annotated data sets exist for a small fraction of possible tasks, genres, and languages. The would-be tool builder is thus often faced with the prospect of annotating data, using crowd-sourcing or domain experts. With limited time and budget, the amount of data to be annotated might be small, especially in the prototyping stage, when the exact specification of the prediction

task may still be in flux, and rapid prototypes are desired.

In this paper, we propose the problem of unsupervised, optimal data set selection. Formally, given a large set \mathcal{X} of n unlabeled examples, we must select a subset $\mathcal{S} \subset \mathcal{X}$ of size $k \ll n$ to label. Our goal is to select such a subset which, when labeled, will yield a high performance supervised model over the entire data set \mathcal{X} . This task can be thought of as a zero-stage version of active learning: we must choose a single batch of examples to label, without the benefit of any prior labelled data points. This problem definition avoids the practical complexity of the active learning set-up (many iterations of learning and labeling), and ensures that the labeled examples are not tied to one particular model class or task, a well-known danger of active learning (Settles, 2010). Alternatively, our methods may be used to create the initial seed set for the active learner.

Our initial testbed for optimal data set selection is the task of grapheme-to-phoneme conversion. In this task, we are given an out-of-vocabulary word, with the goal of predicting a sequence of phonemes corresponding to its pronunciation. As training data, we are given a pronunciation dictionary listing words alongside corresponding sequences of phones, representing canonical pronunciations of those words. Such dictionaries are used as the final bridge between written and spoken language for technologies that span this divide, such as speech recognition, text-to-speech generation, and speech-to-speech language translation. These dictionaries are necessary: the pronunciation of words

continues to evolve after their written form has been fixed, leading to a large number of rules and irregularities. While large pronunciation dictionaries of over 100,000 words exist for several major languages, these resources are entirely lacking for the majority of the world’s languages. Our goal is to automatically select a small but optimal subset of words to be annotated with pronunciation data.

The main intuition behind our approach is that the subset of selected data points should efficiently cover the range of phenomena most commonly observed across the pool of unlabeled examples. We consider two methods. The first comes from a line of research initiated by the numerical linear algebra community (Golub, 1965) and taken up by computer science theoreticians (Boutsidis et al., 2009), with the name COLUMN SUBSET SELECTION PROBLEM (CSSP). Given a matrix A , the goal of CSSP is to select a subset of k columns whose span most closely captures the range of the full matrix. In particular, the matrix \tilde{A} formed by orthogonally projecting A onto the k -dimensional space spanned by the selected columns should be a good approximation to A . By defining A^T to be our data matrix, whose rows correspond to words and whose columns correspond to features (character 4-grams), we can apply the CSSP randomized algorithm of (Boutsidis et al., 2009) on A to obtain a subset of k words which best span the entire space of words.

Our second approach is based on a notion of *feature coverage*. We assume that the benefit of seeing a feature f in a selected word bears some positive relationship to the frequency of f in the unlabeled pool. However, we further assume that the lion’s share of benefit accrues the first few times that we label a word with feature f , with the marginal utility quickly tapering off as more such examples have been labeled. We formalize this notion and provide an exact greedy algorithm for selecting the k data points with maximal feature coverage.

To assess the benefit of these methods, we apply them to a suite of 8 languages with pronunciation dictionaries. We consider ranges from 500 to 2000 selected words and train a start-of-the-art grapheme-to-phoneme prediction model (Bisani and Ney, 2008). Our experiments show that both methods produce significant improvements in prediction quality over randomly selected words, with our fea-

ture coverage method consistently outperforming the randomized CSSP algorithm. Over the 8 languages, our method produces average reductions in error of 20%.

2 Background

Grapheme-to-phoneme Prediction The task of grapheme-to-phoneme conversion has been considered in a variety of frameworks, including neural networks (Sejnowski and Rosenberg, 1987), rule-based FSA’s (Kaplan and Kay, 1994), and pronunciation by analogy (Marchand and Damper, 2000). Our goal here is not to compare these methods, so we focus on the probabilistic joint-sequence model of Bisani and Ney (2008). This model defines a joint distribution over a grapheme sequence $\mathbf{g} \in G^*$ and a phoneme sequence $\phi \in \Phi^*$, by way of an unobserved *co-segmentation* sequence \mathbf{q} . Each co-segmentation unit q_i is called a *graphone* and consists of an aligned pair of zero or one graphemes and zero or one phonemes: $q_i \in G \cup \{\epsilon\} \times \Phi \cup \{\epsilon\}$.¹ The probability of a joint grapheme-phoneme sequence is then obtained by summing over all possible co-segmentations:

$$P(\mathbf{g}, \phi) = \sum_{\mathbf{q} \in S(\mathbf{g}, \phi)} P(\mathbf{q})$$

where $S(\mathbf{g}, \phi)$ denotes the set of all graphone sequences which yield \mathbf{g} and ϕ . The probability of a graphone sequence of length K is defined using an h -order Markov model with multinomial transitions:

$$P(\mathbf{q}) = \prod_{i=1}^{k+1} P(q_i | q_{i-h}, \dots, q_{i-1})$$

where special start and end symbols are assumed for $q_{j < 1}$ and q_{k+1} , respectively.

To deal with the unobserved co-segmentation sequences, the authors develop an EM training regime that avoids overfitting using a variety of smoothing and initialization techniques. Their model produces state-of-the-art or comparable accuracies across a

¹The model generalizes easily to graphones consisting of more than one grapheme or phoneme, but in both (Bisani and Ney, 2008) and our initial experiments we found that the 01-to-01 model always performed best.

wide range of languages and data sets.² We use the publicly available code provided by the authors.³ In all our experiments we set $h = 4$ (i.e. a 5-gram model), as we found that accuracy tended to be flat for $h > 4$.

Active Learning for G2P Perhaps most closely related to our work are the papers of Kominek and Black (2006) and Dwyer and Kondrak (2009), both of which use active learning to efficiently bootstrap pronunciation dictionaries. In the former, the authors develop an active learning word selection strategy for inducing pronunciation rules. In fact, their greedy n-gram selection strategy shares some of the same intuition as our second data set selection method, but they were unable to achieve any accuracy gains over randomly selected words without active learning.

Dwyer and Kondrak use a Query-by-Bagging active learning strategy over decision tree learners. They find that their active learning strategy produces higher accuracy across 5 of the 6 languages that they explored (English being the exception). They extract further performance gains through various refinements to their model. Even so, we found that the Bisani and Ney grapheme-to-phoneme (G2P) model (Bisani and Ney, 2008) always achieved higher accuracy, even when trained on random words. Furthermore, the relative gains that we observe using our optimal data set selection strategies (without any active learning) are much larger than the relative gains of active learning found in their study.

Data Set Selection and Active Learning
Eck et al (2005) developed a method for training compact Machine Translation systems by selecting a subset of sentences with high n-gram coverage. Their selection criterion essentially corresponds to our feature coverage selection method using coverage function cov_2 (see Section 3.2). As our results will show, the use of a geometric feature discount (cov_3) provided better results in our task.

Otherwise, we are not aware of previous work

²We note that the discriminative model of Jiampojamarn and Kondrak (2010) outperforms the Bisani and Ney model by an average of about 0.75 percentage points across five data sets.

³<http://www-i6.informatik.rwth-aachen.de/web/Software/g2p.html>

proposing optimal data set selection as a general research problem. Of course, active learning strategies can be employed for this task by starting with a small random seed of examples and incrementally adding small batches. Unfortunately, this can lead to datasets that are biased to work well for one particular class of models and task, but may otherwise perform worse than a random set of examples (Settles, 2010, Section 6.6). Furthermore the active learning set-up can be prohibitively tedious and slow. To illustrate, Dwyer and Kondrak (2009) used 190 iterations of active learning to arrive at 2,000 words. Each iteration involves bootstrapping 10 different samples, and training 10 corresponding learners. Thus, in total, the underlying prediction model is trained 1,900 times. In contrast, our selection methods are fast, can select any number of data points in a single step, and are not tied to a particular prediction task or model. Furthermore, these methods can be combined with active learning in selecting the initial seed set.

Unsupervised Feature Selection Finally, we note that CSSP and related spectral methods have been applied to the problem of *unsupervised feature selection* (Stoppiglia et al., 2003; Mao, 2005; Wolf and Shashua, 2005; Zhao and Liu, 2007; Boutsidis et al., 2008). These methods are related to dimensionality reduction techniques such as Principal Components Analysis (PCA), but instead of truncating features in the eigenbasis representation (where each feature is a linear combination of all the original features), the goal is to remove dimensions in the standard basis, leading to a compact set of interpretable features. As long as the discarded features can be well approximated by a (linear) function of the selected features, the loss of information will be minimal.

Our first method for optimal data-set creation applies a randomized CSSP approach to the transpose of the data matrix, A^T . Equivalently, it selects the optimal k rows of A for embedding the full set of unlabeled examples. We use a recently developed randomized algorithm (Boutsidis et al., 2009), and an underlying rank-revealing QR factorization (Golub, 1965).

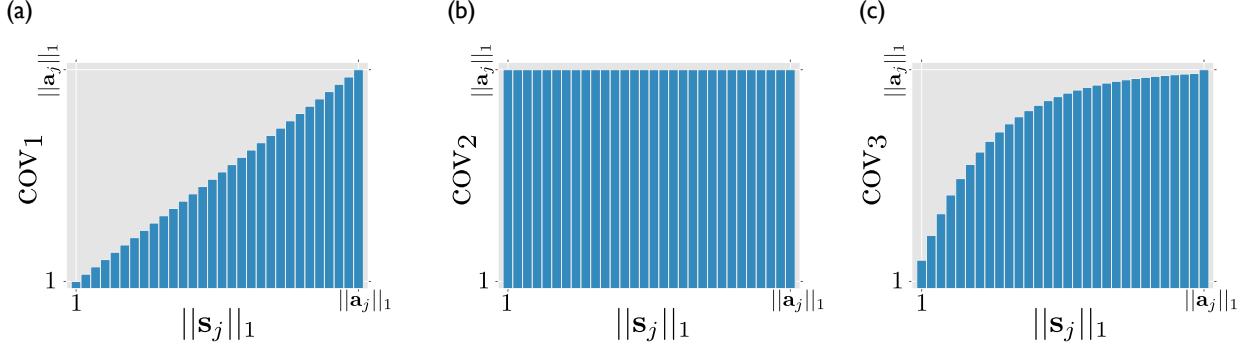

Figure 1: Various versions of the feature coverage function. Panel (a) shows cov_1 (Equation 5). Panel (b) shows cov_2 (Equation 6). Panel (c) shows cov_3 (Equation 7) with discount factor $\eta = 1.2$.

3 Two Methods for Optimal Data Set Selection

In this section we detail our two proposed methods for optimal data set selection. The key intuition is that we would like to pick a subset of data points which broadly and efficiently cover the features of the full range of data points. We assume a large pool \mathcal{X} of n unlabeled examples, and our goal is to select a subset $\mathcal{S} \subset \mathcal{X}$ of size $k \ll n$ for labeling. We assume that each data point $x \in \mathcal{X}$ is a vector of m feature values. Our first method applies to any real or complex feature space, while our second method is specialized for binary features. We will use the $(n \times m)$ matrix A to denote our unlabeled data: each row is a data point and each column is a feature. In all our experiments, we used the presence (1) or absence (0) of each character 4-gram as our set of features.

3.1 Method 1: Row Subset Selection

To motivate this method, first consider the task of finding a rank k approximation to the data matrix A . The SVD decomposition yields:

$$A = U\Sigma V^T$$

- U is $(n \times n)$ orthogonal and its columns form the eigenvectors of AA^T
- V is $(m \times m)$ orthogonal and its columns form the eigenvectors of A^TA
- Σ is $(n \times m)$ diagonal, and its diagonal entries are the singular values of A (the square roots of the eigenvalues of both AA^T and A^TA).

To obtain a rank k approximation to A , we start by rewriting the SVD decomposition as a sum:

$$A = \sum_{i=1}^{\rho} \sigma_i \mathbf{u}_i \mathbf{v}_i^T \quad (1)$$

where $\rho = \min(m, n)$, σ_i is the i^{th} diagonal entry of Σ , \mathbf{u}_i is the i^{th} column of U , and \mathbf{v}_i is the i^{th} column of V . To obtain a rank k approximation to A , we simply truncate the sum in equation 1 to its first k terms, yielding A_k . To evaluate the quality of this approximation, we can measure the Frobenius norm of the residual matrix $\|A - A_k\|_F$.⁴ The Eckart-Young theorem (Eckart and Young, 1936) states that A_k is optimal in the following sense:

$$A_k = \underset{\tilde{A} \text{ s.t. } \text{rank}(\tilde{A})=k}{\operatorname{argmin}} \|A - \tilde{A}\|_F \quad (2)$$

In other words, truncated SVD gives the best rank k approximation to A in terms of minimizing the Frobenius norm of the residual matrix. In CSSP, the goal is similar, with the added constraint that the approximation to A must be obtained by projecting onto the subspace spanned by a k -subset of the original rows of A .⁵ Formally, the goal is to produce a $(k \times m)$ matrix S formed from rows of A , such that

$$\|A - AS^+S\|_F \quad (3)$$

⁴The Frobenius norm $\|M\|_F$ is defined as the entry-wise L_2 norm: $\sqrt{\sum_{i,j} m_{ij}^2}$

⁵Though usually framed in terms of column selection, we switch to row selection here as our goal is to select data points rather than features.

is minimized over all $\binom{n}{k}$ possible choices for S . Here S^+ is the $(m \times k)$ Moore-Penrose pseudo-inverse of S , and S^+S gives the orthogonal projector onto the rowspace of S . In other words, our goal is to select k data points which serve as a good approximate basis for *all* the data points. Since AS^+S can be at most rank k , the constraint considered here is stricter than that of Equation 1, so the truncated SVD A_k gives a lower bound on the residual.

Boutsidis et al (2009) develop a randomized algorithm that produces a submatrix S (consisting of k rows of A) which, with high probability, achieves a residual bound of:

$$\|A - AS^+S\|_F \leq O(k\sqrt{\log k})\|A - A_k\|_F \quad (4)$$

in running time $O(\min\{mn^2, m^2n\})$. The algorithm proceeds in three steps: first by computing the SVD of A , then by randomly sampling $O(k \log k)$ rows of A with importance weights carefully computed from the SVD, and then applying a deterministic rank-revealing QR factorization (Golub, 1965) to select k of the sampled rows. To give some intuition, we now provide some background on rank revealing factorizations.

Rank revealing QR / LQ (RRQR) Every real $(n \times m)$ matrix can be factored as $A = LQ$, where Q is $(m \times m)$ orthogonal and L is $(n \times m)$ lower triangular.⁶ It is important to notice that in this triangular factorization, each successive row of A introduces exactly one new basis vector from Q . We can thus represent row i as a linear combination of the first $i - 1$ rows along with the i^{th} row of Q .

A *rank-revealing* factorization is one which displays the numerical rank of the matrix — defined to be the singular value index r such that

$$\sigma_r \gg \sigma_{r+1} = O(\epsilon)$$

for machine precision ϵ . In the case of the LQ factorization, our goal is to order the rows of A such that each successive row has decreasing representational importance as a basis for the future rows. More formally, If there exists a row permutation Π such that ΠA has a triangular factorization

⁶We replace the standard upper triangular QR factorization with an equivalent lower triangular factorization LQ to focus intuition on the rowspace of A .

Language	Training	Test	Total
Dutch	11,622	104,589	116,211
English	11209	100891	112100
French	2,748	24,721	27,469
Frisian	6,198	55,778	61,976
German	4,942	44,460	49,402
Italian	7,529	79,133	86,662
Norwegian	4,172	37,541	41,713
Spanish	3,150	28,341	31,491

Table 1: Pronunciation dictionary size for each of the languages.

$\Pi A = LQ$ with $L = \begin{bmatrix} L_{11} & 0 \\ L_{21} & L_{22} \end{bmatrix}$, where the smallest singular value of L_{11} is much greater than the spectral norm of L_{22} , which is itself almost zero:

$$\sigma_{\min}(L_{11}) \gg \|L_{22}\|_2 = O(\epsilon)$$

then we say that $\Pi A = LQ$ is a *rank-revealing LQ factorization*. Both L_{11} and L_{22} will be lower triangular matrices and if L_{11} is $(r \times r)$ then A has numerical rank r (Hong and Pan, 1992).

Implementation In our implementation of the CSSP algorithm, we first prune away 4-gram features that appear in fewer than 3 words, then compute the SVD of the pruned data matrix using the PROPACK package,⁷ which efficiently handles sparse matrixes. After sampling $k \log k$ words from A (with sampling weights calculated from the top- k singular vectors), we form a submatrix B consisting of the sampled words. We then use the RRQR implementation from ACM Algorithm 782 (Bischof and Quintana-Ortí, 1998) (routine DGEQPX) to compute $\Pi B = LQ$. We finally select the first k rows of ΠB as our optimal data set. Even for our largest data sets (English and Dutch), this entire procedure runs in less than an hour on a 3.4Ghz quad-core i7 desktop with 32 GB of RAM.

3.2 Method 2: Feature Coverage Maximization

In our previous approach, we adopted a general method for approximating a matrix with a subset of rows (or columns). Here we develop a novel objective function with the specific aim of optimal data set selection. Our key assumption is that the benefit of

⁷<http://soi.stanford.edu/~rmunk/PROPACK/>

seeing a new feature f in a selected data point bears a positive relationship to the frequency of f in the unlabeled pool of words. However, we further assume that the lion’s share of benefit accrues quickly, with the marginal utility quickly tapering off as we label more and more examples with feature f . Note that for this method, we assume a boolean feature space.

To formalize this intuition, we will define the *coverage* of a selected $(k \times m)$ submatrix S consisting of rows of A , with respect to a feature index j . For illustration purposes, we will list three alternative definitions:

$$\text{cov}_1(S; j) = \|\mathbf{s}_j\|_1 \quad (5)$$

$$\text{cov}_2(S; j) = \|\mathbf{a}_j\|_1 \mathbb{I}(\|\mathbf{s}_j\|_1 > 0) \quad (6)$$

$$\text{cov}_3(S; j) = \|\mathbf{a}_j\|_1 - \frac{\|\mathbf{a}_j\|_1}{\eta \|\mathbf{s}_j\|_1} \mathbb{I}(\|\mathbf{s}_j\|_1 < \|\mathbf{a}_j\|_1) \quad (7)$$

In all cases, \mathbf{s}_j refers the j^{th} column of S , \mathbf{a}_j refers the j^{th} column of A , $\mathbb{I}(\cdot)$ is a 0-1 indicator function, and η is a scalar discount factor.⁸

Figure 1 provides an intuitive explanation of these functions: cov_1 simply counts the number of selected data points with boolean feature j . Thus, full coverage ($\|\mathbf{a}_j\|_1$: the entire number of data points with the feature) is only achieved when *all* data points with the feature are selected. cov_2 lies at the opposite extreme. Even a single selected data point with feature j triggers coverage of the entire feature. Finally, cov_3 is designed so that the coverage scales monotonically as additional data points with feature j are selected. The first selected data point will capture all but $\frac{1}{\eta}$ of the total coverage, and each further selected data point will capture all but $\frac{1}{\eta}$ of whatever coverage remains. Essentially, the coverage for a feature scales as a geometric series in the number of selected examples having that feature.

To ensure that the total coverage ($\|\mathbf{a}_j\|_1$) is achieved when all the data points are selected, we add an indicator function for the case of $\|\mathbf{c}_j\|_1 = \|\mathbf{a}_j\|_1$.⁹

⁸Chosen to be 5 in all our experiments. We experimented with several values between 2 and 10, without significant differences in results.

⁹Otherwise, the geometric coverage function would converge to $\|\mathbf{a}_j\|$ only as $\|\mathbf{c}_j\| \rightarrow \infty$.

Table 2: Test word accuracy across the 8 languages for randomly selected words (RAND), CSSP matrix subset selection (CSSP), and Feature Coverage Maximization (FEAT). We show results for 500 and 2000 word training sets.

Setting our feature coverage function to cov_3 , we can now define the overall feature coverage of the selected points as:

$$\text{coverage}(S) = \frac{1}{\|A\|_1} \sum_j \text{cov}_3(S; j) \quad (8)$$

where $\|A\|_1$ is the L_1 entrywise matrix norm, $\sum_{i,j} |A_{ij}|$, which ensures that $0 \leq \text{coverage}(S) \leq 1$ with equality only achieved when $S = A$, i.e. when all data points have been selected.

We provide a brief sketch of our optimization algorithm: To pick the subset S of k words which optimizes Equation 8, we incrementally build optimal subsets $S' \subset S$ of size $k' < k$. At each stage, we keep track of the unclaimed coverage associated with each feature j :

$$\text{unclaimed}(j) = \|\mathbf{a}_j\|_1 - \text{cov}_3(S'; j)$$

To add a new word, we scan through the pool of remaining words, and calculate the additional coverage that selecting word w would achieve:

$$\Delta(w) = \sum_{\text{feature } j \text{ in } w} \text{unclaimed}(j) \left(\frac{\eta - 1}{\eta} \right)$$

We greedily select the word which adds the most coverage, remove it from the pool, and update the unclaimed feature coverages. It is easy to show that this greedy algorithm is globally optimal.

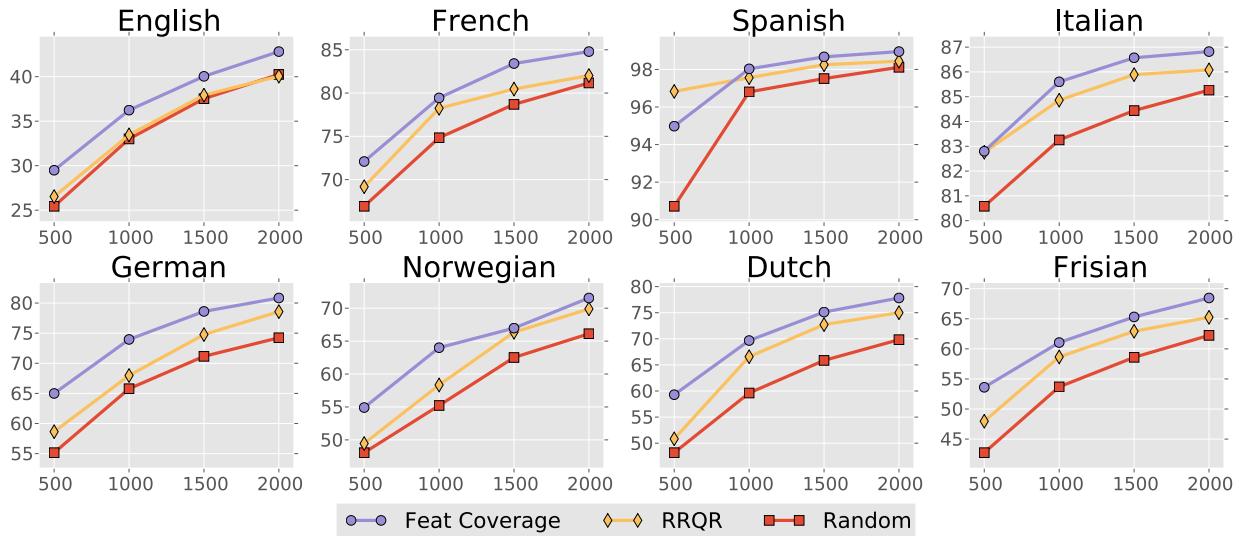

Figure 2: Test word accuracy across the 8 languages for (1) feature coverage, (2) CSSP matrix subset selection, (3) and randomly selected words.

4 Experiments and Analysis

To test the effectiveness of the two proposed data set selection methods, we conduct grapheme-to-phoneme prediction experiments across a test suite of 8 languages: Dutch, English, French, Frisian, German, Italian, Norwegian, and Spanish. The data was obtained from the PASCAL Letter-to-Phoneme Conversion Challenge,¹⁰ and was processed to match the setup of Dwyer and Kondrak (2009). The data comes from a range of sources, including CELEX for Dutch and German (Baayen et al., 1995), BRULEX for French (Mousty et al., 1990), CMUDict for English,¹¹ the Italian Festival Dictionary (Cosi et al., 2000), as well as pronunciation dictionaries for Spanish, Norwegian, and Frisian (original provenance not clear).

As Table 1 shows, the size of the dictionaries ranges from 31,491 words (Spanish) up to 116,211 words (Dutch). We follow the PASCAL challenge training and test folds, treating the training set as our pool of words to be selected for labeling.

Results We consider training subsets of sizes 500, 1000, 1500, and 2000. For our baseline, we train the

G2P model (Bisani and Ney, 2008) on randomly selected words of each size, and average the results over 10 runs. We follow the same procedure for our two data set selection methods. Figure 2 plots the word prediction accuracy for all three methods across the eight languages with varying training sizes, while Table 2 provides corresponding numerical results. We see that in all scenarios the two data set selection strategies fare better than random subsets of words.

In all but one case, the feature coverage method yields the best performance (with the exception of Spanish trained with 500 words, where the CSSP yields the best results). Feature coverage achieves average error reduction of 20% over the randomly selected training words across the different languages and training set sizes.

Coverage variants We also experimented with the other versions of the feature coverage function discussed in Section 3.2 (see Figure 1). While cov₁ tended to perform quite poorly (usually worse than random), cov₂ — which gives full credit for each feature the first time it is seen — yields results just slightly worse than the CSSP matrix method on average, and always better than random. In the 2000 word scenario, for example, cov₂ achieves average accuracy of 74.0, just a bit below the 74.4 accuracy of the CSSP method. It is also possible that more

careful tuning of the discount factor η of cov_3 would yield further gains.

Optimization Analysis Both the CSSP and feature coverage methods have clearly defined objective functions — formulated in Equations 3 and 8, respectively. We can therefore ask how well each methods fares in optimizing either one of the two objectives.

First we consider the objective of the CSSP algorithm: to find k data points which can accurately embed the entire data matrix. Once the data points are selected, we compute the orthogonal projection of the data matrix onto the submatrix, obtaining an approximation matrix \tilde{A} . We can then measure the residual norm as a fraction of the original matrix norm:

$$\frac{\|A - \tilde{A}\|_F}{\|A\|_F} \quad (9)$$

As noted in Section 3.1, truncated SVD minimizes the residual over all rank k matrices, so we can com-

pare our three methods — random selections, CSSP, and feature coverage — all of which select k examples as a basis, against the lower bound given by SVD. Table 3 shows the result of this analysis for $k = 2000$ (Note that we were unable to compute the projection matrices for English and Dutch due to the size of the data and memory limitations). As expected, SVD fares the best, with CSSP as a somewhat distant second. On average, feature coverage seems to do a bit better than random.

A similar analysis for the feature coverage objective function is shown in Table 4. Unsurprisingly, this objective is best optimized by the feature coverage method. Interestingly though, CSSP seems to perform about halfway between random and the feature coverage method. This makes some sense, as good basis data points will tend to have frequent features, while at the same time being maximally spread out from one another. We also note that the poor coverage result for English in Table 4 mirrors its overall poor performance in the G2P prediction task — not only are the phoneme labels unpredictable, but the input data itself is wild and hard to compress.

Stratified length sampling As Table 5 shows, the top 10 words selected by the feature coverage method are mostly long and unusual, averaging 13.3 characters in length. In light of the potential annotation burden, we developed a stratified sampling strategy to ensure typical word lengths. Before selecting each new word, we first sample a word length according to the empirical word length distribution. We then choose among words of the sampled length

according to the feature coverage criterion. This results in more typical words of average length, with only a very small drop in performance.

5 Conclusion and Future Work

In this paper we proposed the task of optimal data set selection in the unsupervised setting. In contrast to active learning, our methods do not require repeated training of multiple models and iterative annotations. Since the methods are unsupervised, they also avoid tying the selected data set to a particular model class (or even task).

We proposed two methods for optimally selecting a small subset of examples for labeling. The first uses techniques developed by the numerical linear algebra and theory communities for approximating matrices with subsets of columns or rows. For our second method, we developed a novel notion of *feature coverage*. Experiments on the task of grapheme-to-phoneme prediction across eight languages show that our method yields performance improvements in all scenarios, averaging 20% reduction in error. For future work, we intend to apply the data set selection strategies to other NLP tasks, such as the optimal selection of sentences for tagging and parsing.

Abstract

We present a morphology-aware nonparametric Bayesian model of language whose prior distribution uses manually constructed finite-state transducers to capture the word formation processes of particular languages. This relaxes the word independence assumption and enables sharing of statistical strength across, for example, stems or inflectional paradigms in different contexts. Our model can be used in virtually any scenario where multinomial distributions over words would be used. We obtain state-of-the-art results in language modeling, word alignment, and unsupervised morphological disambiguation for a variety of morphologically rich languages.

1 Introduction

Despite morphological phenomena’s salience in most human languages, many NLP systems treat fully inflected forms as the atomic units of language. By assuming independence of lexical stems’ various surface forms, this *avoidance approach* exacerbates the problem of data sparseness. If it is employed at all, morphological analysis of text tends to be treated as a preprocessing step to other NLP modules. While this latter *disambiguation approach* helps address data sparsity concerns, it has substantial drawbacks: it requires supervised learning from expert-annotated corpora, and determining the optimal morphological granularity is labor-intensive (Habash and Sadat, 2006).

Neither approach fully exploits the finite-state transducer (FST) technology that has been so successful for modeling the mapping between surface

forms and their morphological analyses (Karttunen and Beesley, 2005), and the mature collections of high quality transducers that already exist for many languages (e.g., Turkish, Russian, Arabic). Much linguistic knowledge is encoded in such FSTs.

In this paper, we develop morphology-aware nonparametric Bayesian language models that bring together hand-written FSTs with statistical modeling and require no token-level annotation. The sparsity issue discussed above is addressed by hierarchical priors that share statistical strength across different inflections of the same stem by backing off to word formation models that piece together morphemes using FSTs. Furthermore, because of the nonparametric formulation of our models, the regular morphological patterns found in the long tail of word types will rely more heavily on deeper analysis, while frequent and idiosyncratically behaved forms are modeled opaquely.

Our prior can be used in virtually any generative model of language as a replacement for multinomial distributions over words, bringing morphological awareness to numerous applications. For various morphologically rich languages, we show that:

- our model can provide rudimentary unsupervised disambiguation for a highly ambiguous analyzer;
- integrating morphology into n -gram language models allows better generalization to unseen words and can improve the performance of applications that are truly open vocabulary; and
- bilingual word alignment models also benefit greatly from sharing translation information

across stems.

We are particularly interested in low-resource scenarios, where one has to make the most of the small quantity of available data, and overcoming data sparseness is crucial. If analyzers exist in such settings, they tend to be highly ambiguous, and annotated data for learning to disambiguate are also likely to be scarce or non-existent. Therefore, in our experiments with Russian, we compare two analyzers: a rapidly-developed *guesser*, which models regular inflectional paradigms but contains no lexicon or irregular forms, and a high-quality analyzer.

2 Word Models with Morphology

In this section, we describe a generative model of word formation based on Pitman-Yor processes that generates word types using a finite-state morphological generator. At a high level, the process first produces lexicons of stems and inflectional patterns; then it generates a lexicon of inflected forms using the finite-state generator. Finally, the inflected forms are used to generate observed data. Different independence assumptions can be made at each of these levels to encode beliefs about where stems, inflections, and surface forms should share statistical strength.

2.1 Pitman-Yor Processes

Our work relies extensively on Pitman-Yor processes, which provide a flexible framework for expressing backoff and interpolation relationships and extending standard models with richer word distributions (Pitman and Yor, 1997). They have been shown to match the performance of state-of-the-art language models and to give estimates that follow appropriate power laws (Teh, 2006).

A draw from a Pitman-Yor process (PYP), denoted $G \sim \text{PY}(d, \theta, G_0)$, is a discrete distribution over a (possibly infinite) set of events, which we denote abstractly \mathcal{E} . The process is parameterized by a discount parameter $0 \leq d < 1$, a strength parameter $\theta > -d$, and a base distribution G_0 over the event space \mathcal{E} .

In this work, our focus is on the base distribution G_0 . We place vague priors on the hyperparameters $d \sim \mathbb{U}([0, 1])$ and $(\theta + d) \sim \text{Gamma}(1, 1)$. Inference in PYPs is discussed below.

2.2 Unigram Morphology Model

The most basic expression of our model is a unigram model of text. So far, we only assume that each word can be analyzed into a stem and a sequence of morphemes forming an inflection pattern. Let G_s be a distribution over stems, G_p be a distribution over inflectional patterns, and let GENERATE be a deterministic mapping from $\langle \text{stem}, \text{pattern} \rangle$ pairs to inflected word forms.¹ An inflected word *type* is generated with the following process, which we designate $\text{MP}(G_s, G_p, \text{GENERATE})$:

$$\begin{aligned} \text{stem} &\sim G_s \\ \text{pattern} &\sim G_p \\ \text{word} &= \text{GENERATE}(\text{stem}, \text{pattern}) \end{aligned}$$

For example, in Russian, we might sample stem = прочий,² pattern = STEM+Adj+Pl+Dat, and obtain word = прочим.

This model could be used directly to generate observed tokens. However, we have said nothing about G_s and G_p , and the assumption that stems and patterns are independent is clearly unsatisfying. We therefore assume that both the stem and the pattern distributions are generated from PY processes, and that $\text{MP}(G_s, G_p, \text{GENERATE})$ is itself the base distribution of a PYP.

$$\begin{aligned} G_s &\sim \text{PY}(d_s, \theta_s, G_s^0) \\ G_p &\sim \text{PY}(d_p, \theta_p, G_p^0) \\ G_w &\sim \text{PY}(d, \theta, \text{MP}(G_s, G_p, \text{GENERATE})) \end{aligned}$$

A draw G_w from this PYP is a unigram distribution over tokens.

2.3 Base Stem Model G_s^0

In general there are an unbounded number of stems possible in any language, so we set G_s^0 to be character trigram model, which we statically estimate, with Kneser-Ney smoothing, from a large corpus of word types in the language being modeled. While using fixed parameters estimated to maximize likelihood is

¹The assumption of determinism is only inappropriate in cases of inflectional spelling variants (e.g., *modeled* vs. *modelled*) or pronunciation variants (e.g., reduced forms in certain environments).

²прочий (pronounced [prət̪sij]) = *other*

questionable from the perspective of Bayesian learning, it is tremendously beneficial for computational reasons. For some applications (e.g., word alignment), the set of possible stems for a corpus S can be precomputed, so we will also experiment with using a uniform stem distribution based on this set.

2.4 Base Pattern Model G_p^0

Several choices are possible for the base pattern distribution:

MP₀ We can assume a uniform G_p^0 when the number of patterns is small.

MP₁ To be able to generalize to new patterns, we can draw the length of the pattern from a Poisson distribution and generate morphemes one by one from a uniform distribution.

MP₂ A more informative prior is a Markov chain of morphemes, where each morpheme is generated conditional on the preceding morpheme.

The choice of the base pattern distribution could depend on the complexity of the inflectional patterns produced by the morphological analyzer, reflecting the type of morphological phenomena present in a given language. For example, the number of possible patterns can practically be considered finite in Russian, but this assumption is not valid for languages with more extensive derivational morphology like Turkish.

2.5 Posterior Inference

For most applications, rather than directly generating from a model using the processes outlined above, we seek to infer posterior distributions over latent parameters and structures, given a sample of data.

Although there is no known analytic form of the PYP density, it is possible to marginalize the draws from it and to work directly with observations. This marginalization produces the classical Chinese restaurant process representation (Teh, 2006). When working with the morphology models we are proposing, we also need to marginalize the different latent forms (stems s and patterns p) that may have given rise to a given word w . Thus, we require that the inverse relation of GENERATE is

available to compute the marginal base word distribution:

$$p(w \mid G_w^0) = \sum_{\text{GENERATE}(s,p)=w} p(s \mid G_s) p(p \mid G_p)$$

Since our approach encodes morphology using FSTs, which are invertible, this poses no problem.

To illustrate, consider the Russian word прочим, which may be analyzed in several ways:

прочий	+Adj	+Sg	+Neut	+Instr
прочий	+Adj	+Sg	+Masc	+Instr
прочий	+Adj	+Pl	+Dat	
прочить	+Verb	+Pl	+1P	
прочее	+Pro	+Sg	+Ins	

Because the set of possible analyses is in general small, marginalization is fast and complex blocked sampling is not necessary.

Finally, to infer hyperparameter values (d, θ, \dots) , a Metropolis-Hastings update is interleaved with Gibbs sampling steps for the rest of the hidden variables.³

Having described a model for generating words, we now show its usage in several contexts.

3 Unsupervised Morphological Disambiguation

Given a rule-based morphological analyzer encoded as an unweighted FST and a corpus on which the analyzer has been run – possibly generating multiple analyses for each token – we can use our unigram model to learn a probabilistic model of disambiguation in an unsupervised setting (i.e., without annotated examples). The corpus is assumed to be generated from the unigram distribution G_w , and the base stem model is set to a fixed character trigram model.⁴ After learning the parameters of the model, we can find for each word in the vocabulary its most likely analysis and use this as a crude disambiguation step.

³The proposal distribution for Metropolis-Hastings is a Beta distribution (d) or a Gamma distribution ($\theta + d$) centered on the previous parameter values.

⁴Experiments suggest that this is important to constrain the model to realistic stems.

3.1 Morphological Guessers

Finite-state morphological analyzers are usually specified in three parts: a **stem lexicon**, which defines the words in the language and classifies them into several categories according to their grammatical function and their morphological properties; a set of **prefixes and suffixes** that can be applied to each category to form surface words; and possibly **alternation rules** that can encode exceptions and spelling variations. The combination of these parts provides a powerful framework for defining a generative model of words. Such models can be reversed to obtain an analyzer. However, while the two latter parts can be relatively easy to specify, enumerating a comprehensive stem lexicon is a time consuming and necessarily incomplete process, as some categories are truly open-class.

To allow unknown words to be analyzed, one can use a *guesser* that attempts to analyze words missing in the lexicon. Can we eliminate the stem lexicon completely and use only the guesser? This is what we try to do by designing a lexicon-free analyzer for Russian. A guesser was developed in three hours; it is prone to over-generation and produces ambiguous analyses for most words but covers a large number of morphological phenomena (gender, case, tense, etc.). For example, the word *иврите*⁵ can be correctly analyzed as *иврит+Noun+Masc+Prep+Sg* but also as the incorrect forms: *иврить+Verb+Pres+2P+Pl*, *иврита+Noun+Fem+Dat+Sg*, *иври-ти+Noun+Fem+Prep+Sg*, and more.

3.2 Disambiguation Experiments

We train the unigram model on a 1.7M-word corpus of TED talks transcriptions translated into Russian (Cettolo et al., 2012) and evaluate our analyzer against a test set consisting of 1,500 gold-standard analyses obtained from the morphology disambiguation task of the DIALOG 2010 conference (Lyaševskaya et al., 2010).⁶

Each analysis is composed of a lemma (*иврит*), a part of speech (*Noun*), and a sequence of additional functional morphemes (*Masc, Prep, Sg*). We consider only open-class categories: nouns, ad-

jjectives, adverbs and verbs, and evaluate the output of our model with three metrics: the lemma accuracy, the part-of-speech accuracy, and the morphology *F*-measure.⁷

As a baseline, we consider picking a random analysis from output of the analyzer or choosing the most frequent lemma and the most frequent morphological pattern.⁸ Then, we use our model with each of the three versions of the pattern model described in §2.2. Finally, as an upper bound, we use the gold standard to select one of the analyses produced by the guesser.

Since our evaluation is not directly comparable to the standard for this task, we use for reference a high-quality analyzer from Xerox⁹ disambiguated with the MP_0 model (all of the models have very close accuracy in this case).

Model	Lemma	POS	Morph.
Random	29.8	70.9	50.2
Frequency	31.1	74.4	48.8
Guesser MP_0	60.0	82.2	66.3
Guesser MP_1	58.9	82.5	69.5
Guesser MP_2	59.9	82.4	65.5
Guesser oracle	68.4	84.9	83.0
Xerox MP_0	83.6	96.4	78.1

Table 1: Russian morphological disambiguation.

Considering the amount of effort put in developing the guesser, the baseline POS tagging accuracy is relatively good. However, the disambiguation is largely improved by using our unigram model with respect to all the evaluation categories. We are still far from the performance of a high-quality analyzer but, in absence of such a resource, our technique might be a sensible option. We also note that there is no clear winner in terms of pattern model, and conclude that this choice is task-specific.

⁷*F*-measure computed for the set of additional morphemes and averaged over the words in the corpus.

⁸We estimate these frequencies by assuming each analysis of each token is uniformly likely, then summing fractional counts.

⁵иврите = Hebrew (masculine noun, prepositional case)

⁶<http://ru-eval.ru>

4 Open Vocabulary Language Models

We now integrate our unigram model in a hierarchical Pitman-Yor n -gram language model (Fig. 1). The training corpus words are assumed to be generated from a distribution G_w^n drawn from $\text{PY}(d_n, \theta_n, G_w^{n-1})$, where G_w^{n-1} is defined recursively down to the base model G_w^0 . Previous work Teh (2006) simply used $G_w^0 = \mathbb{U}(V)$ where V is the word vocabulary, but in our case G_w^0 is the MP defined in §2.2.

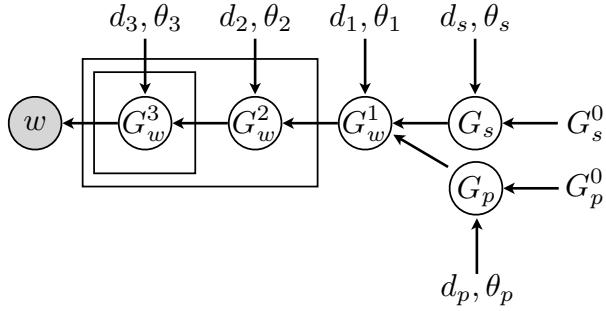

Figure 1: The trigram version of our language model represented as a graphical model. G_w^1 is the unigram model of §2.2.

We are interested in evaluating our model in an open vocabulary scenario where the ability to explain new unseen words matters. We expect our model to be able to generalize better thanks to the combination of a morphological analyzer and a stem distribution which is less sparse than the word distribution (for example, for the 1.6M word Turkish corpus, $|V| \approx 3.5|S| \approx 140k$).

To integrate out-of-vocabulary words in our evaluation, we use infinite base distributions: G_w^0 (in the baseline model) or G_s^0 (in the MP) are character trigram models. We define perplexity of a held-out test corpus in the standard way:

$$\text{ppl} = \exp \left(-\frac{1}{N} \sum_{i=1}^N \log p(w_i | w_{i-n+1} \dots w_{i-1}) \right)$$

but compared to the common practice, we do not need to discount OOVs from this sum since the model vocabulary is infinite. Note that we also marginalize by summing over all the possible analyses for a given word when computing its base probability according to the MP.

4.1 Language Modeling Experiments

We train several trigram models on the Russian TED talks corpus used in the previous section. Our baseline is a hierarchical PY trigram model with a trigram character model as the base word distribution. We compare it with our model using the same character model for the base *stem* distribution. Both of the morphological analyzers described in the previous section help obtaining perplexity reductions (Table 2). We ran a similar experiment on the Turkish version of this corpus (1.6M words) with a high-quality analyzer (Oflazer, 1994) and obtain even larger gains (Table 3).

Model	ppl
PY-character LM	563
Guesser MP ₂	530
Xerox MP ₂	522

Table 2: Evaluation of the Russian n -gram model.

Model	ppl
PY-character LM	1,640
Oflazer MP ₂	1,292

Table 3: Evaluation of the Turkish n -gram model.

These results can partly be attributed to the high OOV rate in these conditions: 4% for the Russian corpus and 6% for the Turkish corpus.

4.2 Predictive Text Input

It is difficult to know whether a decrease in perplexity, as measured in the previous section, will result in a performance improvement in downstream applications. As a confirmation that correctly modeling new words matters, we consider a predictive task with a truly open vocabulary and that requires *only* a language model: predictive text input.

Given some text, we encode it using a lossy deterministic character mapping, and try to recover the original content by computing the most likely word sequence. This task is inspired by predictive text input systems available on cellphones with a 9-key keypad. For example, the string *gave me a cup* is encoded as 4283 63 2 287, which could also be decoded as: *hate of a bus*.

Silfverberg et al. (2012) describe a system designed for this task in Finnish, which is composed of a weighted finite-state morphological analyzer trained on IRC logs. However, their system is restricted to words that are encoded in the analyzer’s lexicon and does not use context for disambiguation.

In our experiments, we use the same Turkish TED talks corpus as the previous section. As a baseline, we use a trigram character language model. We produce a character lattice which encodes all the possible interpretations for a word and compose it with a finite-state representation of the character LM using OpenFST (Allauzen et al., 2007). Alternatively, we can use a unigram word model to decode this lattice, backing off to the character language model if no solution is found. Finally, to be able to make use of word context, we can extract the k most likely paths according to the character LM and produce a word lattice, which is in turn decoded with a language model defined over the extracted vocabulary.

Model	WER	CER
Character LM	48.37	16.72
1-gram + character LM	8.50	3.28
1-gram MP ₂	6.46	2.37
3-gram + character LM	7.86	3.07
3-gram MP ₂	5.73	2.15

Table 4: Evaluation of Turkish predictive text input.

We measure word and character error rate (WER, CER) on the predicted word sequence and observe large improvements in both of these metrics by modeling morphology, both at the unigram level and when context is used (Table 4).

Preliminary experiments with a corpus of 1.6M Turkish tweets, an arguably more appropriate domain this task, show smaller but consistent improving: the trigram word error rate is reduced from 26% to 24% when our model is used.

4.3 Limitations

While our model is an important step forward in practical modeling of OOVs using morphological processes, we have made the linguistically naive assumption that morphology applies inside the language’s lexicon but has no effect on the process that put inflected lexemes together into sentences. In this

regard, our model is a minor variant on traditional n -gram models that work with “opaque” word forms. How to best relax this assumption in a computationally tractable way is an important open question left for future work.

5 Word Alignment Model

Monolingual models of language are not the only models that can benefit from taking into account morphology. In fact, alignment models are a good candidate for using richer word distributions: they assume a target word distribution conditioned on each source word. When the target language is morphologically rich, classic independence assumptions produce very weak models unless some kind of preprocessing is applied to one side of the corpus. An alternative is to use our unigram model as a word translation distribution for each source word in the corpus.

Our alignment model is based on a simple variant of IBM Model 2 where the alignment distribution is only controlled by two parameters, λ and p_0 (Dyer et al., 2013). p_0 is the probability of the null alignment. For a source sentence f of length n , a target sentence e of length m and a latent alignment a , we define the following alignment link probabilities ($j \neq 0$):

$$p(a_i = j \mid n, m) \propto (1 - p_0) \exp\left(-\lambda \left| \frac{i}{m} - \frac{j}{n} \right|\right)$$

λ controls the flatness of this distribution: larger values make the probabilities more peaked around the diagonal of the alignment matrix.

Each target word is then generated given a source word and a latent alignment link from the word translation distribution $p(e_i \mid f_{a_i}, G_w)$. Note that this is effectively a unigram distribution over target words, albeit conditioned on the source word f_j . Here is where our model differs from classic alignment models: the unigram distribution G_w is assumed be generated from a PY process. There are two choices for the base word distribution:

- As a baseline, we use a uniform base distribution over the target vocabulary: $G_w^0 = U(V)$.
- We define a stem distribution $G_s[f]$ for each source word f , a shared pattern distribution G_p , and set $G_w^0[f] = \text{MP}(G_s[f], G_p)$. In this case,

we obtain the model depicted in Fig. 2. The stem and the pattern models are also given PY priors with uniform base distribution ($G_s^0 = \mathbb{U}(S)$).

Finally, we put uninformative priors on the alignment distribution parameters: $p_0 \sim \text{Beta}(\alpha, \beta)$ is collapsed and $\lambda \sim \text{Gamma}(k, \theta)$ is inferred using Metropolis-Hastings.

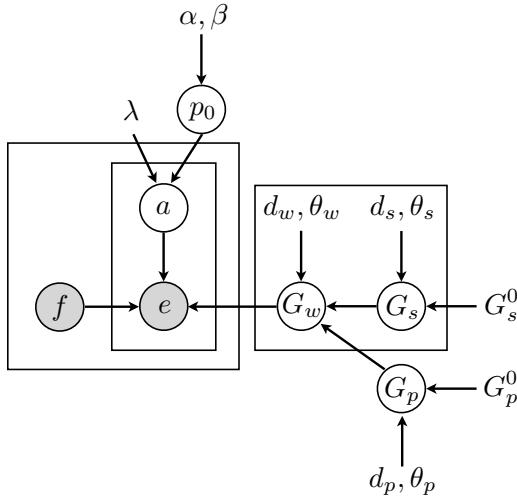

Figure 2: Our alignment model, represented as a graphical model.

Experiments

We evaluate the alignment error rate of our models for two language pairs with rich morphology on the target side. We compare to alignments inferred using IBM Model 4 trained with EM (Brown et al., 1993),¹⁰ a version of our baseline model (described above) without PY priors (learned using EM), and the PY-based baseline. We consider two language pairs.

English-Turkish We use a 2.8M word cleaned version of the South-East European Times corpus (Tyers and Alperen, 2010) and gold-standard alignments from Çakmak et al. (2012). Our morphological analyzer is identical to the one used in the previous sections.

English-Czech We use the 1.3M word News Commentary corpus and gold-standard alignments

¹⁰We use the default GIZA++ stage training scheme: Model 1 + HMM + Model 3 + Model 4.

from Bojar and Prokopová (2006). The morphological analyzer is provided by Xerox.

Results Results are shown in Table 5. Our lightly parameterized model performs much better than IBM Model 4 in these small-data conditions. With an identical model, we find PY priors outperform traditional multinomial distributions. Adding morphology further reduced the alignment error rate, for both languages.

Model	AER	
	en-tr	en-cs
Model 4	52.1	34.5
EM	43.8	28.9
PY- $\mathbb{U}(V)$	39.2	25.7
PY- $\mathbb{U}(S)$	33.8	24.8

Table 5: Word alignment experiments on English-Turkish (en-tr) and English-Czech (en-cs) data.

As an example of how our model generalizes better, consider the sentence pair in Fig. 3, taken from the evaluation data. The two words composing the Turkish sentence are not found elsewhere in the corpus, but several related inflections occur.¹¹ It is therefore trivial for the stem-base model to find the correct alignment (marked in black), while all the other models have no evidence for it and choose an arbitrary alignment (gray points).

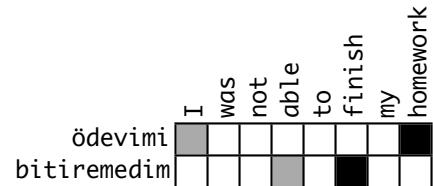

Figure 3: A complex Turkish-English word alignment (alignment points in gray: EM/PY- $U(V)$; black: PY- $U(S)$).

6 Related Work

Computational morphology has received considerable attention in NLP since the early work on *two-level morphology* (Koskenniemi, 1984; Kaplan and

¹¹ödevinin, ödevini, ödevleri; bitmez, bitirileceğinden, bitmesiyle, ...

Kay, 1994). It is now widely accepted that finite-state transducers have sufficient power to express nearly all morphological phenomena, and the XFST toolkit (Beesley and Karttunen, 2003) has contributed to the practical adoption of this modeling approach. Recently, open-source tools have been released: in this paper, we used Foma (Hulden, 2009) to develop the Russian guesser.

Since some inflected forms have several possible analyses, there has been a great deal of work on selecting the intended one in context (Hakkani-Tür et al., 2000; Hajíč et al., 2001; Habash and Rambow, 2005; Smith et al., 2005; Habash et al., 2009). Our disambiguation model is closely related to generative models used for this purpose (Hakkani-Tür et al., 2000).

Rule-based analysis is not the only approach to modeling morphology, and many unsupervised models have been proposed.¹² Heuristic segmentation approaches based on the minimum description length principle (Goldsmith, 2001; Creutz and Lagus, 2007; de Marcken, 1996; Brent et al., 1995) have been shown to be effective, and Bayesian model-based versions have been proposed as well (Goldwater et al., 2011; Snyder and Barzilay, 2008; Snover and Brent, 2001). In §3, we suggested a third way between rule-based approaches and fully unsupervised learning that combines the best of both worlds.

Morphological analysis or segmentation is crucial to the performance of several applications: machine translation (Goldwater and McClosky, 2005; Al-Haj and Lavie, 2010; Oflazer and El-Kahlout, 2007; Minkov et al., 2007; Habash and Sadat, 2006, *inter alia*), automatic speech recognition (Creutz et al., 2007), and syntactic parsing (Tsarfaty et al., 2010). Several methods have been proposed to integrate morphology into n -gram language models, including factored language models (Bilmes and Kirchhoff, 2003), discriminative language modeling (Ari soy et al., 2008), and more heuristic approaches (Monz, 2011).

Despite the fundamentally open nature of the lexicon (Heaps, 1978), there has been distressingly lit-

tle attention to the general problem of open vocabulary language modeling problem (most applications make a closed-vocabulary assumption). The classic exploration of open vocabulary language modeling is Brown et al. (1992), which proposed the strategy of interpolating between word- and character-based models. Character-based language models are reviewed by Carpenter (2005). So-called *hybrid* models that model both words and sublexical units have become popular in speech recognition (Shaik et al., 2012; Parada et al., 2011; Bazzi, 2002). Open-vocabulary language language modeling has also recently been explored in the context of assistive technologies (Roark, 2009).

Finally, Pitman-Yor processes (PYPs) have become widespread in natural language processing since they are natural power-law generators. It has been shown that the widely used modified Kneser-Ney estimator (Chen and Goodman, 1998) for n -gram language models is an approximation of the posterior predictive distribution of a language model with hierarchical PYP priors (Goldwater et al., 2011; Teh, 2006).

7 Conclusion

We described a generative model which makes use of morphological analyzers to produce richer word distributions through sharing of statistical strength between stems. We have shown how it can be integrated into several models central to NLP applications and have empirically validated the effectiveness of these changes. Although this paper mostly focused on languages that are well studied and for which high-quality analyzers are available, our models are especially relevant in low-resource scenarios because they do not require disambiguated analyses. In future work, we plan to apply these techniques to languages such as Kinyarwanda, a resource-poor but morphologically rich language spoken in Rwanda. It is our belief that knowledge-rich models can help bridge the gap between low- and high-resource languages.

Acknowledgments

We thank Kemal Oflazer for making his Turkish language morphological analyzer available to us and Brendan O’Connor for gathering the Turkish tweets used in

¹²Developing a high-coverage analyzer can be a time-consuming process even with the simplicity of modern toolkits, and unsupervised morphology learning is an attractive problem for computational cognitive science.
